THE FIRST EDITION OF THIS BOOK

WAS DEDICATED TO

SIR BENJAMIN COLLINS BRODIE, BART.,

F.R.S., D.C.L.,

IN ADMIRATION OF HIS GREAT TALENTS AND IN REMEMBRANCE OF MANY ACTS OF KINDNESS SHOWN TO THE ORIGINAL AUTHOR OF THE BOOK FROM AN EARLY PERIOD OF HIS PROFESSIONAL CAREER.

PREFACE

TO

THE TWENTY-SEVENTH EDITION

In this Edition the section of Arthrology and the section dealing with the Lymphatic System have been rewritten almost in their entirety. Our knowledge of the mechanism of Joints in the living subject has been greatly extended by the progress of Orthopaedic Surgery and the scientific investigation of the *rationale* of Manipulative Surgery, and in rewriting the description of the movements of the various joints I have incorporated much of the modern teaching of Orthopaedics in this respect. With the advice and help of Mr. T. T. Stamm, F.R.C.S., Assistant Orthopaedic Surgeon to Guy's Hospital, to whom I am very specially indebted, much new matter has been added, for, in addition to the movements which can be performed actively, those movements which can be produced only passively or when resistance is encountered to active movements are described, for the first time—so far as I am aware—in a text-book of Human Anatomy. For want of a better name I have called them 'accessory movements', since the term in common use—'passive movements'—logically used, is applicable to all movements which can be carried out passively and therefore is too comprehensive.

The rewriting and rearrangement of the Lymphatic System has been undertaken, almost entirely, by my colleague, Dr. J. Whillis, who has endeavoured to help the student by dealing with the subject on the basis of areas of lymphatic drainage. He has also assisted me throughout the whole work of revision and has earned my most grateful thanks.

In addition, many parts of the other sections have been rewritten and the whole work has been carefully revised. The description now given of the connexions of the thalamus and the new description of the nuclei of the hypothalamus have been based to a large extent on the work of Professor W. E. Le Gros Clark, and I gratefully acknowledge the valuable help I have received both from him personally and from his writings. Many other friends have helped me by criticism and suggestion and, as in previous editions, I am especially indebted to Dr. E. B. Jamieson, and also to Professor D. M. Blair, Professor R. D. Lockhart and Dr. A. J. E. Cave.

The inclusion of a number of X-ray photographs is an innovation which some may regard as overdue, but it must be remembered that in the past an X-ray photograph often proved more confusing than informative to the medical student in the preclinical period. Recently, however, most Departments of Human Anatomy have been equipped with their own X-ray plants, and the student now has the opportunity, in the preclinical period, of acquainting

himself with the appearances shown by the X-rays, so that the inclusion of a limited number of plates is fully justified. All those included are the work of Dr. H. M. Worth, Surgical Radiologist to Guy's Hospital, and I am exceedingly grateful to him for all the care and trouble which he devoted to their preparation and selection.

Many of the older figures have been discarded, and nearly 100 new figures have been introduced in their place, including, in the Myology section, twenty in which the muscles are shown in colour. For many of the new figures I am indebted to Mr. A. K. Maxwell, whose beautiful drawings are so characteristic of his skilful draughtsmanship that they will be identified readily; others are the work of Miss P. A. Larivière, to whom I owe my grateful thanks for her skill, care and willing co-operation. The remainder, eleven in number, have been borrowed from the Myology section of Quain's *Anatomy* (11th edition), and I am greatly indebted to Professor T. H. Bryce for granting me permission to reproduce them. I am also indebted to Professor Bryce for eight of the new figures in the Blood Vascular Section. These were drawn for him some years ago by Mr. A. K. Maxwell, but have not hitherto been published.

The new index is the work of my demonstrator, Mr. H. R. S. Harley, who has earned the grateful thanks of myself and all readers of Gray's *Anatomy* by the care he has taken to maintain the high standard set by his predecessors.

T. B. JOHNSTON.

GUY'S HOSPITAL,
LONDON, 1938.

HENRY GRAY, F.R.S., F.R.C.S.

Henry Gray

As the readers of Gray's Anatomy may be interested to learn something of its original author, Henry Gray, the following information as to his career has been extracted from an article which appeared in the *St. George's Hospital Gazette* of May 21st, 1908.

Gray, whose father was private messenger to George IV. and also to William IV., was born in 1827, but of his childhood and early education nothing is known.

On the 6th of May, 1845, he entered as a perpetual student at St. George's Hospital, London, and he is described by those who knew him as "a most painstaking and methodical worker, and one who learnt his anatomy by the slow but invaluable method of making dissections for himself."

While still a student he secured, in 1848, the triennial prize of the Royal College of Surgeons for an essay entitled, "The origin, connexions and distribution of the nerves to the human eye and its appendages, illustrated by comparative dissections of the eye in other vertebrate animals."

At the early age of twenty-five he was, in 1852, elected a Fellow of the Royal Society, and in the following year he obtained the Astley Cooper prize of three hundred guineas for a dissertation "On the structure and use of the spleen."

He held successively the posts of demonstrator of anatomy, curator of the museum, and lecturer on anatomy at St. George's Hospital, and was in 1861 a candidate for the post of assistant-surgeon. Unfortunately he was struck down by an attack of confluent smallpox, which he contracted while looking after a nephew who was suffering from that disease, and died at the early age of thirty-four. A career of great promise was thus untimely cut short. Writing on June 15th, 1861, Sir Benjamin Brodie said, "His death, just as he was on the point of obtaining the reward of his labours . . . is a great loss to the Hospital and School."

In 1858 Gray published the first edition of his *Anatomy* which covered 750 pages and contained 363 figures. He had the good fortune to secure the help of his friend, Dr. H. Vandyke Carter, a skilled draughtsman and formerly a demonstrator of anatomy at St. George's Hospital. Carter made the drawings from which the engravings were executed, and the success of the book was, in the first instance, undoubtedly due in no small measure to the excellence of its illustrations. A second edition was prepared by Gray and published in 1860.

The portrait here given of Gray is a reproduction of one which appeared in the *St. George's Hospital Gazette* of May 21st, 1908, where the original is described as being "a very faded photograph taken by Mr. Henry Pollock, second son of the late Lord Chief Baron Sir Frederick Pollock, and one of the earliest members of the photographic society of London."

GLOSSARY

LIST OF ALTERATIONS IN THE B.N.A., APPROVED BY THE ANATOMICAL SOCIETY OF GREAT BRITAIN AND IRELAND, AND INCLUDED IN THE TEXT

Region or Structure	B.R.* English Form	B.R.* Latin Form	Original B.N.A.
Parts of the Body	Neck	Cervix	Collum
	Limbs	Membra	Extremitates
Regions of Body	Nape of neck	Nucha	
	Nuchal furrow	Sulcus nuchæ	Fovea nuchæ
	Root of neck	Radix cervicis	
	Suprasternal fossa	Fossa suprasternalis	Fossa jugularis
	Infraclavicular fossa	Fossa infraclavicularis	Trigonum deltoideopectorale
	Palm of hand	Palma manus	Vola manus
	Fold of buttock	Sulcus natis	Sulcus glutaeus
OSTEOLOGY			
General Terms			
Typical Vertebra	Pedicle	Pediculus [arcus vertebræ]	Radix arcus vertebræ
	Lamina	Lamina [arcus vertebræ]	
	Neural arch	*Arcus neuralis*	
	Centrum	*Centrum*	
	Neurocentral joint	*Articulatio neurocentralis*	
	Costal facet [on transverse process]	Facies costalis [processus transversi]	Fovea costalis transversalis
Atlas	Facet for odontoid process	Facies processus odontoidei	Fovea dentis
Axis	Odontoid process	Processus odontoideus	Dens
Sacrum	Lateral mass	Massa lateralis	Pars lateralis
	Spinous tubercles	Tubercula spinosa	Crista sacralis media
	Transverse tubercles	Tubercula transversa	Cristae sacrales laterales
	Articular tubercles	Tubercula articularia	Cristae sacrales articulares
Thorax	Inlet of thorax	Aditus thoracis	Apertura thoracis superior
	Outlet of thorax	Exitus thoracis	Apertura thoracis inferior
1st Rib	Groove for subclavian artery	Sulcus arteriæ subclaviæ	Sulcus subclaviæ
2nd Rib	Tubercle for serratus anterior	Tuberculum m. serrati anterioris	Tuberositas costæ II
Sternum	Suprasternal notch	Incisura suprasternalis	Incisura jugularis
Skull (as a whole)	Impressions for [cerebral] gyri	Impressiones gyrorum [cerebri]	Impressiones digitatæ
	Pterygomaxillary fissure	Fissura pterygomaxillaris	
	Greater palatine canal	Canalis palatinus major	Canalis pterygopalatinus
	Bony palate	Palatum osseum	Palatum durum
	Incisive fossa	Fossa incisiva	Foramen incisivum
	Incisive foramina (lateral and median)	Foramina incisiva (lateralia et mediana)	
	Anterior (bony) aperture of nose	Apertura (ossea) nasi anterior	Apertura piriformis
	Posterior (bony) aperture of nose	Apertura (ossea) nasi posterior	Choanæ
	Anterior fontanelle	Fonticulus anterior	Fonticulus frontalis (major)
	Posterior fontanelle	Fonticulus posterior	Fonticulus occipitalis (minor)
	Posterolateral fontanelle	Fonticulus posterolateralis	Fonticulus mastoideus
	Anterolateral fontanelle	Fonticulus anterolateralis	Fonticulus sphenoidalis
Occipital Bone	Condylar part	Pars condylaris	Pars lateralis
	Posterior condylar canal	Canalis condylaris posterior	Canalis condyloideus
	Anterior condylar canal	Canalis condylaris anterior	Canalis hypoglossi
Sphenoid Bone	Sphenoid bone	Os sphenoideum	Os sphenoidale
	Optic groove	Sulcus opticus	Sulcus chiasmatis
	Lesser wing	Ala minor	Ala parva
	Greater wing	Ala major	Ala magna
	Spine of sphenoid	Spina ossis sphenoidei	Spina angularis
	Groove for pharyngotympanic tube	Sulcus tubæ pharyngotympanicæ	Sulcus tubæ auditivæ
	Lateral pterygoid plate	Lamina pterygoidea lateralis	Lamina lateralis processus pterygoidei
	Medial pterygoid plate	Lamina pterygoidea medialis	Lamina medialis processus pterygoidei
	Palatinovaginal canal	Canalis palatinovaginalis	Canalis pharyngeus
Temporal Bone	Sigmoid groove	Sulcus sinus sigmoidei	Sulcus sigmoideus
	Internal auditory meatus	Meatus auditorius internus	Meatus acusticus internus
	Canal for facial nerve	Canalis nervi facialis	Canalis facialis [Fallopii]
	Canal for tensor tympani	Canalis m. tensoris tympani	Semicanalis m. tensoris tympani
	Canal for pharyngotympanic tube	Canalis tubæ pharyngotympanicæ	Semicanalis tubæ auditivæ
	Anterior canaliculus for chorda tympani	Canaliculus anterior chordæ tympani	Canaliculus chordæ tympani

* B.R. = British revision.

Region or Structure	B.R. English Form	B.R. Latin Form	Original B.N.A.
OSTEOLOGY *(continued)*			
Temporal Bone *(continued)*	Posterior canaliculus for chorda tympani	Canaliculus posterior chordæ tympani	
	Squamotympanic fissure	Fissura squamotympanica	Fissura petrotympanica (Glaseri)
	Petrotympanic fissure	Fissura petrotympanica	
	External auditory meatus	Meatus auditorius externus	Meatus acusticus externus
	Zygomatic process [Zygoma]	Processus zygomaticus [Zygoma]	Processus zygomaticus
	Roots of zygoma	Radices zygomatis	
	Tubercle of root of zygoma	Tuberculum radicis zygomatis	
	Supramastoid crest	Crista supramastoidea	
	Articular fossa	Fossa articularis	Fossa mandibularis
	Articular eminence	Eminentia articularis	Tuberculum articulare
Parietal Bone	Parietal eminence	Eminentia parietalis	Tuber parietale
	Groove for sigmoid sinus	Sulcus sinus sigmoidei	Sulcus transversus
Frontal Bone	Frontal eminence	Eminentia frontalis	Tuber frontale
	Orbital plate	Lamina orbitalis	Pars orbitalis
	Nasal spine	Spina nasalis	Spina frontalis
Ethmoid Bone	Ethmoid bone	Os ethmoideum	Os ethmoidale
	Cribriform plate	Lamina cribriformis	Lamina cribrosa
	Ala (cristæ galli)	Ala cristæ galli	Processus alaris (cristæ galli)
	Ethmoidal sinuses	Sinus ethmoidales	Cellulæ ethmoidales
	Orbital plate	Lamina orbitalis	Lamina papyracea
Lacrimal Bone	Crest of lacrimal bone	Crista ossis lacrimalis	Crista lacrimalis posterior
Maxilla	Posterior surface	Facies posterior	Facies infratemporalis
	Dental foramina	Foramina dentalia	Foramina alveolaria
	Dental canals	Canales dentales	Canales alveolares
	Nasolacrimal groove	Sulcus nasolacrimalis	Sulcus lacrimalis
	Lacrimal crest [of maxilla]	Crista lacrimalis [ossis maxillæ]	Crista lacrimalis anterior
	Alveolar arch	Arcus alveolaris	Limbus alveolaris
Palatine Bone	Perpendicular plate	Lamina perpendicularis	Pars perpendicularis
	Greater palatine groove	Sulcus palatinus major	Sulcus pterygopalatinus
	Lesser palatine canals	Canales palatini minores	Canales palatini
	Horizontal plate	Lamina horizontalis	Pars horizontalis
	Tubercle [of palatine bone]	Tuberculum [ossis palatini]	Processus pyramidalis
Zygomatic Bone	Frontal process	Processus frontalis	Processus frontosphenoidalis
	Marginal tubercle	Tuberculum marginale	(Processus marginalis)
Mandible	Alveolar arch	Arcus alveolaris	Limbus alveolaris
	Genial tubercles	Tubercula geniaca	Spina mentalis
	Sublingual fossa	Fossa sublingualis	Fovea sublingualis
	Submandibular fossa	Fossa submandibularis	(Fovea submaxillaris)
	Head of mandible	Caput mandibulæ	Capitulum (processus condyloidei) mandibulæ
	Neck of mandible	Collum mandibulæ	Collum (processus condyloidei) mandibulæ
Bones of Upper Limb	Shoulder girdle	Cingulum membri superioris	Cingulum extremitatis superioris
Scapula	Crest [of scapular spine]	Crista [spinæ scapulæ]	
	Acromial angle	Angulus acromialis	
	Medial border	Margo medialis	Margo vertebralis
	Lateral border	Margo lateralis	Margo axillaris
	Suprascapular notch	Incisura suprascapularis	Incisura scapulæ
	Superior angle	Angulus superior	Angulus medialis
	Spinoglenoid notch	Incisura spinoglenoidalis	
Clavicle	Impression for costoclavicular ligament	Impressio ligamenti costoclavicularis	Tuberositas costalis
	Conoid tubercle	Tuberculum conoideum	Tuberositas coracoidea
	Trapezoid line	Linea trapezoidea	
Skeleton of Free Upper Limb			
Humerus	Greater tuberosity	Tuberositas major	Tuberculum majus
	Lesser tuberosity	Tuberositas minor	Tuberculum minus
	Bicipital groove	Sulcus musculi bicipitis	Sulcus intertubercularis
	Lateral lip	Labium laterale	Crista tuberculi majoris
	Medial lip	Labium mediale	Crista tuberculi minoris
	Spiral groove	Sulcus spiralis	Sulcus nervi radialis
Radius	Head of radius	Caput radii	Capitulum radii
	Interosseous border	Margo interossea	Crista interossea
Ulna	Trochlear notch	Incisura trochlearis	Incisura semilunaris
	Interosseous border	Margo interossea	Crista interossea
Carpus	Carpal bones	Ossa carpalia	Ossa carpi
	Scaphoid bone	Os scaphoideum	Os naviculare manus
	Tubercle of scaphoid	Tuberculum oss. scaph.	Tuberculum oss. nav. man.
	Trapezium	Os trapezium	Os multangulum majus
	Crest of trapezium	Crista ossis trap.	Tuberculum oss. mult. maj.
	Trapezoid	Os trapezoideum	Os multangulum minus
Phalanges	Proximal phalanx	Phalanx proximalis	Phalanx prima
	Middle phalanx	Phalanx media	Phalanx secunda
	Distal phalanx	Phalanx distalis	Phalanx tertia
	Tuberosity of distal phalanx	Tuberositas phalangis distalis	Tuberositas unguicularis
	Head of phalanx	Caput phalangis	Trochlea phalangis
Bones of Lower Limb	Girdle of lower limb	Cingulum membri inferioris	Cingulum extremitatis inferioris

Region or Structure	B.R. English Form	B.R. Latin Form	Original B.N.A.
OSTEOLOGY (*continued*)			
Hip Bone	Articular surface	Facies articularis	Facies lunata
Ilium	Intermediate area [of iliac crest]	Area intermedia [cristæ iliacæ]	Linea intermedia [cristæ iliacæ]
	Middle gluteal line	Linea glutæa media	Linea glutæa anterior
Ischium	Ramus of ischium	Ramus ossis ischii	Ramus inferior ossis ischii
	Ischial tuberosity	Tuberositas ischiadica	Tuber ischiadicum
Pubis	Pubic crest	Crista pubica	
	Pectineal line	Linea pectinea	Pecten ossis pubis
	Iliopubic eminence	Eminentia iliopubica	Eminentia iliopectinea
Pelvis	Subpubic angle	Angulus subpubicus	Angulus pubis
	False pelvis	Pelvis spuria	Pelvis major
	True pelvis	Pelvis vera	Pelvis minor
	Arcuate line	Linea arcuata	Linea terminalis
	Inlet of pelvis	Aditus pelvis [veræ]	Apertura [pelvis minoris] superior
	Outlet of pelvis	Exitus pelvis [veræ]	Apertura [pelvis minoris] inferior
Femur	Trochanteric line	Linea trochanterica	Linea intertrochanterica
	Trochanteric crest	Crista trochanterica	Crista intertrochanterica
	Spiral line	Linea spiralis	
	Supracondylar lines	Lineæ supracondylares	
	Intercondylar notch	Incisura intercondylaris	Fossa intercondyloidea
	Popliteal surface	Facies poplitea	Planum popliteum
Tibia	Intercondylar area	Area intercondylaris	Fossa intercondyloidea anterior Fossa intercondyloidea posterior
	Tubercle of tibia	Tuberculum tibiæ	Tuberositas tibiæ
	Soleal line	Linea m. solei	Linea poplitea
Fibula	Styloid process	Processus styloideus fibulæ	Apex capituli fibulæ
	Interosseous border	Margo interossea	Crista interossea
	Anterior border	Margo anterior	Crista anterior
	Posterior border	Margo posterior	Crista lateralis
	Anterior surface	Facies anterior *	Facies medialis
	Posterior surface	Facies posterior †	Facies posterior
	Malleolar fossa	Fossa malleoli lateralis	
Tarsus			
Talus	Upper surface of talus	Facies superior tali	Facies superior [trochleæ tali]
	Medial surface of talus	Facies medialis tali	
	Malleolar facet	Facies articularis malleolaris medialis	Facies malleolaris medialis
	Lateral surface of talus	Facies lateralis tali	
	Malleolar facet	Facies articularis malleolaris lateralis	Facies malleolaris lateralis
	Lateral tubercle	Tuberculum laterale	Processus lateralis tali
	Anterior surface of talus	Facies anterior tali	
	Lower surface of talus	Facies inferior tali	
	Posterior surface of talus	Facies posterior tali	
	Medial tubercle Posterior tubercle	Tuberculum mediale Tuberculum posterius	Processus posterior tali
Calcaneum	Calcaneum	Calcaneum	Calcaneus
	Posterior surface	Facies posterior	Tuber calcanei
	Medial tubercle [of calcaneum]	Tuberculum mediale [calcanei]	Processus medialis tuberis calcanei
	Lateral tubercle [of calcaneum]	Tuberculum laterale [calcanei]	Processus lateralis tuberis calcanei
	Anterior tubercle [of calcaneum]	Tuberculum anterius [calcanei]	
	(Peroneal tubercle)	(Tuberculum tendinum mm. peronæorum)	(Processus trochlearis)
Cuneiform Bones	Medial cuneiform bone	Os cuneiforme mediale	Os cuneiforme primum
	Intermediate cuneiform bone	Os cuneiforme intermedium	Os cuneiforme secundum
	Lateral cuneiform bone	Os cuneiforme laterale	Os cuneiforme tertium
Phalanges	Proximal phalanx	Phalanx proximalis	Phalanx prima
	Middle phalanx	Phalanx media	Phalanx secunda
	Distal phalanx	Phalanx distalis	Phalanx tertia
	Tuberosity of distal phalanx	Tuberositas phalangis distalis	Tuberositas unguicularis
	Head of phalanx	Caput phalangis	Trochlea phalangis
Joints	Arthrology	Arthrologia	Syndesmologia
	Joint	Articulatio	Junctura ossium
	Fibrous joint	Articulatio fibrosa	Synarthrosis
	Denticulate suture	Sutura denticulata	
	Flat suture	Sutura plana	Harmonia
	Limbous suture	Sutura limbosa	
	Wedge and groove suture	Schindylesis	
	Cartilaginous joint	Articulatio cartilaginea	Synchondrosis
	Primary cartilaginous joint	Articulatio cartilaginea primaria	
	Secondary cartilaginous joint	Articulatio cartilaginea secundaria	Amphiarthrosis
	Synovial joint	Articulatio synovialis	Diarthrosis
	Plane joint	Articulatio plana	Arthrodia
	Condyloid joint	Articulatio condyloidea	
	Ball and socket joint	Articulatio cotylica	Enarthrosis

* Between anterior and interosseous borders.

† Between interosseous and posterior borders, and subdivided by the medial crest.

JOINTS *(continued)*			
Tibiofibular Joints	Superior tibiofibular joint	Articulatio tibiofibularis superior	Articulatio tibiofibularis
	Inferior tibiofibular joint	Articulatio tibiofibularis inferior	Syndesmosis tibiofibularis
	Interosseous tibiofibular ligament	Ligamentum tibiofibulare interosseum	
	Anterior inferior tibiofibular ligament	Ligamentum tibiofibulare inferius anterius	Ligamentum malleoli lateralis anterius
	Posterior inferior tibiofibular ligament	Ligamentum tibiofibulare inferius posterius	Ligamentum malleoli lateralis posterius
Tarsal Joints	Lateral calcaneonavicular ligament	Ligamentum calcaneonaviculare laterale	Pars calcaneonavicularis [ligamenti bifurcati]
	Medial calcaneocuboid ligament	Ligamentum calcaneocuboideum mediale	Pars calcaneocuboidea [ligamenti bifurcati]
	Short plantar ligament	Ligamentum plantare breve	Ligamentum calcaneocuboideum plantare
Intermetatarsal Joints	Interosseous metatarsal ligaments	Ligamenta metatarsea interossea	Ligamenta basium [oss. metatars.] interossea
	Dorsal metatarsal ligaments	Ligamenta metatarsea dorsalia	Ligamenta basium [oss. metatars.] dorsalia
	Plantar metatarsal ligaments	Ligamenta metatarsea plantaria	Ligamenta basium [oss. metatars.] plantaria
Metatarsophalangeal Joints	Deep transverse ligaments of sole	Ligamenta plantæ transversa profunda	Ligamenta capitulorum [oss. metatars.] transversa
MYOLOGY			
General Terms	Tendinous intersection	Intersectio tendinea	Inscriptio tendinea
	Synovial sheath of tendon	Vagina synovialis tendinis	Vagina mucosa tendinis
	Synovial bursa	Bursa synovialis	Bursa mucosa
	Deep fascia	Fascia profunda	
Muscles of Back	Iliocostocervicalis	Musculus iliocostocervicalis	Musculus iliocostalis
	Iliocostalis	M. iliocostalis	M. iliocostalis lumborum
	Costalis	M. costalis	M. iliocostalis thoracis
	Costocervicalis	M. costocervicalis	M. iliocostalis cervicis
	Longissimus thoracis	M. longissimus thoracis	M. longissimus dorsi
	Spinalis thoracis	M. spinalis thoracis	M. spinalis dorsi
	Semispinalis thoracis	M. semispinalis thoracis	M. semispinalis dorsi
	Lumbar fascia	Fascia lumbalis	Fascio lumbodorsalis
Muscles of Head	*Latin form used*	M. occipitofrontalis	M. epicranius
	Frontal belly	Venter frontalis	M. frontalis
	Occipital belly	Venter occipitalis	M. occipitalis
	Epicranial aponeurosis	Aponeurosis epicranialis	Galea aponeurotica
	Latin form used	M. compressor naris	M. nasalis, pars transversa
	Latin form used	M. dilator naris	Pars alaris
	Latin form used	M. depressor anguli oris	M. triangularis
	Latin form used	M. zygomaticus major	M. zygomaticus
			M. quadratus labii superioris
	Latin form used	M. zygomaticus minor	Caput zygomaticum
	Latin form used	M. levator labii superioris	Caput infra-orbitale
	Latin form used	M. levator labii superioris alaeque nasi	Caput angulare
	Latin form used	M. depressor anguli oris	M. quadratus labii inferioris
	Latin form used	M. levator anguli oris	M. Caninus
	Lateral pterygoid muscle	M. pterygoideus lateralis	M. pterygoideus externus
	Medial pterygoid muscle	M. pterygoideus medialis	M. pterygoideus internus
	Parotid fascia	Fascia parotidea	Fascia parotideomasseterica
Muscles of Neck	*Latin form used*	M. longus cervicis	M. longus colli
	Cervical fascia	Fascia cervicis	Fascia colli
Muscles of Thorax	Anterior intercostal membranes	Membranæ intercostales anteriores	Ligamenta intercostalia externa
	Posterior intercostal membranes	Membranæ intercostales posteriores	Ligamenta intercostalia interna
	Latin form used	M. transversus thoracis	M. transversus thoracis
	Latin form used	M. sternocostalis	
	Latin form used	Mm. intercostales intimi	
	Vertebral part [of diaphragm]	Pars vertebralis [diaphragmatis]	Pars lumbalis [diaphragmatis]
	Crus [right and left]	Crus [dextrum et sinistrum]	Crus mediale Crus intermedium Crus laterale
	Medial arcuate ligament	Ligamentum arcuatum mediale	Arcus lumbocostalis medialis [Halleri]
	Lateral arcuate ligament	Ligamentum arcuatum laterale	Arcus lumbocostalis lateralis [Halleri]
Rectus Abdominis	Tendinous intersections	Intersectiones tendineæ	Inscriptiones tendineæ
	Arcuate line	Linea arcuata	Linea semicircularis [Douglasi]
External Oblique	Pectinate part [of inguinal ligament]	Pars pectinea [ligamenti inguinalis]	Ligamentum lacunare [Gimbernati]
	(Reflected part [of inguinal ligament])	(Pars reflexa [ligamenti inguinalis])	Ligamentum inguinale reflexum
Internal Oblique and Transversus	Pectineal ligament	Ligamentum pectineale	
	Conjoint tendon	Tendo conjunctus	Falx inguinalis aponeurotica
Inguinal Canal	Superficial inguinal ring	Annulus inguinalis superficialis	Annulus inguinalis subcutaneus
	Deep inguinal ring	Annulus inguinalis profundus	Annulus inguinalis abdominalis

MYOLOGY (*continued*)			
Muscles of Pelvis	Fascia of pelvic muscles	Fascia musculorum pelvinorum	Fascia pelvis
			Fascia endopelvina
	Visceral fascia	Fascia viscerum pelvinorum	Fascia diaphragmatis pelvis superior
	Tendinous arch	Arcus tendineus	Arcus tendineus fasciæ pelvis
			Fascia diaphragmatis pelvis inferior
	[Fascial] sheath of prostate	Vagina [fascialis] prostatæ	Fascia prostatæ
	Rectovesical septum	Septum rectovesicale	
	Retropubic space	Spatium retropubicum	
	Retropubic pad of fat	Corpus adiposum retropubicum	
Muscles of Perineum	Anococcygeal body	Corpus anococcygeum	Ligamentum anococcygeum
	Bulbospongiosus	M. bulbospongiosus	Musculus bulbocavernosus
	Perineal membrane	Membrana perinealis	Fascia diaphragmatis urogenitalis inferior
	Perineal body	Corpus perineale	
	Pudendal canal [of obturator fascia]	Canalis pudendalis [fasciae obturatoriæ]	
Muscles of Upper Limb	*Latin form used*	(Musculus dorso-epitrochlearis)	
	Clavipectoral fascia	Fascia clavipectoralis	Fascia coracoclavicularis
	Bicipital aponeurosis	Aponeurosis m. bicipitis	Lacertus fibrosus
	Humero-ulnar head [of flex. dig. sublim.]	Caput humero-ulnare [m. flex. dig. sublim.]	Caput humerale [m. flexor digit. sublimis]
	Latin form used	M. extensor digitorum	M. extensor digitorum communis
	Latin form used	M. extensor digiti minimi	M. extensor digiti quinti proprius
	Latin form used	M. extensor indicis	M. extensor indicis proprius
	Oblique head [of adductor pollicis]	Caput obliquum [m. adductoris pollicis]	
	Transverse head [of adductor pollicis]	Caput transversum [m. adductoris pollicis]	
	Latin form used	M. abductor digiti minimi	M. abductor digiti quinti
	Extensor retinaculum	Retinaculum tendinum mm. extensorum	Ligamentum carpi dorsale
	Superficial transverse lig. of palm	Lig. palmæ transversum superficiale	Fasciculi transversi
	Flexor retinaculum	Retinaculum tendinum mm. flexorum	Lig. carpi transversum
	Superficial part	Pars superficialis	Lig. carpi volare
Muscles of Lower Limb	Opening in adductor magnus	Hiatus m. adductoris magni	Hiatus tendineus [adductorius]
	Latin form used	M. abductor digiti minimi	M. abductor digiti quinti
	Latin form used	(M. abductor ossis metatarsi quinti)	
	Latin form used	M. flexor digitorum accessorius	M. quadratus plantæ
	Subsartorial canal	Canalis subsartorialis	Canalis adductorius [Hunteri]
	Saphenous opening [of fascia lata]	Hiatus saphenus [fasciæ latæ]	Fossa ovalis
	Cribriform fascia	Fascia cribriformis	Fascia cribrosa
	Anterior intermuscular septum [of leg]	Septum [cruris] intermusculare anterius	Septum intermusculare anterius [fibulare]
	Posterior intermuscular septum [of leg]	Septum [cruris] intermusculare posterius	Septum intermusculare posterius [fibulare]
	Superior extensor retinaculum	Retinaculum tendinum mm. extensorum superius	Lig. transversum cruris
	Inferior extensor retinaculum	Retinaculum tendinum mm. extensorum inferius	Lig. cruciatum cruris
	Flexor retinaculum	Retinaculum tendinum mm. flexorum	Lig. laciniatum
	Superficial transverse lig. of sole	Lig. plantæ transversum superficiale	
	Fibrous flexor sheaths	Vaginæ fibrosæ digitales tendinum mm. flexorum	
Bursæ and Synovial Sheaths	Synovial bursæ and sheaths	Bursæ et vaginæ synoviales	Bursæ et vaginæ mucosæ
	Bursa of superior oblique muscle of eye	Bursa m. obliqui superioris oculi	Bursa musculi trochlearis
	Bursa of tensor palati muscle	Bursa m. tensoris palati	Bursa m. tensoris veli palatini
	Bursa of tendon of triceps muscle	Bursa tendinis m. tricipitis	Bursa subtendinea olecrani
	Synovial sheath of flexor carpi radialis tendon	Vagina synovialis tendinis m. flex. carp. rad.	Bursa m. flexoris carpi radialis
	Trochanteric bursa of gluteus medius muscle	Bursa trochanterica m. glutæi medii	Bursa trochanterica m. glutæi medii anterior
	Bursa of psoas major tendon	Bursa tendinis m. psoadis majoris	Bursa iliopectinea
	Tibial intertendinous bursa	Bursa intertendinea tibialis	Bursa m. sartorii propria
			Bursa anserina

Sympathetic Trunk	White communicating brs.	Rami communicantes albi	Ramus communicans
	Grey communicating brs.	Rami communicantes grisei	
Lumbar Part	Lumbar part of sympathetic system	Pars lumbalis systematis sympathici	Pars abdominalis systematis sympathici
Parasympathetic	Parasympathetic nervous system	Systema nervosum parasympathicum	
	Cranial part	Pars cranialis	
	Spinal part	Pars spinalis	
	Pelvic splanchnic nerves	N. splanchnici pelvini	
	Parasympathetic ganglia	Ganglia parasympathica	
SPECIAL SENSES	Spaces of iridocorneal angle	Spatia anguli iridocornealis	Spatia anguli iridis [Fontanæ]
	Optic disc	Discus opticus	Papilla n. optici
	Iridocorneal angle	Angulus iridocornealis	Angulus iridis
Eyeball	Lens	Lens	Lens crystallina
	Fascial sheath of eyeball	Vagina fascialis bulbi	Fascia bulbi [Tenoni]
Conjunctiva	Ocular part [of conjunctiva]	Pars ocularis [conjunctivæ]	Tunica conjunctiva bulbi
	Palpebral part [of conjunctiva]	Pars palpebralis [conjunctivæ]	Tunica conjunctiva palpebrarum
Lacrimal Apparatus	Lacrimal gland	Glandula lacrimalis	Glandula lacrimalis superior
	Palpebral process	Processus palpebralis	Glandula lacrimalis inferior
	Ducts of lacrimal gland	Ductus glandulæ lacrimalis	Ductuli excretorii
	Lacrimal canaliculi	Canaliculi lacrimales	Ductus lacrimales
The Ear	Maculæ of membranous labyrinth	Maculæ labyrinthi membranacei	Maculæ acusticæ
	Aqueduct of cochlea	Aquæductus cochleæ	Ductus perilymphaticus
Bony Labyrinth	Semicircular canals	Canales semicirculares	Canales semicirculares ossei
	Internal auditory meatus	Meatus auditorius internus	Meatus acusticus internus
Middle Ear	Middle ear [tympanum]	Auris media [tympanum]	
	Roof of tympanum	Tegmen tympani	Paries tegmentalis
	Floor of tympanum	Solum tympani	Paries jugularis
	Medial wall	Paries medialis	Paries labyrinthica
	Posterior wall	Paries posterior	Paries mastoidea
	Anterior wall	Paries anterior	Paries carotica
	Lateral wall	Paries lateralis	Paries membranacea
	Aditus to tympanic antrum	Aditus ad antrum tympanicum	
	Pyramid [of tympanum]	Pyramis [tympani]	Eminentia pyramidalis
Tympanic Membrane	Fibrous layer	Stratum fibrosum	Stratum radiatum Stratum circulare
	Radial fibres	Fibræ radiatæ	
	Circular fibres	Fibræ circulares	
	Pharyngotympanic tube	Tuba pharyngotympanica	Tuba auditiva [Eustachii]
	External ear	Auris externa	
	External auditory meatus	Meatus auditorius externus	Meatus acusticus externus
Auricle	Scaphoid fossa	Fossa scaphoidea	Scapha
Skin	Horny zone [of epidermis]	Zona cornea [epidermis]	Stratum corneum [epidermis]
	Horny layer	Stratum corneum	
	Clear layer	Stratum lucidum	
	Granular layer	Stratum granulosum	
	Germinative zone [of epidermis]	Zona germinativa [epidermis]	Stratum germinativum [epidermis]
	Prickle-cell layer	Stratum aculeatum	
	Basal-cell layer	Stratum basale	
Subcutaneous Tissue	Subcutaneous fatty tissue	Tela adiposa subcutanea	Panniculus adiposus
Breast	Mammary gland	Glandula mammaria	
	Lobes [of mammary gland]	Lobi [glandulæ mammariæ]	Lobi mammæ
VASCULAR SYSTEM	Blood vascular system	Systema vasorum sanguineorum	Angiologia
General Term	Emissary vein	Vena emissaria	Emissarium
Heart	Left surface	Facies sinistra	
	Anterior interventricular groove	Sulcus interventricularis anterior	Sulcus longitudinalis anterior
	Inferior interventricular groove	Sulcus interventricularis inferior	Sulcus longitudinalis posterior
	Atrioventricular groove	Sulcus atrioventricularis	Sulcus coronarius

Region or Structure	B.R. English Form	B.R. Latin Form	Original B.N.A.
VASCULAR SYSTEM (*continued*)			
Heart (*continued*)	Auricles of atria	Auriculæ atriorum	Auricula cordis
	Membranous part [of ventricular septum]	Pars membranacea [septi ventriculorum]	Septum membranaceum ventriculorum
	Right atrioventricular [tricuspid] orifice	Orificium [tricuspidatum] atrioventriculare dextrum	Ostium venosum
	Left atrioventricular [mitral] orifice	Orificium [mitrale] atrioventriculare sinistrum	
	Pulmonary orifice	Orificium trunci pulmonalis	Ostium arteriosum
	Aortic orifice	Orificium aortæ	
Right Atrium	*Latin form used*	Annulus ovalis	Limbus fossae ovalis [Vieussenii]
Right Ventricle	Right atrioventricular [tricuspid] valve	Valvula [tricuspidalis] atrioventricularis dextra	Valvula tricuspidalis
	Inferior cusp	Cuspis inferior	Cuspis posterior
	Infundibuloventricular crest	Crista infundibuloventricularis	Crista supraventricularis
	Latin form used	Infundibulum	Conus arteriosus
	Pulmonary valve	Valvula trunci pulmonalis	Valvulæ semilunares a. pulmonalis
	Right cusp	Cuspis dextra	Valvula semilunaris anterior
	Posterior cusp	Cuspis posterior	Valvula semilunaris dextra
	Left cusp	Cuspis sinistra	Valvula semilunaris sinistra
	Nodules of pulmonary valve	Noduli valvulæ trunci pulmonalis	Noduli valvularum semilunarium
	Lunules of pulmonary valve	Lunulae valvulæ trunci pulmonalis	Lunulæ valvularum semilunarium
	Moderator band	Fasciculus moderator	
Left Ventricle	Left atrioventricular [mitral] valve	Valvula [mitralis] atrioventricularis sinistra	Valvula bicuspidalis [mitralis]
	Aortic valve	Valvula aortæ	Valvulæ semilunares aortæ
	Left cusp	Cuspis sinistra	Valvula semilunaris posterior
	Right cusp	Cuspis dextra	Valvula semilunaris dextra
	Anterior cusp	Cuspis anterior	Valvula semilunaris sinistra
Myocardium	*Latin form used*	Neuromyocardium	
	Sinu-atrial node	Nodulus sinu-atrialis	
	Atrioventricular node	Nodulus atrioventricularis	
	Atrioventricular bundle	Fasciculus atrioventricularis	
Pericardium	Fibrous pericardium	Pericardium fibrosum	
	Serous pericardium	Pericardium serosum	
	Parietal layer	Lamina parietalis	
	Visceral layer [Epicardium]	Lamina visceralis [Epicardium]	
	Oblique sinus of pericardium	Sinus obliquus pericardii	
	Fold of left vena cava	Plica venæ cavæ sinistræ	
Arteries	Pulmonary trunk [stem]	Truncus pulmonalis	A. pulmonalis
	Right pulmonary artery	A. pulmonalis dextra	Ramus dexter
	Left pulmonary artery	A. pulmonalis sinistra	Ramus sinister
Coronary Arteries	Interventricular br. [of right coronary a.]	R. interventricularis [a. coronariæ dextræ]	R. descendens posterior [a. coronariæ dextræ]
	Interventricular br. [of left coronary a.]	R. interventricularis [a. coronariæ sinistræ]	R. descendens anterior [a. coronariæ sinistræ]
Common Carotid Artery	Carotid sinus	Sinus carotis	
External Carotid	Facial artery	A. facialis	A. maxillaris externa
Superficial Temporal Artery	Zygomatic br.	R. zygomaticus	A. zygomatico-orbitalis
	Anterior br.	R. anterior	R. frontalis
	Posterior br.	R. posterior	R. parietalis
Maxillary Artery	Maxillary a.	A. maxillaris	A. maxillaris interna
	Inferior dental a.	A. dentalis inferior	A. alveolaris inferior
	Buccal a.	A. buccalis	A. buccinatoria
	Posterior superior dental arteries	Aa. dentales superiores posteriores	A. alveolaris superior posterior
	Anterior superior dental arteries	Aa. dentales superiores anteriores	Aa. alveolares superiores anteriores
Ophthalmic Artery	Supratrochlear a.	A. supratrochlearis	A. frontalis
Anterior Cerebral Artery	Cortical brs.	Rami corticales	
	Central branches	Rami centrales	
Middle Cerebral Artery	Cortical brs.	Rami corticales	
	Central brs.	Rami centrales	
	Striate brs.	Rr. striati	
Internal Carotid Artery	Anterior choroid a.	A. chorioidea anterior	A. chorioidea
Basilar Artery	Internal auditory a.	A. auditoria interna	A. auditiva interna
Posterior Cerebral Artery	Cortical brs.	Rami corticales	
	Central brs.	Rami centrales	
	Posterior choroid a.	A. chorioidea posterior	
Internal Mammary Artery	Anterior intercostal arteries	Aa. intercostales anteriores	Rr. intercostales
Thyro-cervical Trunk	Transverse cervical a.	A. cervicalis transversa	A. transversa colli
	Suprascapular a.	A. suprascapularis	A. transversa scapulæ
Axillary Artery	Acromiothoracic a.	A. acromiothoracalis	A. thoracoacromialis

PLEURA (*continued*)	Mediastinum	Mediastinum	Septum mediastinale
	Anterior mediastinum	Mediastinum thoracis anterius	Cavum mediastinale anterius
	Posterior mediastinum	Mediastinum thoracis posterius	Cavum mediastinale posterius
	Middle mediastinum	Mediastinum thoracis medium	
	Superior mediastinum	Mediastinum thoracis superius	
UROGENITAL SYSTEM	Urogenital system	Systema urogenitale	Apparatus urogenitalis
KIDNEY	Renal fat	Adeps renis	Capsula adiposa
URETER	Pelvis of ureter	Pelvis ureteris	Pelvis renalis
URINARY BLADDER	Apex of bladder	Apex vesicæ	Vertex vesicæ
	Neck of bladder	Cervix vesicæ	
URETHRA (MALE)	Spongy part	Pars spongiosa	Pars cavernosa
	Fossa terminalis	Fossa terminalis	Fossa navicularis urethræ [Morgagnii]
PENIS	*Latin form used*	Corpus spongiosum penis	Corpus cavernosum urethræ
	Bulb of penis	Bulbus penis	Bulbus urethræ
EPIDIDYMIS	Canal of epididymis	Canalis epididymidis	Ductus epididymidis
SPERMATIC CORD	Internal spermatic fascia	Fascia spermatica interna	Tunica vaginalis communis [testis et funiculi spermatici]
	Cremaster muscle and fascia	M. cremaster et fascia cremasterica	M. cremaster Fascia cremasterica [Cooperi]
	External spermatic fascia	Fascia spermatica externa	
	Latin form used	Vas deferens	Ductus deferens
SEMINAL VESICLE	Duct of seminal vesicle	Ductus vesiculæ seminalis	Ductus excretorius
PROSTATE	Median lobe	Lobus medianus	Lobus medius
	Sheath of prostate	Vagina [fascialis] prostatæ	Fascia prostatæ
OVARY	Ligament of ovary	Ligamentum ovarii	Lig. ovarii proprium
	Latin form used	Cumulus ovaricus	Cumulus oöphorus
EPOÖPHORON	Tubules of epoöphoron	Tubuli epoöphori	Ductuli transversi
UTERINE TUBE	Pelvic opening of tube	Ostium pelvinum tubæ uterinæ	Ostium abdominale tubæ uterinæ
UTERUS	Internal os of uterus	Os uteri internum	Orificium uteri internum
CERVIX UTERI	Arbor vitæ	Arbor vitæ uteri	Plicæ palmatæ
	External os of uterus	Os uteri externum	Orificium uteri externum
PUDENDUM MULIEBRE	Vestibular fossa	Fossa vestibuli vaginæ	Fossa navicularis [vestibuli vaginæ]
ONTOGENETIC TERMS	*Latin form used*	Decidua parietalis	Decidua vera
	Greek form used	Mesonephros	Corpus Wolffi
	Mesonephric duct	Ductus mesonephricus	Ductus Wolffi
	Paramesonephric duct	Ductus paramesonephricus	Ductus Muelleri
PERITONEUM	Extraperitoneal tissue	Tela extraperitonealis	Tela subserosa
	Greater sac of peritoneum	Saccus major peritonæi	
	Lesser sac of peritoneum	Saccus minor peritonæi	Bursa omentalis
	Opening into lesser sac	Aditus ad saccum minorem	Foramen epiploicum
	Pelvic mesocolon	Mesocolon pelvinum	Mesocolon sigmoideum Mesorectum
	Superior duodenal recess	Recessus duodenalis superior	Recessus duodenojejunalis
	Superior duodenal fold	Plica duodenalis superior	Plica duodenojejunalis
	Recess of pelvic mesocolon	Recessus mesocoli pelvini	Recessus intersigmoideus
	Paracolic grooves	Sulci paracolici	Recessus paracolici
	Infundibulopelvic ligament	Lig. infundibulopelvinum	Lig. suspensorium ovarii
	Sacrogenital fold	Plica sacrogenitalis	Plica rectovesicalis
DUCTLESS GLANDS	Parathyroid glands	Glandulæ parathyreoideæ	
SPLEEN	Medial end	Extremitas medialis	Extremitas superior
	Lateral end	Extremitas lateralis	Extremitas inferior
	Lower border	Margo inferior	Margo posterior
	Upper border	Margo superior	Margo anterior

HUMAN ANATOMY

INTRODUCTION

THE term *human anatomy* comprises a consideration of the various structures which make up the human body. In a restricted sense it deals merely with the parts which form the fully developed individual, and can be demonstrated to the naked eye by various methods of dissection. Regarded from that standpoint, human anatomy may be studied by two methods: (1) the various structures may be considered as individual entities—*systematic anatomy*; or (2) the organs and tissues may be studied as they lie in relationship with one another in the different regions of the body—*topographical* or *regional anatomy*.

It is, however, of great advantage to supplement the facts ascertained by naked-eye dissection by those observed by means of the microscope. In this way two fields of investigation are opened, viz. the study of the minute structure of the various component parts of the body—*histology*; and the study of the human organism in its immature condition, from the fertilisation of the ovum to the birth of the child—*embryology*. The changes through which any organism passes from the fertilisation of the ovum until the fully adult form is reached constitute its *ontogenetic history* or *ontogeny*. *Phylogeny*, on the other hand, comprises the evolutionary history of the group to which the organism belongs. Owing to the difficulty of obtaining material illustrating the earliest stages of human development, recourse must be had to observations on the development of lower but allied forms—*comparative embryology*.

In its broader conception anatomy deals with the factors which have influenced and determined the form, structure and functions of the constituent parts of the body, and this aspect of the subject is termed *morphology*. In this branch much valuable information is obtained from the study of the anatomy of other animals, or *comparative anatomy*.

The direct application of the facts of human anatomy to medicine and surgery constitutes the subject of *applied anatomy*. Finally, the identification of structures underlying the surface of the body may be made the subject of special study, and is termed *surface anatomy*.

In the earlier stages of the development of all vertebrates there are abundant signs of their evolution from a segmented invertebrate type. In their simplest forms the segments are identical with one another, save for their topographical position, and the individual structures contained in each segment are repeated in the other segments. The segments are said to be *serially homologous* with one another, and identical individual structures, repeated from segment to segment, provide further examples of *serial homology*.

When two structures occurring in different animals have similar ontogenetic histories, even though they may show individual differences in other ways, they are said to be *homologous* with each other. Thus, the wing of a bird, the fore-limb of a horse and the upper limb of a man are homologous structures, for, although they differ widely in their structure and functions, they all develop from identical cell-groups in the embryo. Structures which fulfil the same functions in different animals are not necessarily homologous with one another. The gills, which constitute the respiratory apparatus of the

fish, are not homologous with the lungs, which carry out a precisely similar function in man, because they have different ontogenetic histories. Such organs are said to be *analogous*.

SYSTEMATIC ANATOMY.—The various tissues of which the body is composed are built up in different combinations and in varying proportions into organs and structures, which can be arranged in a number of groups or *systems*, according to the functions which they perform.

1. *Osteology*—the bony system or skeleton.
2. *Arthrology*—the articulatory system or joints.
3. *Myology*—the muscular system.

It may be noted that the bony, articulatory and muscular systems, grouped together, constitute the *locomotor apparatus*.

4. *The Blood Vascular System*—comprising the heart, blood-vessels, lymph vessels and lymph glands.
5. *Neurology*—the nervous system. It is convenient to include the organs of the senses in this system.
6. *Splanchnology*—the visceral system. The heart, a thoracic viscus, is included in the blood vascular system, and the remaining viscera are grouped into : (*a*) the *respiratory system* ; (*b*) the *digestive system* ; and (*c*) the *urogenital system*.

For descriptive purposes the body is always assumed to be in the erect posture, with the arms hanging by the side, and the head, the eyes and the palms of the hands directed forwards. The position is an unnatural one, for it entails lateral rotation of the humeri at the shoulder joints. The *median plane* is a vertical plane which passes through the centre of the trunk and divides the body into superficially symmetrical right and left halves. This plane cuts the anterior surface of the body along the *anterior median line*, and the posterior surface, along the *posterior median line*. The median plane will pass approximately through the sagittal suture of the skull, and hence any plane parallel to it is termed a *sagittal plane*. Vertical planes at right angles to the median plane pass through or parallel to the central part of the coronal suture of the skull ; such planes are termed *coronal planes*. Planes drawn at right angles to both sagittal and coronal planes are termed *horizontal planes*.

The terms *anterior* or *ventral* and *posterior* or *dorsal* are employed to describe the front or back of the body or limbs, and the relations of structures within the body to one another. The terms *superior* and *inferior* are used to indicate the relative levels of different structures, but in the study of embryology it is frequently convenient to use the terms *cephalic* and *caudal* to denote relationships to the head and tail ends of the embryo. The terms *proximal* and *distal* are frequently used in the description of the limbs in place of the terms *superior* and *inferior*. To denote relative distances from the median plane, the terms *medial* (nearer to) and *lateral* (further from) are employed.

The terms *superficial* and *deep* are strictly confined to descriptions of the relative depth from the surface of the various structures ; *external* and *internal* are reserved, almost entirely, for describing the walls of cavities or of hollow viscera. For example, a rib possesses an external surface, which is directed away from the thoracic cavity, and an internal surface, which is directed towards the thoracic cavity.

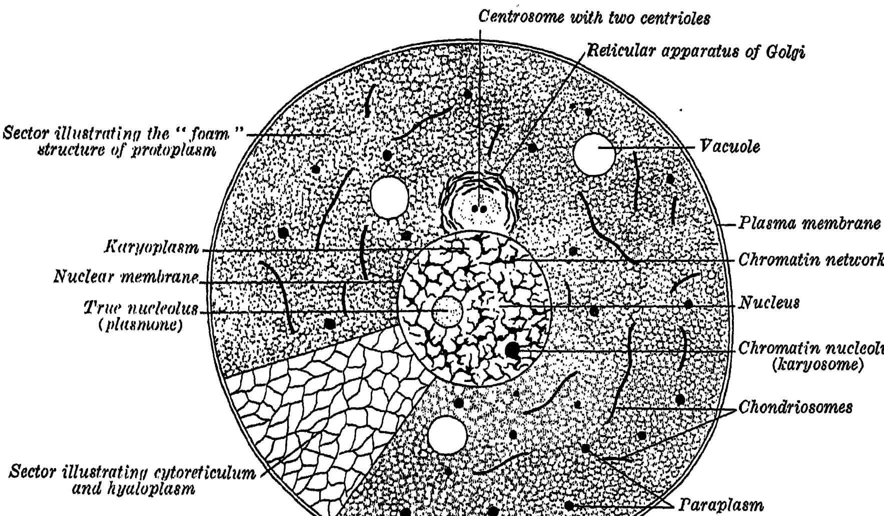
Special terms are restricted for use to certain regions of the body. For example, *palmar* is frequently used instead of *anterior* in the palm of the hand, and *plantar* is employed in descriptions of the sole of the foot and *peroneal* in descriptions of the lateral or fibular aspect of the leg.

HISTOLOGY

THE ANIMAL CELL (fig. 1) *

ALL the tissues and organs of the body originate from the germ-cell (*ovum*) of the female after it has been fertilised by the germ-cell (*spermatozoön*) of the male. The fertilised ovum divides into an enormous number of cells which become variously modified in size, shape and other characteristics according to their positions and functions. All, however, consist of a viscid, unstable, semifluid substance named *protoplasm*. This is a highly complex material of a colloidal nature which consists of water and the following substances in solution or suspension, viz. nitrogenous substances (proteins), fatty bodies (lipoids and phospholipins), starches and sugars (carbohydrates), and inorganic and organic salts. When examined under the high powers of the microscope it may appear

FIG. 1.—A diagram of a cell.



homogeneous, or show some degree of differentiation into fibrils, granules, etc. Within the body of each cell there is usually a small, globular, more solid portion, named the *nucleus*. A cell is therefore frequently defined as "a mass of protoplasm containing a nucleus," but this definition is not altogether satisfactory, because some cells (e.g. red blood-cells of mammals) are non-nucleated, and may carry on their functions for a limited time, while others (e.g. white blood-cells) may be multinucleated.

The **cell-body**. *After fixation with reagents,* such as mercuric chloride, the protoplasm of the body of the cell is seen to consist of a delicate network or *cytoreticulum*, the meshes of which are filled with a more fluid material, named *hyaloplasm*. Granules of fat, pigment or glycogen may be imbedded in the

* Consult *The Cell in Development and Heredity*, by Professor Edmund B. Wilson, 3rd ed. 1925.

cell-protoplasm, and are collectively spoken of as *paraplasm*; vacuoles or spherical spaces filled with fluid may also be present. Most cells are surrounded by a thin wall or *plasma-membrane*, formed by a condensation of the cell-protoplasm.

There are two chief views as to the structure of protoplasm: (*a*) that it consists of a *cytoreticulum* the meshes of which are filled with a more fluid material, named *hyaloplasm*, as described above, and (*b*) that it has an *alveolar* or *foam-like* structure consisting of a viscid interalveolar material having the appearance of a honey-comb, and a more fluid substance consisting of separate alveolar spheres suspended in the interalveolar material; when closely packed the spheres assume a more or less angular form. The supporters of the latter view apply the name *hyaloplasm* to the interalveolar material, and that of *enchylema* to the contents of the spheres.

The **nucleus** is a small, globular structure situated eccentrically within the cell. It contains one or more minute bodies named *nucleoli*, and is readily stained by basic dyes such as carmine or hæmatoxylin. *In fixed and stained preparations* the nucleus exhibits a network (*karyomitome*), the meshes of which are filled with a semifluid substance named *karyoplasm*. The network consists of two constituents, (*a*) a material named *linin*, which stains with acid dyes, and (*b*) a number of more or less discontinuous masses, called *chromatin* because they stain with basic dyes. The karyomitome is condensed around the nucleus to form a distinct *nuclear membrane*.

The **nucleoli** are of two kinds, (*a*) *true nucleoli* or *plasmones*—small, spherical bodies lying in the karyoplasm, and staining readily with acid dyes; one is usually present but sometimes there are two or three; and (*b*) *chromatin nucleoli* or *karyosomes*, which consist of localised thickenings of chromatin.

A **centrosome** is present in most cells. It lies near the nucleus, and has the appearance of a small, spherical mass of clear protoplasm. One or two minute particles, named *centrioles* or *central bodies*, are found within it and play an important part in cell-division. The threads of the protoplasmic reticulum immediately around the centrosome are often radially arranged.

Two other groups of bodies are of general occurrence in animal cells, viz. (*a*) chondriosomes and (*b*) the reticular apparatus of Golgi.

The *chondriosomes*, first described in germ-cells undergoing development into spermatozoa, assume the form of small rods, granules or filaments (*mitochondria*). They are soluble in ether and dilute acetic acid, can be stained by iron-hæmatoxylin and other dyes, and are darkened by osmic acid. When the cell divides they are distributed between the two daughter cells.

The *reticular apparatus of Golgi*, first described in nerve-cells, consists of a network or a group of granules or rods (*Golgi bodies*) in the neighbourhood of the nucleus or of the centrosome. These bodies are blackened by osmic acid, and are best displayed by Golgi's silver-method. During cell-division the reticular apparatus divides into rods or particles which are distributed between the two daughter cells.

Reproduction of cells is effected either by direct or by indirect division.

In *direct division* (*amitosis*) the nucleus becomes constricted in the middle, assuming an hour-glass shape, and then divides into two. This is followed by a cleavage or division of the whole protoplasmic mass of the cell; and thus two daughter cells are formed, each containing a nucleus. The daughter cells are at first smaller than the original mother cell; but they grow, and the process may be repeated in them, so that multiplication may take place rapidly. Direct division is said to occur in leucocytes and bone-cells, and in the epithelial cells lining the urinary bladder.

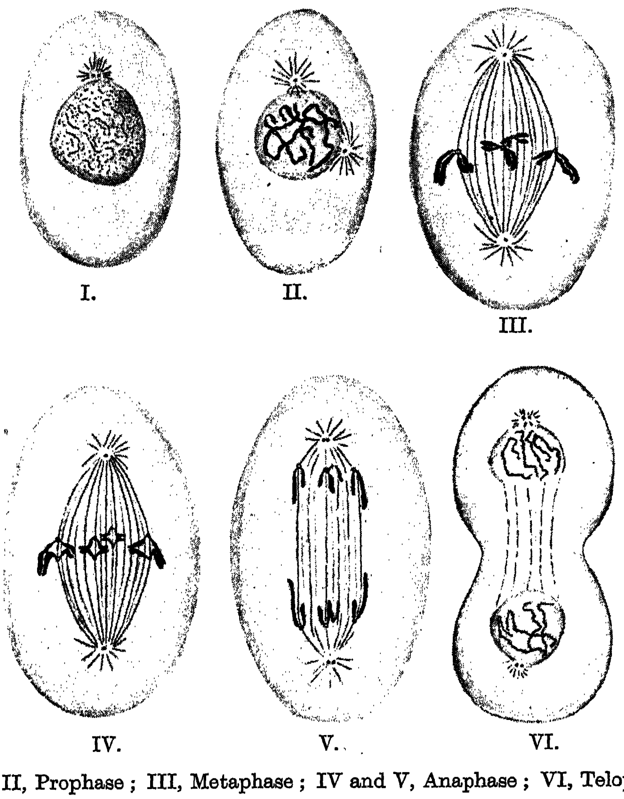
Indirect division or *karyokinesis* (*mitosis*) is the common method of division in the higher animals, and the process is characterised by a series of complex changes in the nucleus, leading to its subdivision; this is followed by cleavage of the cell-protoplasm. Starting with the nucleus in the quiescent or *resting* condition, these changes may be grouped briefly under the four following stages (fig. 2):

1. *Prophase.*—The chromatin network of the nucleus becomes resolved into a number of wavy filaments, termed *chromosomes*, each of which, at the time of its appearance, already consists of two chromatids or daughter chromosomes lying side by side. The number of chromosomes varies widely in different animals but is constant for all the somatic cells in animals of any given species. In man, according to von Winiwarter, the number is forty-eight, of which half

are maternal in origin, and half paternal. Coincident with, or preceding, the definition of the chromosomes, the centrosome divides and the two resulting centrosomes move away from each other—one towards either extremity of the nucleus. As they separate, they are seen to be connected by a spindle of delicate achromatic fibrils, termed the *achromatic spindle*, which elongates proportionately to the separation of the centrosomes. An imaginary line enclosing the spindle midway between its extremities, or *poles*, is named the *equator*.

2. *Metaphase.*—The chromosomes, which have become shorter and irregularly V-shaped, arrange themselves around the equator, each with the apex of the V pointing to the centre of the spindle and linked with one of its fibrils * (fig. 2). This arrangement is termed the equatorial plate, and, when viewed from either pole of the spindle, the plate presents the appearance of an *aster*.

FIG. 2.—A diagram showing the changes which occur in the centrosome and nucleus of a cell in the process of mitotic division.



I and II, Prophase ; III, Metaphase ; IV and V, Anaphase ; VI, Telophase.

3. *Anaphase.*—The two constituent daughter chromosomes of each chromosome separate and travel in opposite directions along the fibrils of the achromatic spindle to group themselves around the centrosomes. Each group contains the same number of daughter chromosomes as there were chromosomes in the equatorial plate, and of these one-half are maternal in origin and one-half paternal.

4. *Telophase.*—The daughter chromosomes lose their identity and the chromatin network, which is characteristic of the resting nucleus, is formed. The nuclear membrane and the nucleolus are differentiated and the cell-protoplasm undergoes constriction around the equator of the achromatic spindle. The constriction deepens and the original cell is gradually divided.

* The changes which the chromosomes undergo in this and in the succeeding stages are exceedingly complicated and a full description would be out of place in this text-book. A detailed account of the present state of our knowledge on the subject will be found in *Recent Advances in Cytology*, by C. D. Darlington, London, 1937.

Homotypical and heterotypical mitosis.—In all somatic cells the process of indirect cell-division conforms to the type described above, and is called *homotypical*. On its completion the nucleus of each daughter cell has as many chromosomes as were present in the nucleus of the mother cell.

During the maturation of a primary oöcyte (p. 46) and also during the subdivision of a primary spermatocyte into spermatids (p. 49) only two consecutive divisions occur, and the nucleus of each of the four resulting cells has only half as many chromosomes as were present in that of the primary oöcyte or spermatocyte. The reduction occurs during the first division, which is named a *heterotypical* or *reduction* division. The second division is homotypical.

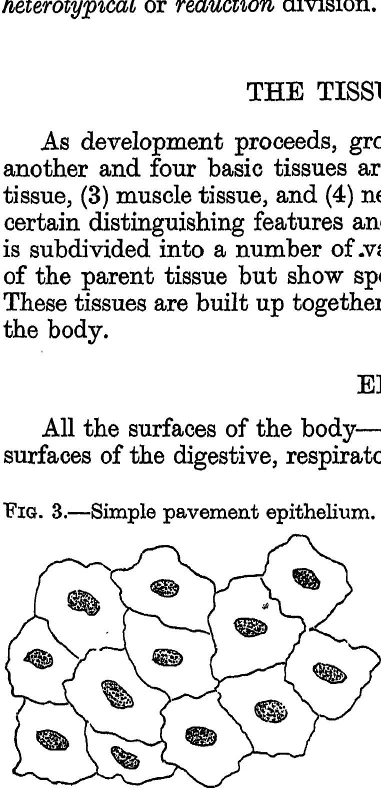
THE TISSUES OF THE BODY

As development proceeds, groups of cells become differentiated from one another and four basic tissues are formed, viz. (1) epithelium, (2) connective tissue, (3) muscle tissue, and (4) nervous tissue. Each of these tissues possesses certain distinguishing features and, with the exception of nervous tissue, each is subdivided into a number of varieties, which retain the essential characters of the parent tissue but show specialisation of one or more of its characters. These tissues are built up together in varying proportions to form the organs of the body.

EPITHELIUM

All the surfaces of the body—the external surface of the skin, the internal surfaces of the digestive, respiratory, and urogenital systems, the closed serous cavities, the inner coats of the vessels, the acini and ducts of all secreting and excreting glands, the ventricles of the brain and the central canal of the spinal cord—are covered with one or more layers of cells, called *epithelium* or *epithelial cells*. These cells serve various purposes. Thus, in the skin, the main purpose served by the epithelium (here called the *epidermis*) is that of protection; as the surface is worn away by the agency of friction new cells are supplied, and thus the true skin and the vessels and nerves which it contains are defended from damage. The epithelial cells of the salivary glands, the pancreas, the gastric glands, and the glands of the small intestine prepare the digestive juices; those covering the intestinal villi are concerned with the absorption of the products of digestion; those lining the serous cavities provide a smooth, moist surface. It should be noted that blood-vessels are absent from all epithelia.

Fig. 3.—Simple pavement epithelium.



The constituent cells of an epithelium are always closely packed together and the intercellular substance is reduced to a minimum. The cells are arranged in one or more layers, usually supported on a basement-membrane, and united together by cement-substance, which is similar in chemical compostion to the matrix or ground-substance of the connective tissues, and has the property of reducing nitrate of silver. Epithelia naturally fall into two groups according to whether there is a single layer of cells (*simple epithelium*), or more than one layer (*stratified epithelium* and *transitional epithelium*).

Figs. 4 and 5.—Columnar epithelial cells, from the small intestine of the cat, stained with picrocarmine. × 600.

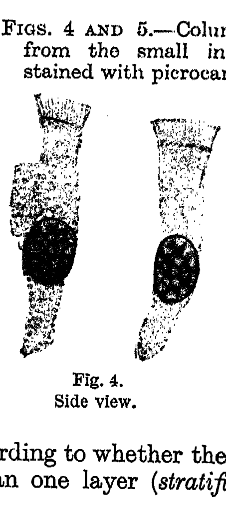


Fig. 4.
Side view.

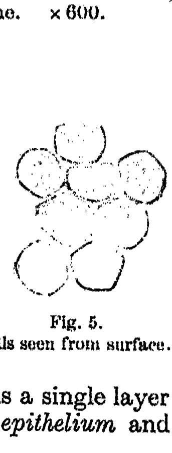

Fig. 5.
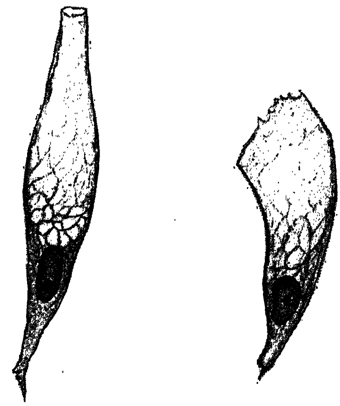
Cells seen from surface.

Simple epithelium.—The different varieties of simple epithelium are squamous or pavement, columnar, and ciliated.

Simple squamous or *pavement* epithelium (fig. 3) is composed of flat, nucleated cells of different shapes, usually polygonal, and varying in size. These cells fit together by their edges, like the tiles of a mosaic pavement. The nucleus is generally flattened, but may be spheroidal. The protoplasm of the cell may be fibrillated, the fibrils of adjacent cells being continuous across the intervening cement. This kind of epithelium forms the lining of the alveoli of the lungs. The epithelium which covers the serous membranes, and which lines the heart, blood-vessels and lymphatics, is also of the pavement type. It is, however, derived from the mesoderm and is usually termed *endothelium*, though some authorities make use of the term *mesothelium* with reference to the lining of serous cavities.

Fig. 6.—Goblet cells of a frog. ×500.



Columnar or *cylindrical* epithelium (fig. 4) consists of cylindrical or rod-shaped cells set together so as to form a complete layer, resembling, when viewed in profile, a palisade. The cells have a prismatic figure, owing to mutual pressure, and are set upright on the surface which supports them. The cell-protoplasm is always more or less reticulated; the nucleus is oval in shape and contains an intranuclear network; the centriole is double and lies near the surface of the cell. In the columnar epithelium of the intestinal villi, the free border of each cell shows a refractive cap, which exhibits well-defined vertical striations. Columnar epithelium lines nearly the whole gastro-intestinal tract and its glands, the greater part of the male urethra, the vas deferens, the tubules and ducts of the prostate, the bulbo-urethral glands and the vestibular glands. In a modified form it also covers the ovary.

Goblet- or *chalice-cells* are modified columnar cells. Each appears to be formed by an alteration in shape of a columnar cell (ciliated or otherwise) consequent on the formation in the interior of the cell of granules which consist of a substance called *mucinogen*. This distends the upper part of the cell, and presses the nucleus down towards its deep part, until the cell bursts and the

Fig. 7.—Isolated liver-cells of a rabbit (dissociated). ×500.

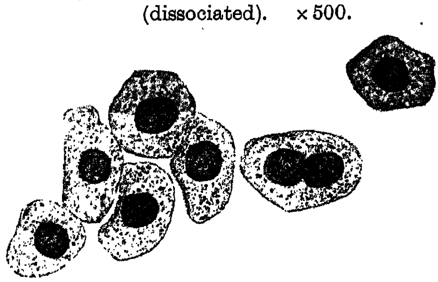


Fig. 8.—Ciliated epithelium from the trachea of a kitten. ×255.

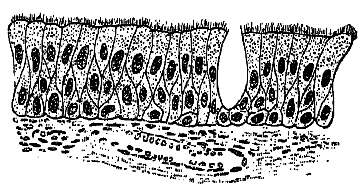


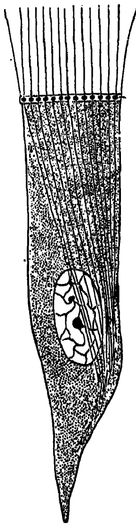
mucus is discharged on to the surface of the mucous membrane (fig. 8), the cell then assuming the shape of an open cup or chalice. A double centriole is found in the mucin-containing part of the goblet-cell. Cells of this kind are especially numerous in the mucous membrane of the stomach, and in the glands of the large intestine; they also occur in the epithelial covering of the villi of the small intestine and in that lining the respiratory tract (fig. 8).

The epithelium of glands is usually columnar, but in some the cells are cubical in shape, in others they are polyhedral. The protoplasm shows a fine reticulum, which gives to the cells a granular appearance (fig. 7). Besides these protoplasmic 'granules,' gland-cells usually contain true granules which

are the products of their own activity. These are in many cases zymogenic in nature, that is, they are, or contain, the precursors of enzymes or ferments.

Ciliated epithelium (fig. 8) is generally columnar in shape. It is distinguished by the presence of minute processes, resembling eyelashes (cilia), standing up from the free surface. The cilia (fig. 9), at their points of attachment to the free border of the cell, possess small nodular enlargements (*basal knobs* of Engelmann); from these knobs fine beaded filaments extend through the cell, and converge to a point near the fixed extremity. The basal knobs or particles have been supposed to be formed by division of the centriole. If the cells are examined during life or immediately on removal from the living body (for which in the human subject the removal of a nasal polypus offers a convenient opportunity) in a weak solution of salt, the cilia will be seen in lashing motion; and if the cells are separated, they will often be seen to be moved about in the field by this ciliary action.

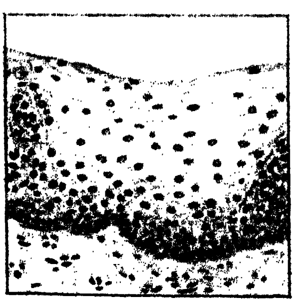
FIG. 9.—A ciliated cell (semidiagrammatic).



Ciliated epithelium lines the respiratory tract from the nose downwards to the smallest ramifications of the bronchial tubes (except in the lower part of the pharynx and on the surfaces of the vocal folds); the tympanic cavity and pharyngotympanic (auditory) tube; the uterine tube and the cavity of the body of the uterus; the efferent ductules of the testis, the lobules of the epididymis and the first part of the vas deferens; the ventricles of the brain and the central canal of the spinal cord.

Stratified epithelium (figs. 10 and 11) consists of several layers of cells. The cells vary greatly in shape; those of the deepest layer are for the most part columnar, and are placed vertically on the basement-membrane; superficial to these the succeeding layers consist of polyhedral cells, which become more and more compressed as they approach the surface; the most superficial cells are found to consist of flattened scales (fig. 10), which overlap one another so as to present an imbricated appearance. The epithelium of the skin is peculiar in that it shows distinct layers. The deep layer consists of columnar and polyhedral cells as in stratified squamous epithelium generally (stratum germinativum). In the next layer, or stratum granulosum, the cells are fusiform in section, and contain granules of a substance called *eleidin*. The third layer, or stratum lucidum, consists of cells in which the eleidin has undergone a transformation into a substance called *keratohyalin*; and the cells of the most superficial layer (stratum corneum) are completely converted into a horny material, known as *keratin* (fig. 11).

FIG. 10.—Stratified squamous epithelium from the œsophagus. (Human). Stained with hæmatoxylin and eosin.



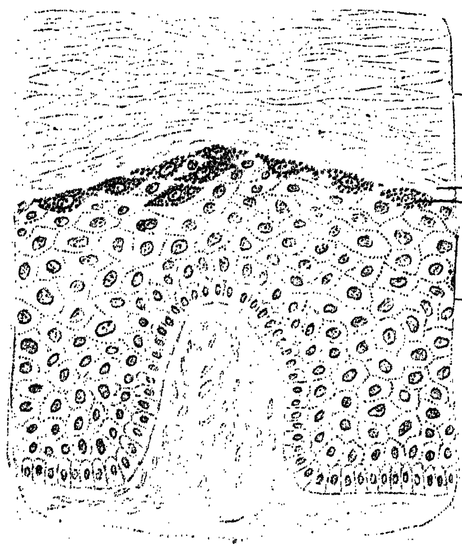
The cells of the deeper layers of stratified squamous epithelium are called *prickle-cells*; they are not closely joined together by cement-substance, but are separated from each other by intercellular channels, between which protoplasmic bridges containing fine fibrils connect the adjacent cells with each other. When a cell is isolated, it appears to be covered over with a number of short spines, in consequence of the bridges being broken through.

Stratified epithelium is found in the skin, in the conjunctiva, on the anterior surface of the cornea, and in the mucous membrane of the mouth, lower part of the pharynx, œsophagus, vagina and part of the cervix uteri.

Transitional epithelium occurs in the ureters and urinary bladder. Here the cells of the most superficial layer are large and flattened, with depressions on their under surfaces to fit on to the rounded ends of the cells of the second

layer, which are pear-shaped, the apices touching the basement-membrane. Between the tapering points of the cells of the second layer is a third variety of cells of smaller size than those of the other two layers (fig. 12). In the distended condition of the bladder the superficial cells are more flattened, and the

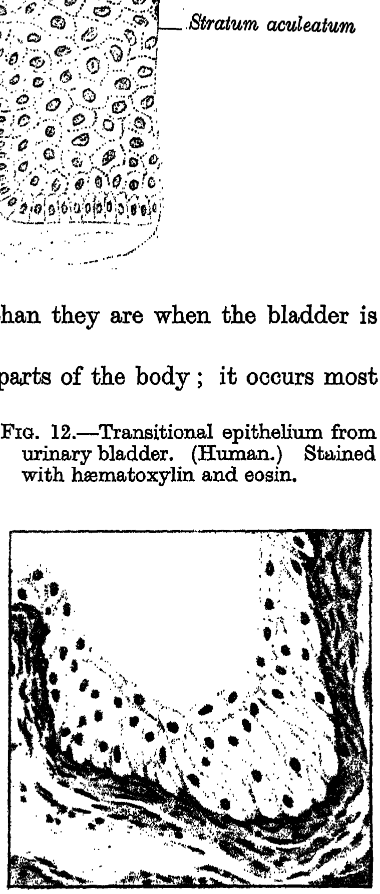
FIG. 11.—A section through the epidermis of the skin of the sole of the foot, stained with hæmatoxylin and van Gieson's stain. ×250.



pear-shaped cells are shorter and broader than they are when the bladder is contracted.

Pigment.—Pigment is found in various parts of the body; it occurs most frequently in epithelial cells and in the cells of connective tissue. Pigmented *epithelial cells* form the external layer of the retina, and are present on the posterior surface of the iris, in the olfactory region of the nose, in the membranous labyrinth of the ear, in the deeper layers of the cuticle, and in the hairs. Pigment is abundantly present in the skin of the coloured races, but in the skin of white races it is well-marked only in the areolæ round the mammary papillæ and in irregular coloured patches.

FIG. 12.—Transitional epithelium from urinary bladder. (Human.) Stained with hæmatoxylin and eosin.



THE CONNECTIVE TISSUES

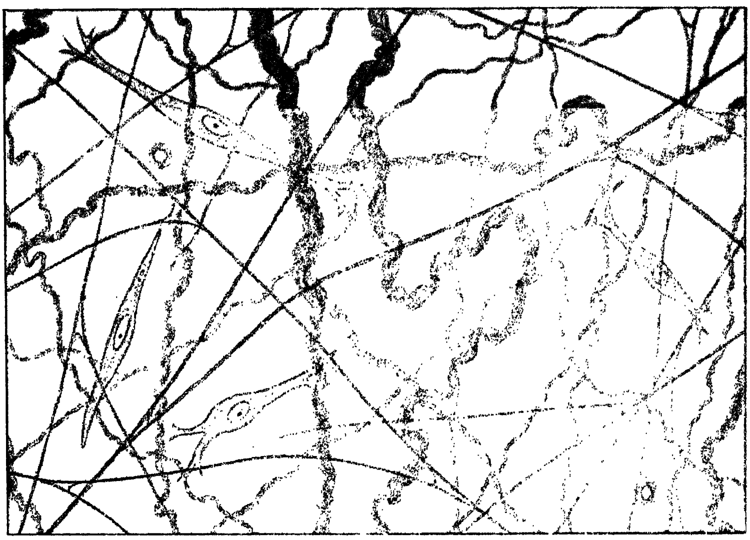
Connective tissues are derived from the mesenchyme, and include a number of tissues which have a passive function, that of binding together or supporting the functionally active structures. They differ considerably from each other in appearance, but present many points of relationship. In contrast to the epithelia the formed matter of the connective tissues lies between and not in the cells.

In a connective tissue the parent cells are separated more or less widely from one another by a homogeneous matrix or ground substance, in which fibres may or may not be present. The most generalised form of connective tissue is termed *areolar tissue* and in it the constituent cells are separated by a semi-fluid matrix in which both white connective tissue and yellow elastic fibres are found

(fig. 13). As contrasted with this generalised form, specialised forms occur in which (*a*) the cells, or (*b*) the matrix, show differentiating characters. In *adipose tissue*, the constituent cells are modified to enable them to contain droplets of oil; in *white fibrous* and *yellow elastic tissue*, it is the fibres which predominate; in *cartilage* and *bone*, the matrix has been rendered solid, whereas in *blood* and *lymph* the cells show special features and the matrix is fluid in character.

Areolar tissue (fig. 13) is so called because, when artificially distended with air or fluid, it exhibits intercommunicating areolæ or spaces. It is extensively distributed and its chief use is to bind parts together, though allowing, in virtue of its extensibility and elasticity, a considerable amount of movement to take place. It occurs as subcutaneous tissue, as the submucous coat in the digestive tract, and as subserous tissue. It is also found between muscles, vessels, and nerves, forming investing sheaths for them, and connecting them with surrounding structures. It is present in the interior of organs, binding together

FIG. 13.—Subcutaneous areolar tissue from a rabbit. Highly magnified.



the lobes and lobules of the compound glands, the various coats of the hollow viscera, and the fibres of muscles and nerves.

When areolar tissue is stretched it is seen to be made up of soft elastic threads, resembling spun silk, and interlacing in all directions. A thin layer, examined under the microscope, shows fibres and cells, imbedded in a homogeneous ground-substance or *matrix*.

The fibres form an irregular meshwork, and are of two kinds—white and yellow. The *white fibres* are exceedingly fine; they are colourless, homogeneous and transparent, and are arranged parallel with each other in bundles which have a wavy course. The individual fibres do not branch, but small bundles of them may leave one large bundle to join another. The *yellow* or *elastic fibres* have well-defined outlines and are usually somewhat larger than the white fibres. They are pale yellow in colour and homogeneous in appearance. They run a comparatively straight course, branch and join up freely with each other. When they are broken across, the ends tend to curl up. They differ from the white fibres also in their staining reactions; they stain a dark red colour with orcein.

The cells of areolar tissue are of four principal kinds: (1) Flattened *lamellar cells*, which may be branched or unbranched. The branched lamellar cells are composed of clear protoplasm, with few granules, and contain oval nuclei; their processes may unite with those of neighbouring cells, so as to form a

syncytium, as in the cornea. Occasionally a cell may be found which shows fibrillation of its protoplasm. Some observers believe such a condition to be a stage in the formation of the white fibres. The unbranched cells are joined edge to edge like the cells of an epithelium ; the flattened cells lining the serous cavities are examples of this variety. (2) *Clasmatocytes* are large irregular cells characterised by the presence of granules or vacuoles in their protoplasm, and containing oval nuclei. (3) *Granule-cells* are ovoid or spheroidal in shape and contain basiphil granules. (4) *Plasma-cells* of Waldeyer are usually spheroidal in shape and distinguished by containing a vacuolated protoplasm ; the vacuoles are filled with fluid, and the protoplasm between them is clear, with occasionally a few scattered basiphil granules.

In addition to these four types of cells, areolar tissue may contain *wandering cells*, i.e. leucocytes which have emigrated from the neighbouring vessels ; in some instances, as in the choroid coat of the eye, cells filled with granules of pigment (*pigment-cells*) are found (p. 13).

FIG. 14.—Areolar tissue of a rabbit, silvered. × 225.
Ground-substance stained, cell-spaces unstained.

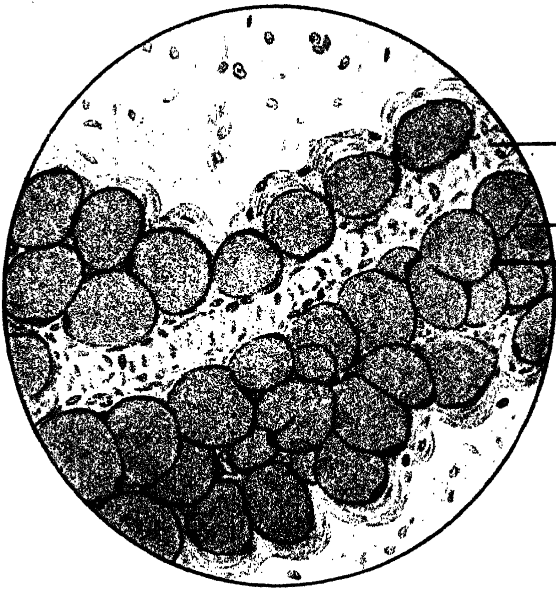
The cells lie in spaces in the ground-substance between the bundles of fibres, and these spaces may be brought into view by treating the tissue with nitrate of silver and exposing it to the light ; this will colour the ground-substance and leave the cell-spaces unstained (fig. 14).

Adipose tissue.—In almost all parts of the body areolar tissue contains a variable quantity of adipose tissue or fat. The principal situations where it is *not* found are the subcutaneous tissue of the eyelids, of the penis and scrotum, and of the labia minora ; within the cavity of the cranium ; and in the lungs, except near their roots. The distribution of adipose tissue is not uniform ; in some parts it is in great abundance, as in the subcutaneous tissue, especially of the abdomen, around the kidneys, and in the mesentery and omentum. Lastly, fat enters largely into the formation of the marrow of bones.

Adipose tissue consists of *fat-cells*, lodged in the meshes of areolar tissue. Fat-cells (fig. 15) vary in size, the average diameter being about 50μ ; each consists of an exceedingly delicate protoplasmic membrane, filled with fatty substance, which is liquid during life, but solidifies after death. They are round or spherical where they are not subjected to pressure ; otherwise they are more or less polygonal. A nucleus is always present under the cell-membrane and can be demonstrated by staining with hæmatoxylin ; in the natural condition

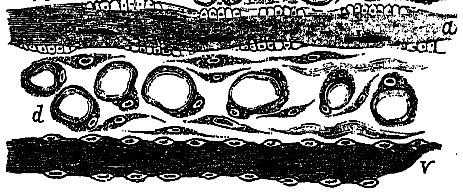
it is so compressed by the contained oily matter as to be scarcely recognisable. The fat-cells are held together mainly by the network of capillary blood-vessels which is distributed to them.

FIG. 15.—Adipose tissue, from the omentum. Stained with Sudan III. and hæmatoxylin. ×350.



Chemically the oily material is composed of olein, palmitin, and stearin, which are glyceryl esters of fatty acids. Sometimes fat-crystals form in the cells after death. By boiling the tissue in ether or strong alcohol, the fat may be extracted from the cells, which are left empty and shrunken.

FIG. 16.—Development of fat. (Klein and Noble Smith)



a. Minute artery. *v.* Minute vein. *c.* Capillary blood-vessels in the course of formation; they are not yet completely hollowed out, there being still left in them protoplasmic septa. *d.* The ground-substance, containing numerous nucleated cells, some of which are more distinctly branched and flattened than others, and appear therefore more spindle-shaped.

Fat first appears in the human embryo about the fourteenth week. The fat-cells are formed by the transformation of connective tissue cells. Small droplets of oil are formed in the protoplasm, and these coalesce to produce a larger drop, which increases until it distends the cell, the remaining protoplasm and the nucleus being displaced towards the periphery (fig. 16).

White fibrous tissue is a true connecting structure which develops in situations where strength is required without rigidity or elasticity. It serves three purposes in the animal economy. In the form of ligaments it binds bones together; in the form of tendons it connects muscles with bones or other structures; it constitutes investing or protecting membranes to various organs. Examples of such membranes are to be found in the fasciæ or sheaths of the muscles, the periosteum, and the perichondrium; the capsules of the various glands; the investing sheaths of the nerves (perineurium) and of various organs, such as the penis and the eye.

In white fibrous tissue, as its name implies, the white fibres (fig. 17) predominate; the matrix is apparent only as a cement-substance, yellow elastic fibres are comparatively few, while the tissue-cells are arranged in a special manner. It presents to the naked eye a silvery white, glistening appearance; it is devoid of elasticity, and has only the very slightest extensibility; it is

FIG. 17.—White fibres. ×350.

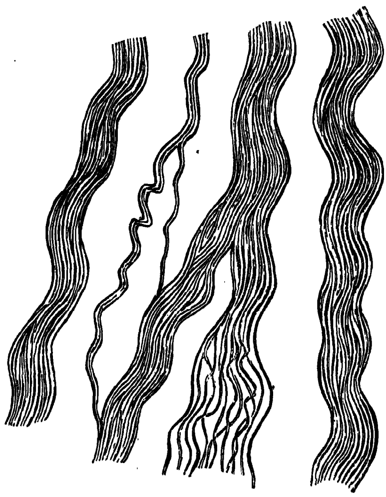


FIG. 18.—Tendon of a rat's tail, stained with gold chloride, showing chains of cells between the tendon-bundles. ×250.

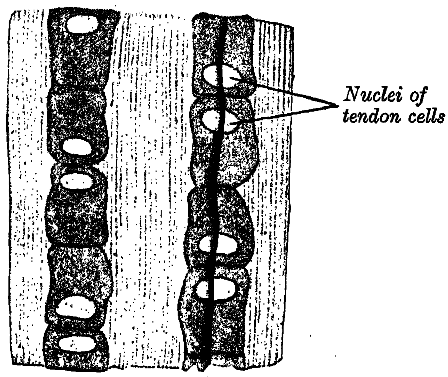
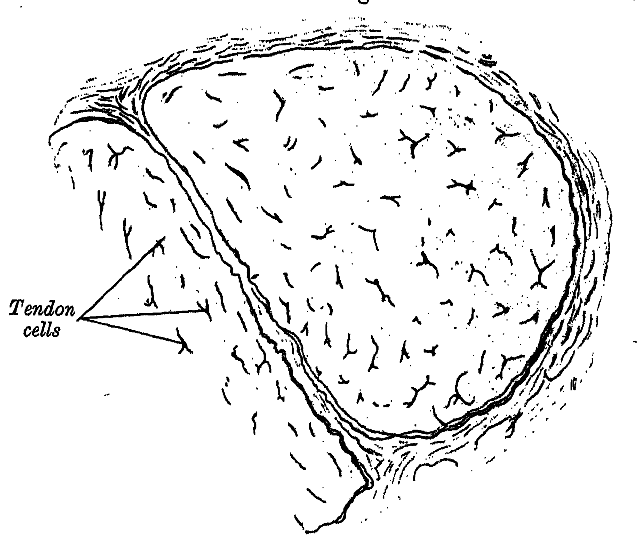


exceedingly strong, so that upon the application of any external violence, a bone with which it is connected may fracture before the fibrous tissue gives way. In ligaments and tendons the bundles of fibres run parallel with each other; in membranes they intersect one another. The cells found in white fibrous tissue are often called 'tendon-cells.' They are situated on the surfaces of groups of fibres, and are arranged in rows, each cell being separated from its

FIG. 19.—A transverse section through a tendon of a rat. ×120.

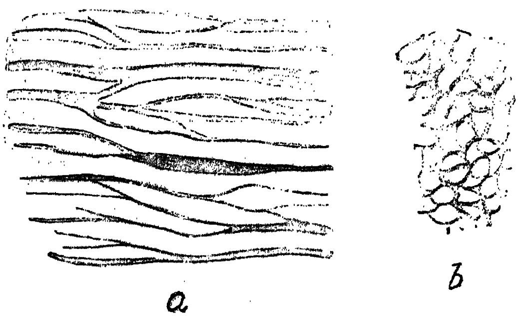


neighbours by a narrow line of cement-substance. The nucleus is generally situated at one end of the cell, the nucleus of the adjoining cell being in close proximity to it (fig. 18). The tendon-cells have wing-like processes which pass between the bundles of fibres, giving a stellate appearance in transverse section (fig. 19). When viewed from this side, the cell with its wings is quadrangular, and there may be the appearance of a vertical line on the body of the cell owing to the projection of a wing towards the eye of the observer (fig. 18). Upon the

addition of acetic acid, white fibrous tissue swells up into a glassy-looking indistinguishable mass. When boiled in water it is converted almost completely into gelatin, the white fibres being composed of *collagen*, which is regarded as the anhydride of gelatin.

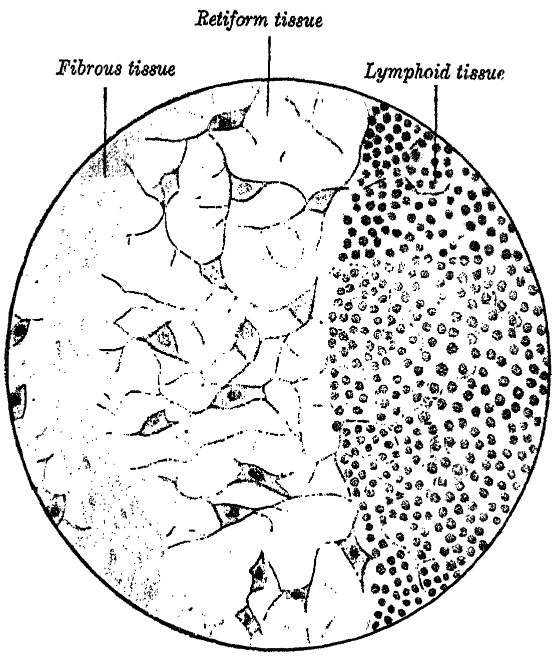
Yellow elastic tissue.—In certain parts of the body a tissue is found which is of a yellowish colour, and possessed of great elasticity. It is capable of considerable extension, and when the extending force is withdrawn returns at once to its original condition. This is *yellow elastic tissue*; it may be regarded as a connective tissue in which the yellow elastic fibres have developed to the practical exclusion of the other elements. It is found in the ligamenta flava, in the vocal folds and the crico-vocal membrane (conus elasticus), in the mucous membrane of the trachea and bronchi, in the walls of the pulmonary air-vesicles, in the coats of the blood-vessels, especially the larger arteries, and to a very considerable extent in the thyrohyoid and stylohyoid ligaments. It is also found in the ligamentum nuchæ of the lower animals (fig. 20). Where the fibres are

Fig. 20.—Ligamentum nuchæ of the ox, stained with picrocarmine. ×280.



a. Longitudinal section. *b.* Transverse section.

Fig. 21.—Retiform and lymphoid tissue from a lymph-gland, stained with picrocarmine. ×255.



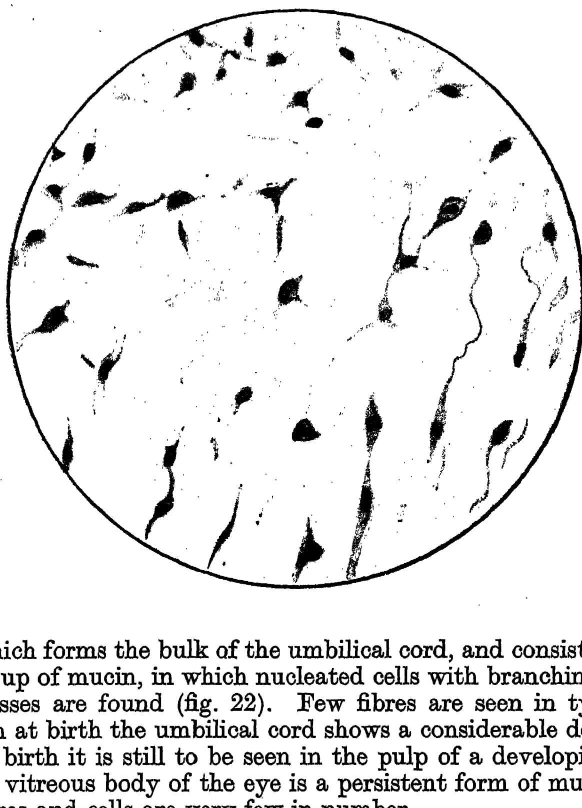
broad and large and the network close, the tissue presents the appearance of a membrane, with gaps or perforations corresponding with the intervening spaces. This is found in the inner coat of the arteries, and to it the name of *fenestrated membrane* has been given by Henle. Yellow elastic fibres remain unaltered by acetic acid; chemically they are composed of the sclero-protein known as *elastin*.

Retiform or reticular tissue (fig. 21) is found extensively in many parts of

the body, constituting the framework of some organs and entering into the construction of many mucous membranes. It is a variety of connective tissue in which the intercellular or ground-substance is, in a great measure, replaced by fluid. It is composed almost entirely of extremely fine bundles of white fibrous tissue, forming an intricate meshwork, and chemically it yields *gelatin* on boiling. The fibres are covered and concealed in places by flattened branched connective tissue-cells. In many situations the interstices of the network are filled with rounded lymph-corpuscles, and the tissue is then termed **lymphoid tissue.**

Mucoid tissue is a fœtal or embryonic type of connective tissue, found chiefly as a stage in the development of connective tissue. It exists in the 'jelly of

FIG. 22.—Mucoid tissue from the umbilical cord of a human fœtus of four months, stained with hæmatoxylin and eosin. ×255.



Wharton,' which forms the bulk of the umbilical cord, and consists of a matrix, largely made up of mucin, in which nucleated cells with branching and anastomosing processes are found (fig. 22). Few fibres are seen in typical mucoid tissue, though at birth the umbilical cord shows a considerable development of fibres; after birth it is still to be seen in the pulp of a developing tooth. In the adult the vitreous body of the eye is a persistent form of mucoid tissue, in which the fibres and cells are very few in number.

Pigmented connective tissue-cells are frequently met with in the lower vertebrates. In man they are found in the choroid coat of the eye (fig. 23), and in the iris of all but the light blue eyes and the albino. The cells are usually large and branched, and are filled with brown or black granules, consisting of *melanin.* In the retina the processes of the cells extend between the rods and cones; when the eye is exposed to light the pigment-granules extend into these processes, and under the influence of darkness they are withdrawn into the body of the cell.

The pigment-granules are of very small size and are closely packed within the cells, but do not invade the nuclei. Occasionally they are yellow, and when occurring in the cells of the cuticle constitute 'freckles.' In the retina another variety of pigment occurs, known as *rhodopsin* or *visual purple,* which is bleached on exposure to light.

Applied Anatomy.—Congenital absence of pigment from the skin and other tissues constitutes the condition known as albinism. Localised patches of skin from which pigment is absent are found in leucoderma; linear white streaks may result from old scars or from

overdistension of the skin, particularly that over the abdomen following pregnancy or ascites. A congenital excessive pigmentation may be general, or may occur locally in the form of dark brown or black nævi (moles). Pigmented patches occasionally follow the continued action of local irritants, and a general swarthiness may result from excessive exposure to the sun, particularly in association with uncleanliness (vagabondinismus). A rare form of general pigmentation ensues on the prolonged administration of salts of silver or of arsenic. Disorders of the endocrine organs may be associated with much discoloration of the skin; this is particularly noticeable in Addison's disease (suprarenal glands) where the pigmentation occurs mostly on the face, exposed parts of the neck, backs of hands, axillary and umbilical regions, genital organs, and medial surfaces of the thighs, but invades also the buccal and lingual mucous membranes. In pregnancy and in some uterine disorders patches of discoloration may be seen round the nipples, over the linea alba, and on the face. Many chronic wasting diseases are accompanied by peculiar colorations of the skin, notably cancer and phthisis; in the latter there may be much deepening of the tint over the zygomatic bones and round the orbits.

Basement-membranes consist of thin sheets of modified connective tissue, and are found underlying layers of epithelial cells, for example, in mucous membranes and secreting glands. They may be formed of cells or of condensed ground-substance. In the former case, flattened cells, which are modified

FIG. 23.—Pigmented connective tissue cells.

connective tissue corpuscles, are united by their edges by means of cement-substance, which can be demonstrated by staining with silver nitrate; if the cells are unbranched, the membrane is continuous; if they are branched, the processes are united, and the membrane is fenestrated. The basement-membrane underlying the epithelium on the anterior surface of the cornea is composed of ground-substance.

Vessels and nerves of connective tissue.—The *blood-vessels* of connective tissue are very few—that is to say, few are supplied to the tissue itself, although many carrying blood to other structures may permeate one of its forms, viz. areolar tissue. In white fibrous tissue the blood-vessels usually run parallel to and between the longitudinal bundles, sending communicating branches across the bundles; in some forms, as in the periosteum and dura mater, they are fairly numerous. In yellow elastic tissue the blood-vessels also run between the fibres. *Lymphatic vessels* are very numerous in most forms of connective tissue, especially in the areolar tissue beneath the skin and the mucous and serous surfaces. They are also found in abundance in the sheaths of tendons, as well as in the tendons themselves. *Nerves* are found in white fibrous tissue, where they end in a special manner; but it is doubtful whether any nerves end in areolar tissue; at all events, they have not yet been demonstrated, and the tissue is possessed of very little sensibility.

Cartilage

Cartilage is a variety of connective tissue in which the ground-substance has become solidified. It is a non-vascular structure found in various parts of the body—in the joints, parietes of the thorax, trachea, bronchi, nose, and ears—where it is necessary to have rigidity and strength combined with a certain degree of elasticity. In the fœtus, at an early period, the greater part of the skeleton is cartilaginous; as this cartilage is afterwards replaced by bone, it is called *temporary*, in contradistinction to that which remains unossified and is called *permanent*.

Cartilage is divided, according to its minute structure, into *hyaline cartilage*, *white fibrocartilage*, and *yellow* or *elastic fibrocartilage*. Besides these varieties met with in the adult human subject, there is a variety called *cellular cartilage*, formed entirely, or almost entirely, of cells, separated from each other by their capsules only, which are extremely well marked in this kind of cartilage. Cellular cartilage is found in the external ears of rats, mice, and some other animals, and it also forms a stage in the development of cartilage in human embryonic life.

FIG. 24.—Cartilage-cells in the costal cartilage of a kitten, stained with picrocarmine. ×350.

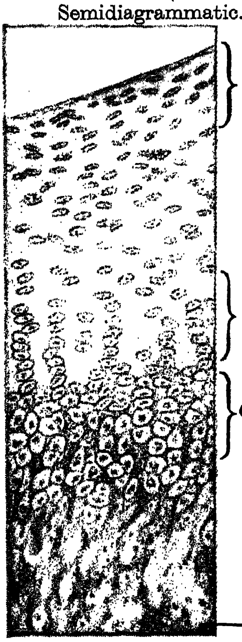
Hyaline cartilage has a pearly bluish colour and consists of a gristly mass of a firm consistence, but of considerable elasticity. Except where it coats the articular ends of bones it is covered by a fibrous membrane, named the *perichondrium*, from the vessels of which it imbibes its nutritive fluids, being itself destitute of blood-vessels. It contains no nerves. If a thin slice be examined under the microscope, it is seen to consist of cells of a rounded or bluntly angular form, lying in spaces in a granular or almost homogeneous matrix (fig. 24). The cells are frequently arranged in groups of two or more, and, when this is so, they have generally straight outlines where they are in contact with each other, but are rounded in the rest of their circumference. They consist of clear translucent protoplasm in which fine interlacing filaments and minute granules are sometimes present; one or two round nuclei, having the usual intranuclear network, are imbedded in the protoplasm.

The matrix is transparent and apparently without structure, or else presents a dimly granular appearance, like ground glass. The portion immediately surrounding each cell-space is often well-defined, and is further characterised by its affinity for basic dyes. It is known as the *capsule* of the space. The matrix of hyaline cartilage, and especially that of the articular variety, can be broken up into fine fibrils after prolonged maceration. These fibrils are probably of the same nature, chemically, as the white fibres of connective tissue. It is believed

by some histologists that the matrix is permeated by a number of fine channels which connect the cell-spaces with each other and with the lymphatics of the perichondrium, and that in this way nutrient fluid obtains access to the cartilage-cells.

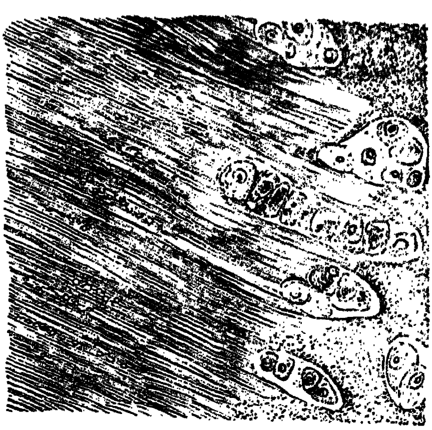
Costal cartilage, temporary cartilage and most of the articular cartilage are of the hyaline variety, but they present differences in the size, shape, and arrangement of their cells.

FIG. 25.—A vertical section through the lower end of the ulna of a human fœtus. Semidiagrammatic.



Articular hyaline cartilage (fig. 25) shows no tendency to ossification; its matrix is finely granular, and its cells are flattened and disposed parallel to the surface in the superficial part of the cartilage, while nearer to the bone they are oval and are arranged in vertical rows. It has a tendency to split in a vertical direction. Its free surface is not covered by perichondrium, but the synovial membrane can be traced over a small part of its circumference, and here the cartilage-cells are more or less branched and pass insensibly into the branched connective tissue cells of the synovial membrane. It forms a thin layer upon the joint-surfaces of the bones, and its elasticity enables it to break the force of concussions, while its smoothness gives ease and freedom of movement. It varies in thickness according to the shape of the articular surface on which it lies; where this is convex the cartilage is thickest at the centre, the reverse being the case on concave articular surfaces. The free surface of the cartilage is constantly being worn away throughout life owing to the joint movements, and this wastage necessitates continuous maintenance growth. In the child mitosis is the normal method of cell division, but at an early age amitotic figures can be observed and in the adult amitosis is the sole mechanism responsible for growth.* Articular cartilage appears to derive its nutriment partly from the vessels of the synovial membrane, partly from those of the bone upon which it is implanted, and possibly from the synovial fluid. The minute vessels of the spongy bone dilate and form arches as they approach the articular lamella, and then return into the substance of the bone.

FIG. 26.—Costal cartilage from a man seventy-six years of age, showing the development of fibrous structure in the matrix. In several portions of the specimen two or three generations of cells are seen enclosed in a parent cell-wall. Highly magnified.



In costal cartilage the cells and nuclei are large, and the matrix, which is usually homogeneous and transparent, has a tendency to fibrous striation, especially in old age (fig. 26). In the thickest parts of the costal cartilages a few large vascular channels may be detected. This appears, at first sight, to be an exception to the statement that cartilage is non-vascular, but is not so

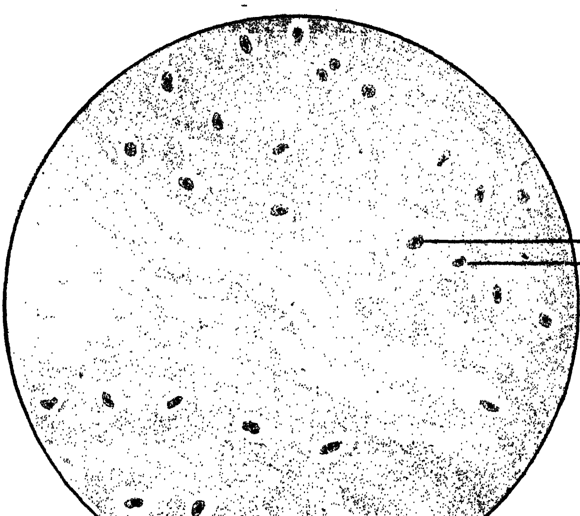
* H. C. Elliott, "Studies on Articular Cartilage," *American Journal of Anatomy*, vol. 58, 1936.

in reality, for the vessels give no branches to the cartilage itself, and the channels may rather be looked upon as involutions of the perichondrium. The xiphoid process of the sternum and the cartilages of the nose, larynx, and trachea (except the epiglottis and corniculate cartilages of the larynx, which are composed of elastic fibrocartilage) resemble the costal cartilages in microscopical characteristics. The arytenoid cartilage of the larynx shows a transition from hyaline cartilage at its base to elastic cartilage at the apex.

The hyaline cartilages, especially in adult and advanced life, are prone to calcify—that is to say, their matrix becomes permeated by calcium salts. Calcification occurs frequently in the costal cartilages, and in the cartilages of the trachea, and may be succeeded by ossification.

White fibrocartilage consists of white fibrous tissue arranged in bundles, with cartilage-cells between the bundles ; the cells are roughly ovoid in shape, and are surrounded by concentrically striated areas of cartilage-matrix (fig. 27). The white fibrocartilages admit of arrangement into five groups—interarticular, connecting, circumferential, stratiform and articular.

FIG. 27.—White fibrocartilage from the intervertebral disc of a sheep, stained with borax-carmine. ×300.



1. The *interarticular fibrocartilages* are flattened fibrocartilaginous plates, of a round, oval, triangular, or sickle-like form, interposed between the articular cartilages of certain joints ; the synovial membrane of the joint covers their free surfaces, where they are not exposed to pressure. They are found in the mandibular, sternoclavicular, acromioclavicular, wrist- and knee-joints. They serve to obliterate the intervals between opposed surfaces in their various motions and to adapt articular surfaces to one another.*

2. The *connecting fibrocartilages* are interposed between the bony surfaces of those joints which admit of only slight mobility, as between the bodies of the vertebræ. They form discs which are closely adherent to the opposed surfaces. Each disc is composed of concentric layers of white fibrous tissue, with cartilaginous laminæ interposed, the former tissue predominating towards the circumference, the latter towards the centre.

3. The *circumferential fibrocartilages* consist of rims of fibrocartilage which surround the margins of some of the articular cavities, e.g. the glenoidal labrum of the shoulder-joint and the acetabular labrum of the hip-joint ; they serve to deepen the articular cavities and to protect their edges.

* *See also* p. 427.

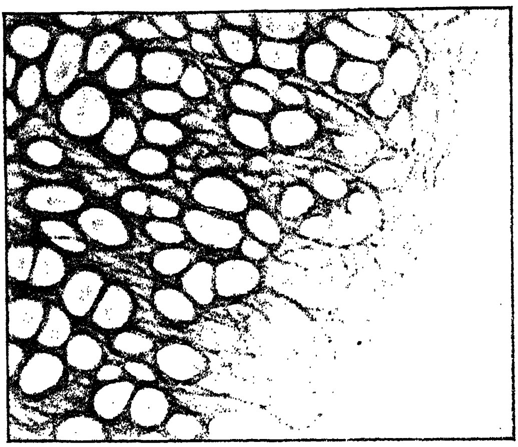
4. The *stratiform fibrocartilages* form thin coatings to osseous grooves through which the tendons of certain muscles glide.

Small masses of fibrocartilage are also developed in the tendons of some muscles, where they glide over bones, as in the tendons of the peroneous longus and tibialis posterior.

5. *Articular fibrocartilage* covers the articular ends of bones which ossify in membrane. In the floor of the articular fossa of the temporal bone the covering consists mainly of white connective tissue fibres, and the cartilage-cells are few in number.

Yellow or elastic fibrocartilage is found in the ears, the corniculate cartilages of the larynx, and the epiglottis. It consists of cartilage-cells and a matrix, the latter being pervaded by a network of yellow elastic fibres, branching and anastomosing in all directions, except immediately around the cells, where there is a variable amount of hyaline substance (fig. 28). The fibres resemble those

FIG. 28.—Yellow or elastic fibrocartilage from the ear of a sheep, stained with orcein.



of yellow elastic tissue, not only in appearance, and in being unaffected by acetic acid, but also in their affinity for orcein; according to Rollett their continuity with the elastic fibres of the neighbouring tissue is demonstrable.

The distinguishing feature of cartilage, chemically, is that on boiling it yields a substance called *chondrin*, a mixture of gelatin with mucinoid substances, chief among which is a compound termed *chondromucoid*.

BONE

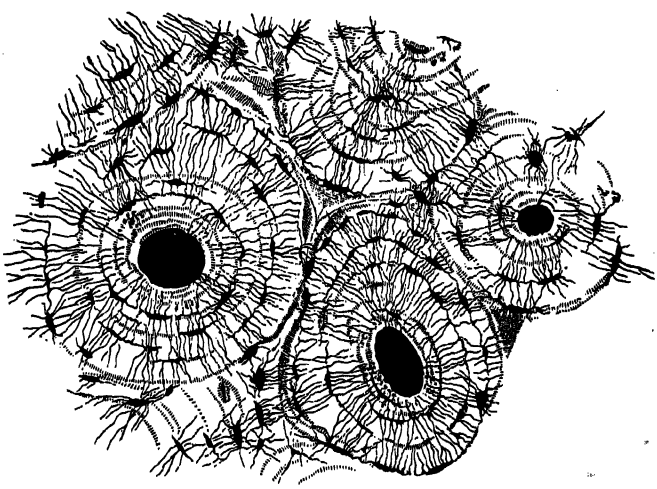
Structure and physical properties.—Bone is a variety of connective tissue which is characterised by the presence of certain inorganic salts in its ground substance. It is one of the hardest structures of the animal body, although it possesses also a certain degree of toughness and elasticity. Its colour, in a fresh state, is pinkish white externally, and deep red within. In section it is seen to be composed of two kinds of tissue, one of which is dense in texture, like ivory, and is termed *substantia compacta*; the other consists of slender fibres and lamellæ, which join to form a reticular structure, and is called *substantia spongiosa*. The compact substance is always placed on the exterior of the bone, the spongy in the interior (fig. 263). The relative quantities of these vary in different bones and in different parts of the same bone, according as strength or lightness is requisite. Close examination of the compact substance shows it to be extremely porous, so that the difference between it and the spongy substance depends merely upon the relative amount of solid matter and the size and number of spaces in each; in the compact substance the spaces are small and the solid matter abundant, while in the spongy substance the spaces are large and the solid matter small in quantity.

During life bone is permeated by vessels, and enclosed, except where it is coated with articular cartilage, in a fibrous membrane termed the *periosteum*, by means of which many of these vessels reach the bone. If the periosteum be stripped from the surface of the living bone, small bleeding points are seen which mark the entrance of the periosteal vessels; and on section every part of the bone exudes blood from the minute vessels which ramify in it. In the interior of the long bones of the limbs there is a cylindrical cavity (*cavum medullare*) filled with *medulla ossium* or *marrow*, and lined with a membrane composed of highly vascular areolar tissue, called the *endosteum*.

The **periosteum** adheres to the surfaces of the bones but it is absent from the cartilage covering their articular surfaces. When strong tendons or ligaments are attached to a bone, the periosteum is incorporated with them. It consists of two layers closely united together, the outer formed chiefly of white fibrous tissue, containing occasionally a few fat-cells; the inner, of elastic fibres of the finer kind, forming dense membranous networks, which can again be separated into several layers. In young bones the periosteum is thick and very vascular, and is separated from the bone by a layer of soft *osteogenetic tissue*, containing a number of granular corpuscles or 'osteoblasts,' by which ossification proceeds on the exterior of the young bone. Later in life the periosteum is thinner and less vascular, and the osteoblasts are represented by a single layer of flattened cells on its deep surface. The periosteum serves as a nidus for the ramification of the vessels previous to their distribution in the bone; hence the liability of bone to exfoliation or necrosis when denuded of this membrane by injury or disease. Fine nerves and lymphatics, which generally accompany the arteries, may also be demonstrated in the periosteum.

Vessels and nerves of bone.—The *blood-vessels* of bone are very numerous. Those of the compact substance are derived from a close network of vessels in

FIG. 29.—A transverse section through the compact substance of bone. Magnified. (Sharpey.) (From Quain's Elements of Anatomy.)

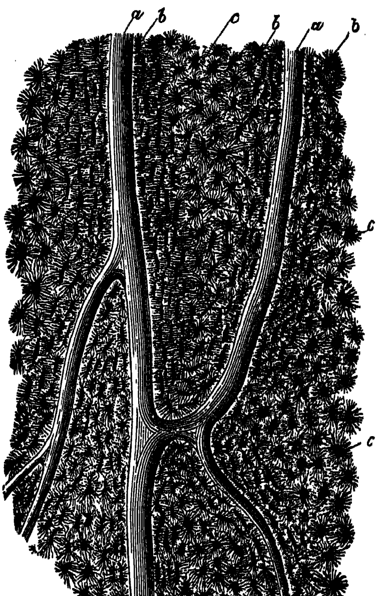


the periosteum. Vessels pass from this network into the minute orifices in the compact substance, and run in the Haversian canals which traverse it. The spongy substance is supplied in a similar way by larger vessels, which perforate the outer compact substance, and are distributed to the cavities of the spongy portion of the bone. In the long bones, numerous apertures may be seen at the ends near the articular surfaces; some of these give passage to arteries, but the greater number transmit veins from the spongy substance. The marrow of a long bone is supplied by an artery which enters the bone at the nutrient foramen (*foramen nutricium*). The *nutrient* artery, usually accompanied by one or two veins, sends branches upwards and downwards, which ramify in the endosteum, and give twigs to the adjoining Haversian canals. The ramifications of this vessel anastomose with the arteries of the spongy and compact substances. In

most of the flat, and in many of the short, bones there are one or more large apertures for the transmission of nutrient vessels. Veins emerge from the long bones as follows :—(1) one or two accompany the nutrient artery ; (2) numerous large and small veins emerge near the articular extremities ; (3) many small veins pass out of the compact substance. In the flat cranial bones the veins are large and run in tortuous canals in the diploic tissue, the walls of the canals being formed by thin lamellæ of bone, perforated here and there for the passage of branches from the adjacent diploë. The same condition is found in all spongy substance, the veins being enclosed and supported by osseous material, and having exceedingly thin coats. When a bone is divided, the vessels remain open, and do not contract in the canals in which they are contained. *Lymphatic vessels,* which communicate with those in the periosteum, are found in the Haversian canals. *Nerves* are distributed freely to the periosteum, and accompany the nutrient arteries into the interior of the bone. They are said to be most numerous in the articular extremities of the long bones, in the vertebræ, and in the larger flat bones.

Minute anatomy.—If a thin transverse section of dense bone be examined with a low power of the microscope it will be seen to be mapped out into a number of circular districts, each consisting of a central hole surrounded by a number of concentric rings. These districts are termed *Haversian systems*; the central hole is a *Haversian canal,* and the rings are *lamellæ* of bony tissue arranged concentrically around the central canal. Between these lamellæ there are a number of small spaces termed *lacunæ,* which are connected with each other and with the central Haversian canal by many fine radiating channels called *canaliculi*. The irregular intervals between these circular districts are occupied by *interstitial* lamellæ, with their lacunæ and canaliculi, running in various directions, but more or less parallel with the surface (fig. 29). Again, other lamellæ are found on the surface of the bone completely encircling it ; they are termed *circumferential* or *primary* lamellæ, to distinguish them from those surrounding the Haversian canals, which are termed *secondary* lamellæ.

FIG. 30.—A longitudinal section of the shaft of the femur. ×100.



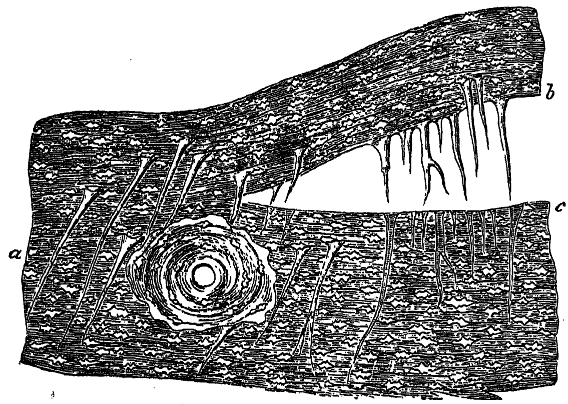
a. Haversian canals. *b.* Lacunæ seen from the side. *c.* Others seen from the surface in lamellæ which are cut horizontally.

In a longitudinal section it will be seen that the Haversian canals run parallel with the long axis of the bone but branch and communicate at short intervals (fig. 30). They vary considerably in size, but their average diameter is about 0·05 mm. The canals near the medullary cavity are larger than those near the surface of the bone. Each canal usually contains a minute artery and vein, a small quantity of delicate connective tissue, and some nerve-filaments ; in the larger ones there are also lymph vessels, and cells with branching processes.

The *lamellæ* are thin plates of bony tissue. They may be stripped off as thin films from a piece of bone which has been macerated in dilute mineral acid. If one of these films be examined with a high power of the microscope, it will be found to be composed of fine fibres identical with the white fibres of areolar tissue. The matrix between the fibres is impregnated with lime-salts which the acid dissolves. The fibres are arranged in bundles, and fibres leave the bundles of one lamella to join those of adjacent lamellæ. Moreover, the fibres of one lamella usually form an acute angle with those of the contiguous layer ; in the Haversian systems, however, the fibres of adjacent lamellæ

run at right angles to each other. In many places the various lamellæ are held together by tapering fibres, which run obliquely through them, pinning or bolting them together; these fibres were first described by Sharpey, and were named by him *perforating fibres* (fig. 31).

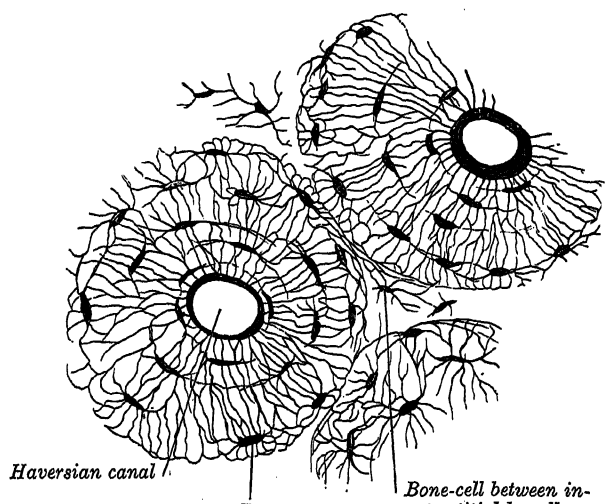
FIG. 31.—The perforating fibres of a human parietal bone, decalcified. (H. Müller.) (From Quain's Elements of Anatomy, vol. ii. pt. i., Microscopic Anatomy.)



a. Perforating fibres *in situ*; *b*. Fibres drawn-out of their sockets; *c*. Sockets.

The *lacunæ* are oblong spaces situated between the lamellæ, and each lacuna is occupied during life by a branched *bone-cell*, the processes from which extend into the canaliculi.

FIG. 32.—A transverse section through a portion of the shaft of a human fibula, decalcified. ×250.



The *canaliculi* are minute channels, crossing the lamellæ and connecting the lacunæ of a Haversian system with one another, and with the Haversian canal. The canaliculi at the periphery of a Haversian system do not as a rule communicate with those of neighbouring systems, but form loops and return to their own lacunæ. Thus every part of a Haversian system is supplied with nutrient fluids derived from the vessels in the Haversian canal and distributed through the canaliculi and lacunæ.

The *bone-cells* occupy, but do not fill, the lacunæ. They are flattened,

nucleated branched cells, homologous with the lamellar cells of connective tissue ; their branches pass into the canaliculi.

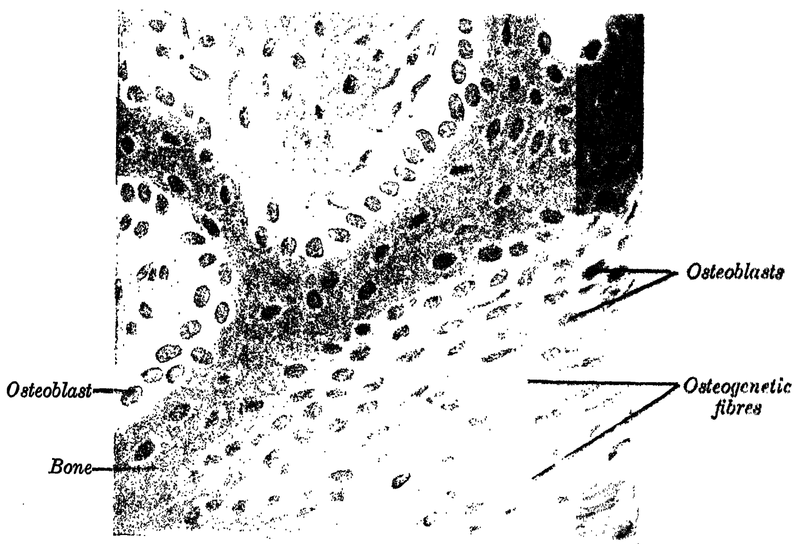
In thin plates of bone Haversian canals are absent.

Chemical composition.—Bone consists of animal or organic, and mineral or inorganic, substances intimately combined.

The animal substance forms about 33 per cent. of the total weight,* and may be obtained by immersing a bone for a considerable time in dilute mineral acid which will dissolve the mineral matter. The bone retains its shape, but is now perfectly flexible, so that a long bone (one of the ribs, for example) can easily be tied in a knot. In a transverse section of such a softened bone (fig. 32), the arrangement of the Haversian canals, lamellæ, lacunæ, and canaliculi can be recognised.

The mineral substance may be obtained by calcination, which destroys the animal matter. The bone retains its original form, but is white and brittle, has

Fig. 33.—Intramembranous ossification.



lost about one-third of its original weight, and crumbles under the slightest force. The mineral substance, composed chiefly of calcium phosphate, forms about 66·7 per cent. of the weight of the bone ; it confers on bone its hardness and rigidity, while the animal matter (*ossein*) determines its resiliency and tenacity.

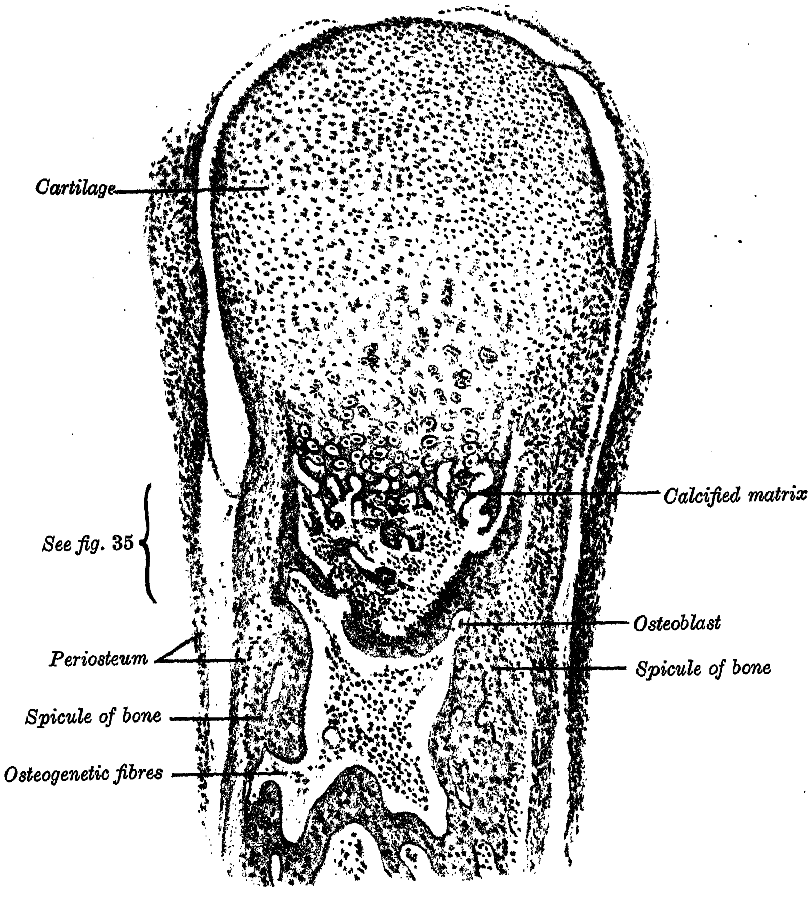
Ossification.—Some bones, such as those of the roof and sides of the skull, are preceded by membrane, but most bones are preceded by rods or masses of cartilage. Hence two kinds of ossification are described ; the *intramembranous* and the *intracartilaginous* ; but there is no essential difference between these two methods of bone formation.

Intramembranous ossification.—The membrane which occupies the place of the future bone is of the nature of connective tissue, and ultimately forms the periosteum ; it is composed of fibres and granular cells in a matrix richly supplied with blood-vessels. The peripheral portion is more fibrous, while in the central portion the cells or *osteoblasts* predominate. At the outset of the process of bone formation a little network of fibres radiates from the centre of ossification. These rays consist at their growing points of a network of fine clear fibres and granular corpuscles with an intervening ground-substance (fig. 33). The fibres are termed *osteogenetic* fibres, and differ little from those of white fibrous tissue. The membrane assumes a dark and granular appearance

* H. E. Radasch (*Proceedings of the American Association of Anatomists, Anatomical Record*, vol. 21) states that in ' green ' bone the organic substance averages 40·75 per cent.

from the deposition of calcareous granules in the matrix between the fibres, and in the calcified material some of the granular cells or osteoblasts are enclosed. By the fusion of the calcareous granules the tissue again assumes a more transparent appearance, but the fibres are no longer so distinctly seen. The osteoblasts form the bone-cells of the future bone, the spaces in which they are enclosed constituting the lacunæ. As this process advances, a network of bone is formed, the meshes of which contain the blood-vessels and a delicate connective tissue crowded with osteoblasts. The bony trabeculæ thicken by the addition of fresh layers formed by the osteoblasts on their surface, and the meshes are correspondingly encroached upon. Subsequently the bone increases in thickness

FIG. 34.—A section through a phalanx of a fœtal finger. ×100. Drawn from a specimen prepared by A. F. Bernard Shaw.



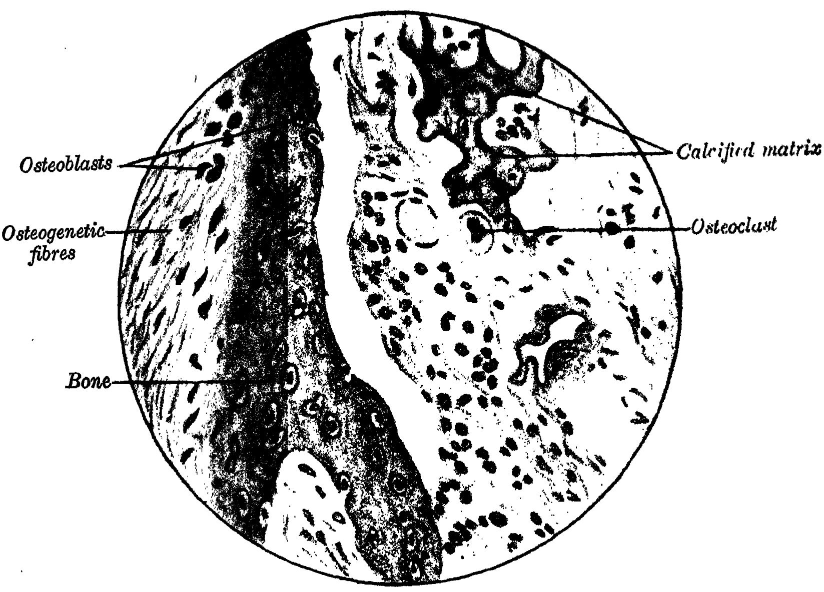
by the deposition of successive layers under the periosteum and round the larger vascular channels, which become the Haversian canals.

Intracartilaginous ossification.—Most of the bones are preformed in cartilage, and each long bone is represented in early fœtal life by a rod of hyaline cartilage. The *primary centre of ossification* appears in the centre of the rod and the process of bone formation extends towards the ends, which remain cartilaginous for a length of time which differs for different bones. Later, ossification begins at one or more *secondary centres* in one or both ends and the portions of bone formed from them constitute *epiphyses*. Most long bones develop an epiphysis at each extremity, but in some (metacarpals, metatarsals, phalanges and ribs) an epiphysis is formed at one end only. The cartilage which intervenes between

the epiphysis and the growing shaft or *diaphysis* is termed the *epiphyseal cartilage*.

The rodlike cartilage model of the bone is surrounded by a very vascular membrane, termed the *perichondrium*, which is formed by connective tissue similar to that already described as constituting the basis of membrane bone. Between this membrane and the underlying cartilage there is a layer of osteogenetic mesenchyme, from which the formative-cells (the *osteoblasts*) are derived. Prior to the appearance of the primary centre of ossification the cartilage-cells in the middle of the shaft become greatly enlarged and the trabeculae between them become reduced to thin partitions. The cartilage-cells, possibly owing to autointoxication due to absorption of the surrounding matrix during the period of growth, undergo degenerative changes and die. Their bodies become shrunken and leave spaces which are termed the *primary areolæ*. Subsequent to the death of their parent cells the thin partitions between these spaces become calcified.

FIG. 35.—A part of fig. 34 (opposite to the bracket) more highly magnified. ×375.



The weakening of the shaft brought about in this way is compensated for by the subperichondral osteoblasts, which lay down a peripheral layer of young bone by the intramembranous method previously described. These changes constitute the first stage in the process of intracartilaginous ossification.

The second stage consists in the prolongation into the cartilage of processes of the deeper or osteogenetic layer of the perichondrium (now periosteum) (fig. 34). The processes consist of blood-vessels and cells—*osteoblasts*, or bone-formers, and *osteoclasts*, or bone-destroyers. The latter are large, multinucleated protoplasmic masses, and they excavate passages through the new-formed bony layer by absorption, and pass through it into the calcified matrix. Wherever these processes of the osteogenetic layer come in contact with the calcified walls of the primary areolæ they absorb them, and thus cause a fusion of the original cavities and the formation of larger spaces, which are termed the *secondary areolæ* or *medullary spaces*. These secondary spaces are filled with embryonic marrow, consisting of osteoblasts and vessels, derived, in the manner described above, from the osteogenetic layer of the periosteum.

The walls of the secondary areolæ increase in thickness by the deposition of layers of bone on their surface. This process takes place in the following manner. Some of the osteoblasts of the embryonic marrow, after undergoing rapid division, arrange themselves as a layer on the surface of the wall of the space (fig. 34). This layer of osteoblasts forms a bony stratum, which gradually

covers the wall of the space and in which some of the osteoblasts are included as bone-cells. The next stage in the process consists in the removal of these primary bone-spicules by the osteoclasts, one of which may be seen lying in a Howship's foveola at the free end of each spicule (fig. 35). The removal of the primary spicules goes on *pari passu* with the formation of permanent bone by the osteogenetic layer of the periosteum, and in this way the medullary cavity of the bone is formed.

While bone is being laid down in the middle of the shaft the adjoining cartilage reacts in a manner which prepares it for the extension of the ossifying process. In the area directed towards the end where an epiphysis appears later, the cartilage cells undergo rapid division, at first in the transverse axis of the bone and then in its long axis, so as to give rise to a great number of parallel rows of disc-shaped cells. This process goes on throughout the period of growth and is responsible for increase in length of long bones.* The older cells, which lie nearest to the primary centre of ossification, become hypertrophied and this enlargement is assocated with the intracellular storage of glycogen.† Most, if not all, of these distended cells die, the trabeculae between the columns undergoing calcification. Osteoclasts and osteoblasts from the primary centre extend the process of ossification in the longitudinal direction by invading the columns, removing the trabeculae and laying down new bone. As ossification extends along the shaft the cartilage-cells at the epiphyseal end of the rows divide rapidly, while those at the opposite end progressively hypertrophy and atrophy.

This series of changes proceeds gradually towards the ends of the bone, so that all the changes described above may be seen in different parts, from the true bone at the centre of the shaft to the hyaline cartilage at the extremities.

While the ossification of the cartilaginous shaft is extending towards the articular ends, the epiphyseal cartilage immediately in advance of the bony tissue continues to grow until the length of the adult bone is reached.

One or more secondary bony centres appear in the cartilaginous extremities and initiate in them the process of ossification ; but the ends remain separated from the shaft of the bone by the epiphyseal cartilages for a definite time. Ossification of epiphyses and ossification of the diaphysis in the direction of an extremity where no epiphysis develops (e.g. the distal ends of the phalanges, etc.) are not marked by the preliminary formation of rows of cells.‡ Instead, the cartilage-cells constitute small groups or cell-nests, which undergo hypertrophy and, later, die, a change accompanied by calcification of the surrounding matrix. These groups become invaded by osteoblasts and osteoclasts and bone is laid down in the manner already described. The epiphyseal cartilages ultimately ossify, and the bone assumes its completed form and shape. The same remark applies to such processes of bone as are ossified from separate epiphyses, e.g. the trochanters of the femur. Bones increase in length by ossification continuing to extend into the epiphyseal cartilages, which go on growing in advance of the ossifying process ; when the growth of the epiphyseal cartilages ceases, the diaphysis and the epiphyses unite. Bones increase in circumference by deposition of new bone from the osteogenetic layer on their sub-periosteal aspects, and at the same time an absorption takes place from within, by which the medullary cavities are increased. It should be observed that, in certain situations, e.g. the ramus of the mandible (p. 282) and the expanded extremities of the shafts of the long bones, a process of remodelling is necessary during the stage of lengthening, in order that the outline of the bone may remain constant throughout the period of growth. This remodelling is brought about by a process of absorption, which goes on side by side with the process of deposition and is an essential feature of normal growth in the situations cited.

The bone first laid down is spongy in structure. Later the osteoblasts contained in its spaces form the concentric layers characteristic of the Haversian systems, and are included as bone-cells.

The number of ossific centres varies in different bones. Most of the short

bones are ossified from a single centre. In each long bone there is a primary centre for the shaft, or diaphysis; and one or more secondary or epiphyseal centres for each extremity. That for the shaft is the first to appear. The times of union of the epiphyses with the shaft vary inversely with the dates at which their ossifications begin (with the exception of the fibula) and regulate the direction of the nutrient arteries of the bones. Thus, the nutrient arteries of the bones of the arm and forearm are directed towards the elbow, since the epiphyses at this joint become united with the shafts of the bones before those at the opposite extremities. In the lower limb, on the contrary, the nutrient arteries are directed away from the knee; that is, upwards in the femur, downwards in the tibia and fibula; and in them it is observed that the epiphyses at the upper end of the femur, and those at the lower ends of the tibia and fibula, unite first with the shafts. Where there is only one epiphysis, the nutrient artery is directed towards the other end of the bone. The growing end of the macerated diaphysis has a curious coral-like appearance, which is quite characteristic.

Epiphyses are essentially a mammalian characteristic, for, apart from the upper tibial epiphysis occurring in birds and some reptiles, they do not occur in lower vertebrates.* There is, however, reason to believe that they were present in the extinct group of mammal-like reptiles.† Their presence at the expanded ends of the long bones reduces very considerably the amount of remodelling by absorption which would be necessary, if they did not develop. Parsons ‡ groups epiphyses under three headings, viz. (1) *pressure epiphyses*, appearing at the articular ends of the bones and transmitting 'the weight of the body from bone to bone'; (2) *traction epiphyses*, associated with the insertion of muscles, and 'originally sesamoid structures though not necessarily sesamoid bones'; and (3) *atavistic epiphyses*, representing parts of the skeleton which at one time formed separate bones, but which have lost their function 'and only appear as separate ossifications in early life.'

The description here given of the development and growth of bone is in accordance with the generally accepted view. Macewen § has, however, given another account. He asserts that the osteoblasts are produced by division of the nuclei of the cartilage-cells, and that bone-formation is brought about by these cells, the periosteum taking no part in the process. He concludes that the function of the periosteum in the development of bone is mechanical, and is confined to limiting the degree of growth and deciding its direction.

Applied Anatomy.—The blood supply of long bones is derived from two sources: (*a*) one (occasionally more) nutrient artery runs through the compact outer layer to reach the medulla where it is distributed; (*b*) a network of vessels in the periosteum anastomoses with the twigs of the nutrient artery and gives branches to the ends of the bone. In young bones the diaphyseal vessels do not penetrate the epiphyseal cartilage, and the epiphysis receives an independent blood supply from the vessels of the capsule of the joint.

Many of the periosteal vessels reach the periosteum through the attachments of the muscles, so that when the latter are well-developed and their blood-supply abundant the periosteum is also well supplied with blood and the bones are strongly developed with prominent ridges. Conversely if the muscular development is poor the bones are thin and light. This is strikingly demonstrated in cases of infantile paralysis where several muscles of a limb become paralysed at an early period of childhood. The periosteal blood-supply suffers and consequently very little fresh osseous tissue is added to the outer surfaces of the bones. In such cases although the limb continues to grow in length at the epiphyseal cartilages, its length is less than that of the normal side; but the most striking feature of the bones is their extreme thinness.

Since increase in the length of a bone depends on continued growth at the epiphyseal cartilages, it is necessary that great care should be taken not to interfere with these in dealing with disease in the neighbourhood of an epiphysis. A knowledge of the periods when the epiphyses join the diaphyses is often of importance in medico-legal enquiries. It is also of practical utility in deciding the nature of an injury in the neighbourhood of a joint, since separation of an epiphysis may simulate a fracture or a dislocation. Further, when amputation through one of the long bones is called for in a young subject the activity

* *Bone Growth in Health and Disease*, by H. A. Harris, 1933.

† *Origin of the Human Skeleton*, by R. Broom, 1930.

‡ *Journal of Anatomy and Physiology*, vols. xxxviii., xxxix., and xlii.

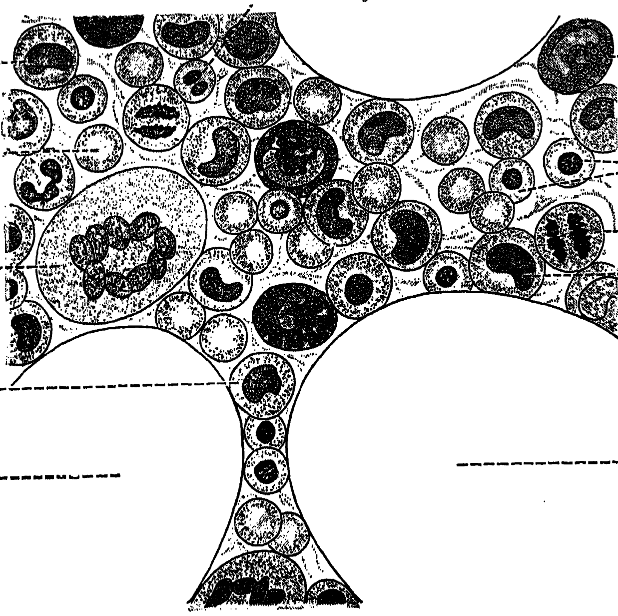
§ *The Growth of Bone*, by Sir William Macewen.

of growth at the epiphyseal cartilage must be borne in mind. As special cases, amputation through the humerus or tibia may be cited, since in these bones the proximal epiphyses are late in joining the diaphyses. If sufficient allowance be not made for this by cutting long flaps, the portion of the diaphysis remaining will continue to grow till its distal end projects through the stump—a condition known as *conical stump*.

Severe illnesses, occurring during the period of active growth of the long bones, cause a temporary arrest of growth which can be recognised later in radiograms as a dense line of bony deposition. This is succeeded by a zone of renewed growth in which it may be possible to detect that the bone laid down during convalescence was poorly differentiated.*

Premature arrest of growth of the epiphyseal cartilages results in too early junction of the epiphyses with the diaphyses (*premature synostosis*). This brings to an end the growth in length of the bones, and is one of the causes of dwarfism. Persons in whom this has occurred will have the head and trunk of normal size, but the legs and arms disproportionately short though often very strong.

FIG. 36.—Human bone-marrow. Highly magnified.



The **medulla ossium** or **bone marrow** is a variety of connective tissue in which the individual cells are the most important constituents. It not only fills up the cylindrical cavities in the bodies of the long bones, but also occupies the spaces of the cancellous tissue and extends into the larger Haversian canals. It differs in composition in different bones. In the shafts of the long bones the marrow is of a *yellow* colour (*medulla ossium flava*), and consists of a basis of connective tissue supporting numerous blood-vessels and cells, most of which are fat-cells, but some are 'marrow-cells,' such as occur in the red marrow. In the flat and short bones, in the articular ends of the long bones, in the bodies of the vertebræ, in the cranial diploë, in the sternum and ribs, the marrow is of a *red* colour (*medulla ossium rubra*).† Red marrow consists of a small quantity of connective tissue, blood-vessels, and numerous cells (fig. 36), a few of which are fat-cells but the great majority are spherical, nucleated cells, termed *myelocytes* or *marrow-cells*. The myelocytes resemble the leucocytes of the blood, and like them are amœboid; they contain granules, either oxyphil, basiphil or neutrophil in reaction. A number of eosinophil cells and a few basiphil cells are also present. Amongst the myelocytes smaller nucleated cells, of a yellowish colour, may be seen; these are the *erythroblasts* or *normoblasts* from which the

* H. A. Harris, *Arch. Int. Med.* vol. xxxviii.

† Alfred Piney (*Lancet*, Sept. 9th, 1922, p. 572) has investigated the naked-eye anatomy of the bone marrow in 1700 post-mortem cases, and concludes that all the bones, except those of the cranium, contain red marrow until puberty.

red corpuscles of the blood are derived by the disappearance of the nuclei. Giant-cells (*myeloplaxes* or *megakaryocytes*) similar to the osteoclasts described in connexion with the development of bone are also found in red marrow. In post-natal life the red marrow is the chief seat of the formation of the corpuscles of the blood.

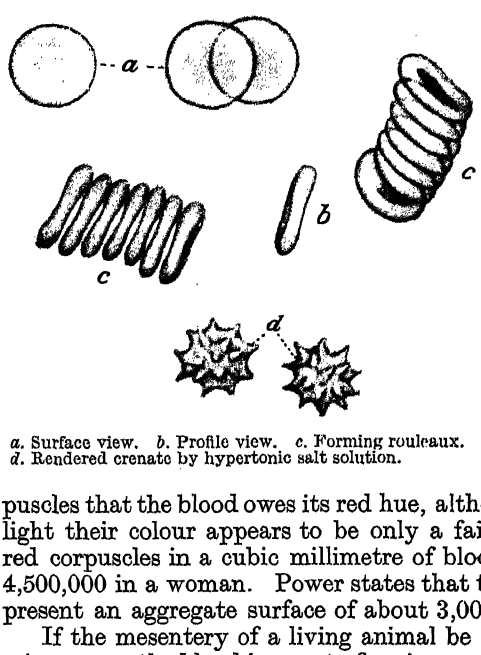
The **blood** is a variety of connective tissue, in which the ground substance is fluid and the constituent cells are highly specialised. It is opaque, rather viscid, of a bright red or scarlet colour when it flows from the arteries, of a dark red or purple colour when it flows from the veins. It is salt to the taste, and has a peculiar faint odour and an alkaline reaction. Its specific gravity is about 1·059, and its temperature is generally about 37° C., though varying slightly in different parts of the body.

If a thin film of blood be examined under the microscope it is seen to consist of a faintly yellow fluid—the *plasma* or *liquor sanguinis*—in which are suspended numerous minute particles—the *blood-corpuscles*.

The **blood-corpuscles** are of three kinds : (1) coloured corpuscles or erythrocytes, (2) colourless corpuscles or leucocytes, (3) blood-platelets.

1. The **coloured or red corpuscles** (*erythrocytes*) are circular discs, biconcave in profile. The disc has no nucleus, but, in consequence of its biconcave shape, it presents, when seen on the flat, a central area which, when the more prominent peripheral zone of the corpuscle is in focus, appears dark, and so simulates a nucleus (fig. 37, *a*). The corpuscles vary slightly in size even in the same drop of blood, but the average diameter of each is about 7·5μ, and the thickness about 2μ. Besides these there are certain smaller corpuscles of about one-half of the size just indicated ; these are termed *microcytes*, and are very scarce in normal blood ; in diseased conditions (e.g. anæmia), however, they are more numerous. It is to the aggregation of the red corpuscles that the blood owes its red hue, although when examined by transmitted light their colour appears to be only a faint reddish yellow. The number of red corpuscles in a cubic millimetre of blood is about 5,000,000 in a man, and 4,500,000 in a woman. Power states that the red corpuscles of an adult would present an aggregate surface of about 3,000 square yards.

FIG. 37.—Human red blood-corpuscles. ×1500.



a. Surface view. *b*. Profile view. *c*. Forming rouleaux. *d*. Rendered crenate by hypertonic salt solution.

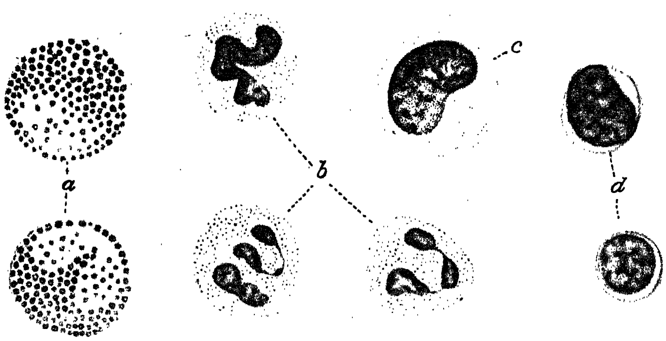
If the mesentery of a living animal be spread out and examined under the microscope, the blood is seen to flow in a continuous stream through the vessels, and the corpuscles show no tendency to adhere to each other or to the walls of the vessels. But when blood is drawn and examined on a slide, the corpuscles tend to collect into heaps like rouleaux of coins (fig. 37, *c*). During life the red corpuscles may be seen to change their shape under pressure so as to adapt themselves, to some extent, to the size of the vessel. They are, however, highly elastic, and speedily regain their form when the pressure is removed. They are readily influenced by the medium in which they are placed. In 0·9 per cent. sodium chloride solution, which is isotonic with human blood-plasma, they are unaltered in shape. In hypotonic solutions they swell up, become globular, and finally rupture, owing to the passage of water from the surrounding medium into the corpuscle (*endosmosis*). In hypertonic solutions, e.g. 2 per cent. sodium chloride, water passes in the reverse direction (*exosmosis*) and the corpuscle shrinks and becomes crenated in appearance (fig. 37, *d*). The surface layer of the erythrocyte thus behaves as a membrane which is permeable to water, but not to salts (semi-permeable membrane), and, for this and other reasons, Sharpey-Schafer believes that each corpuscle consists of an envelope containing the

coloured substance, hæmoglobin. According to another view, the erythrocyte consists of a stroma or sponge-work permeated by the hæmoglobin. The stroma or envelope consists mainly of cholesterol, lecithin, and nucleo-protein.

The **colourless corpuscles** or *leucocytes* are of various sizes. In human blood the majority are rather larger than the red corpuscles, and measure about 10μ in diameter. On the average from 7,000 to 12,000 leucocytes are found in each cubic millimetre of blood.

They consist of minute nucleated masses of protoplasm, and exhibit several varieties, which are differentiated from each other chiefly by the occurrence or non-occurrence of granules in their protoplasm, and by the staining reactions of these granules when present (fig. 38). (1) The most numerous and important are termed *polymorphonuclear* leucocytes; they are possessed of the power of amœboid movement, and contain nuclei which often consist of two or three

FIG. 38.—Varieties of colourless corpuscles found in human blood, stained with Leishman's stain. ×1500.



a. Eosinophil corpuscles. *b*. Polymorphonuclear leucocytes. *c*. Hyaline cell or macrocyte. *d*. Lymphocytes.

parts (multipartite) connected together by fine threads of chromatin. It is probable that the character of the nucleus is associated with the remarkable alterations in shape and form which these cells are capable of undergoing in the living condition. When at rest or dead, they are spherical in shape as a rule. The protoplasm contains a number of very fine granules, some of which stain with acid dyes, others with neutral dyes, and are therefore called *oxyphil* or *neutrophil* respectively. They constitute 60 to 70 per cent. of the total number of the colourless corpuscles. (2) A second variety comprises from 1 to 4 per cent. of the leucocytes; they are larger than the previous kind, and are made up of coarsely granular protoplasm, the granules being highly refractile and grouped round single nuclei of horseshoe shape. The granules stain deeply with eosin, and the cells are therefore often termed *eosinophil* corpuscles. (3) A third variety is called the *hyaline* cell or *macrocyte*. This is usually about the same size as the eosinophil cell, and, when at rest, is spherical in shape and contains a single round or oval nucleus. The protoplasm is free from granules, but is not quite transparent, having the appearance of ground glass. (4) A fourth kind is designated the *lymphocyte*, because it is identical with the cells derived from the lymph-glands, or other lymphoid tissue. They are the smallest of the leucocytes, and each consists of a spheroidal nucleus surrounded by a small quantity of homogeneous protoplasm. The third and fourth varieties together constitute from 20 to 30 per cent. of the colourless corpuscles, but of the two varieties the lymphocytes are by far the more numerous. Leucocytes having in their protoplasm granules which stain with basic dyes (*basiphil*) have been described as occurring in human blood, but they are rarely found except in disease.

The colourless corpuscles are very variable in shape in living blood, because many of them have the power of changing their form by protruding finger-shaped or filamentous processes of their substance, by which they move and take up granules from the surrounding medium. In locomotion the corpuscle pushes out a process of its substance—a *pseudopodium*, as it is called—and

gradually the rest of the body flows into it. In the same way when any granule or particle comes in its way the corpuscle protrudes a pseudopodium towards it, and then draws the particle into its own substance. By means of these amœboid properties the cells have the power of wandering or emigrating from the blood-capillaries by penetrating between the cells which form their walls and thus finding their way into the extravascular spaces. The solid chemical constituents of leucocytes are nucleo-protein, globulin, fat, cholesterol, lecithin, glycogen, and salts.

The **blood-platelets** (fig. 39) are oval, colourless, refractile discs, varying somewhat in size but with an average measurement of 3μ in their longest diameter and numbering between 200,000 and 300,000 per cubic millimetre. They are possessed of no demonstrable nucleus or chromatin material, but consist of a homogeneous cytoplasm in which are imbedded a number of highly refractile granules. These granules are usually grouped centrally, and in fixed preparations they may be so closely packed as to present the appearance of a more or less homogeneous mass, closely simulating a nucleus. In shed blood these elements rapidly disintegrate with the liberation of thrombokinase, and in ordinary blood smears they are frequently so grossly changed as to render observations on their morphology in such preparations of little value. They are best studied in blood which has been drawn directly into an anticoagulant, Toisson's solution (without any stain) preserving their form better perhaps than solutions of citrate or oxalate. They stain readily, but not deeply, with the various basic dyes such as neutral red, methylene blue, brilliant cresyl blue, etc., and in fixed preparations stained with one of the Romanowsky stains (Giemsa, Leishman) the cytoplasm appears a pale blue and the granules imbedded in it a reddish purple. These granules are spoken of as the azurophil granules and are similar in staining properties to those seen in the large mononuclear leucocytes. Recent work has shown that the platelet is undoubtedly an independent formed element of the blood, which does not have its origin either in the disintegration of leucocytes or red corpuscles or the precipitation of one of the proteins present in the plasma. The question of their origin awaits a definite solution, though in the opinion of the majority of hæmatologists they arise from the megakaryocytes or giant cells of the hæmopoietic tissue.

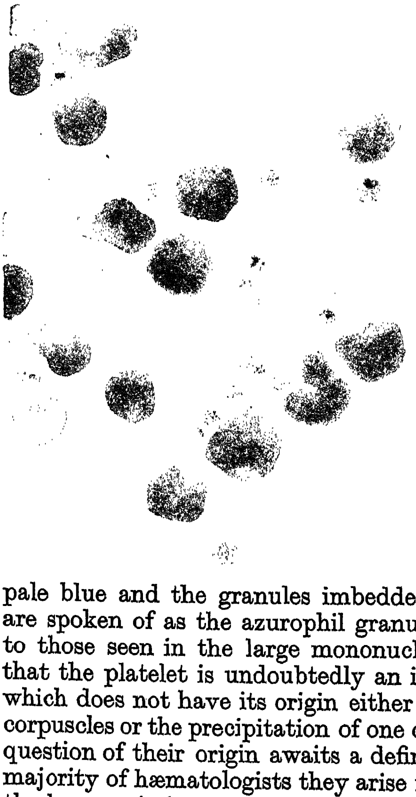


FIG. 39.—Blood-platelets. Highly magnified. (Blood-platelets in blue, red blood cells in pink.) From a preparation supplied by S. Phillips-Bedson of the Lister Institute, London.

Although the functions of the blood-platelet are as yet imperfectly understood, it is generally accepted that they play an important rôle in the process of coagulation. When blood is shed and comes in contact with a foreign and wetable surface, these elements rapidly disintegrate, with the liberation of some substance essential to thrombin formation. This substance has been termed thrombokinase or cytozyme, and although its existence is not generally accepted it can be shown that in the test-tube the coagulation rate of oxalate plasma on the addition of graduated amounts of calcium can be greatly accelerated by the simultaneous addition of platelets or platelet extract, and further, this activity is definitely and specifically neutralised by an anti-platelet serum. In addition to this the presence of platelets is necessary for the retraction which the blood-clot normally undergoes, and it would seem that these elements are essential to the formation of a firm thrombus. A clot formed of fibrin alone, or poor in platelets, is easily dislodged from the wound which it is plugging, but when it is admixed with platelets a much firmer structure results, which, in contracting, knits together to some extent the edges of the wound. It has further been

shown from animal experiments with anti-platelet serum and from observations on purpura in man that a grave destruction of platelets in the circulation is accompanied by extreme capillary bleeding. Recently an attempt has been made to demonstrate that the platelet plays some part in the mechanism of defence against infection. When micro-organisms are introduced into the blood stream the platelets clump round them, forming little masses in which the bacteria are entangled. These masses are held up in the capillaries and the back-waters of the circulation, and are there dealt with by the various phagocytic cells. The same thing occurs if a suspension of inert particles such as Indian ink is introduced into the blood stream; it is the foreign surface which is the exciting cause of this phenomenon.

The development of the blood-corpuscles is described on pp. 132, 133.

The **lymph** is a transparent, colourless or slightly yellow fluid, which is conveyed into the blood by a set of vessels named *lymphatics*. These vessels arise in nearly all parts of the body as *lymph-capillaries*. They take up the fluid which has exuded from the blood-capillaries for the nourishment of the tissues, and return it into the veins through the medium of the thoracic duct or right lymphatic duct.

Lymph is a watery fluid of sp. gr. about 1·015; it closely resembles the blood-plasma, but is more dilute. When it is examined under the microscope, leucocytes of the lymphocyte class are found floating in the transparent fluid; they are always increased in number after the passage of the lymph through lymphoid tissue, as in lymph-glands.

The Reticulo-Endothelial System.

Although they are not usually classified as one of the tissues of the body, the cells which comprise the reticulo-endothelial system may, conveniently, be mentioned at this stage. They form a loose reticulum lying in close relationship to endothelial spaces such as occur in the spleen pulp and bone-marrow, hence the name of the system. The cells, which are highly phagocytic, are found in certain definite situations in the body. When necessity arises, they are able to free themselves from the tissue they help to form, and acquire motility which is amœboid in character.

In the resting condition the cells of the reticulo-endothelial system are found in the following situations: (1) the connective tissues, where they have already been described as clasmatocytes (p. 8); (2) the blood, where they occur as large mononuclear leucocytes; (3) the endothelium lining the vascular sinuses in bone-marrow, the spleen, the liver—where they are termed Kuppfer's cells—the lymph glands, the medulla of the suprarenal gland and the anterior lobe of the hypophysis cerebri; (4) in the retiform tissue of the spleen and the lymph glands, where they can be identified as reticular cells; and (5) in the meninges, where they are termed meningocytes. It has been found experimentally that these cells, and only these cells, will take up such colloidal dyes as trypan blue when they are introduced into the body, subcutaneously, intramuscularly, intravenously or intraperitoneally in dilute solutions. *In situ* they are capable of absorbing hæmoglobin and converting it into bilirubin, and they can take up and store cholesterol.

Although they can be identified as apparently fixed cells in the situations cited, they retain the power of transforming themselves into motile phagocytes when necessity arises. Under these circumstances they become considerably enlarged and have been termed macrophages.* In this condition they migrate from their original position to any point in the body where their phagocytic activity is called for by the presence of foreign substances of various kinds.

It will be observed that no definition of the system is possible, unless the physiological characters of the cells are taken into consideration, for their similarity in function is the only feature which these cells have in common.

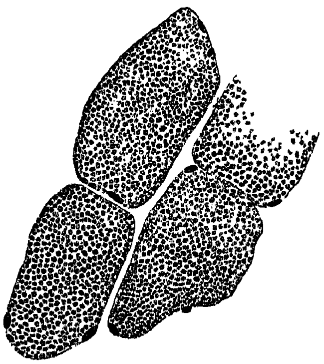
There is some ground for believing that macrophages may become transformed finally into inert fibroblasts, as the last and final stage in their development.

* The term 'histiocytes' is frequently used with approximately the same significance.

MUSCULAR TISSUE

Muscular tissue is composed of bundles of reddish fibres endowed with the property of contractility. There are three varieties of muscle, (1) *striped* or *voluntary*, (2) *unstriped* or *involuntary*, and (3) *cardiac*. The muscles which are concerned with the movements of the bony skeleton—the skeletal muscles—are composed of striped fibres, and are under the control of the will. The muscular coats of the stomach and intestines, uterus, bladder and blood-vessels, on the other hand, are formed of unstriped fibres, and their movements are involuntary. Some striped muscles, however, are not under voluntary control, namely, those forming the walls of the pharynx and upper part of the œsophagus. Cardiac muscle is intermediate in position between the other two varieties. Its fibres are striped, but involuntary, and they differ from both striped and unstriped muscle in structure. With the exception of the arrectores pilorum and the sphincter and dilatator pupillæ muscles, which are derived from the ectoderm, all muscle tissue is mesodermal in origin.

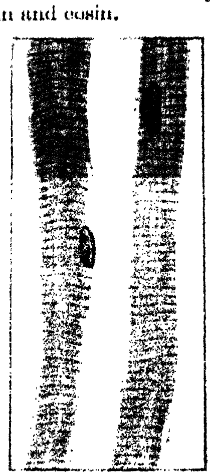
FIG. 40.—A transverse section through human striped muscle-fibres. ×255.



The striped muscular fibres are arranged in bundles or *fasciculi*, in which the individual fibres are parallel to one another. Each fasciculus has a connective tissue sheath, called the *perimysium*, prolongations of which run into the bundle, binding the fibres together and constituting the *endomysium*. A muscle is composed of a number of fasciculi, held together and surrounded by connective tissue which is known as the *epimysium*. The fasciculi are of different sizes in different muscles, and are for the most part placed parallel with one another, though they usually converge towards the tendinous attachments. The connective tissue framework of the muscle contains the blood-vessels and nerves which supply it.

A *muscular fibre* consists of a soft contractile substance, enclosed in a tubular sheath called the *sarcolemma*. The fibres are cylindrical or prismatic in shape (fig. 40), and are of no great length, not exceeding as a rule 40 mm. Their breadth varies in man from 0·01 mm. to 0·1 mm. As a rule, the fibres do not divide or anastomose; but occasionally, especially in the tongue and facial muscles, they may be seen to divide into several branches. In the substance of the muscle the fibres end by tapering extremities which are joined to the ends of other fibres by the sarcolemma. Where a muscle joins its tendon, the sarcolemma covering the end of each muscle-fibre blends with a corresponding group of the fine fibres of the tendon. The muscular substance of the fibre can readily be made to retract from the point of junction. The areolar tissue between the fibres is prolonged into the tendon, so as to form a kind of sheath around the tendon-bundles for a longer or shorter distance. When muscular fibres are attached to skin or mucous membranes, this sheath becomes continuous with the areolar tissue of these structures.

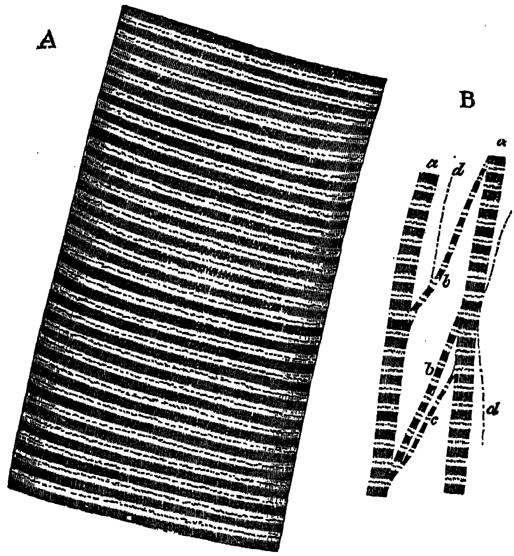
FIG. 41.—Striped muscle fibres (human) from the sternothyroid muscle, stained with hæmatoxylin and eosin.



The *sarcolemma*, or tubular sheath of the fibre, is a transparent, elastic, and apparently homogeneous membrane of considerable toughness, so that it sometimes remains intact when the included substance is ruptured. On the internal surface of the sarcolemma in mammalia, and also in the substance of the fibre in frogs, elongated nuclei are seen, and each of these is surrounded by a little granular protoplasm.

Upon examination of a voluntary muscular fibre by transmitted light, it is found to be marked by alternate light and dark bands or striæ, which pass transversely across the fibre (fig. 41). When examined by polarised light the dark bands are found to be doubly refracting (anisotropic), while the clear stripes are singly refracting (isotropic). The dark and light bands are of nearly equal breadth, and alternate with great regularity; they vary in breadth from about 1μ to 2μ. When the fibre is focussed deeply a dark line may be seen running in the middle of the clear stripe. This is known as *Dobie's line* or *Krause's membrane*. In fibres which are on the stretch the dim stripe is often seen to be divided by a clearer line—*Hensen's line.*

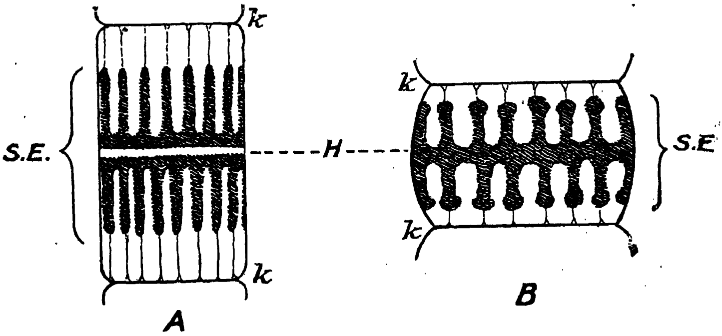
Fig. 42.—A. A portion of a medium-sized human muscular fibre. Magnified nearly 800 diameters. B. Separated bundles of fibrils, equally magnified. (From Quain's Elements of Anatomy.)



a, a. Larger, and *b, b,* smaller collections. *c.* Still smaller. *d, d.* The smallest which could be detached.

Under high magnification there are indications that the striped muscle-fibre is made up of a large number of fibrils, known as *sarcostyles,* together with an interfibrillar material, or *sarcoplasm* (fig. 42, B). When a fibre is treated with weak acid it becomes clearer, and the sarcoplasm is visible as fine, longitudinal, parallel lines. At the junction of the dim and clear stripes these lines often show bead-like enlargements in the stretched condition of the fibre. Examination of transverse sections of individual fibres shows that each sarcostyle is surrounded by sarcoplasm, and that the sarcostyles are arranged in groups, called *muscle-columns,* the groups being separated by a relatively larger amount of sarcoplasm than the separate fibrils. The sections of muscle-columns, defined in this way, constitute what are known as *Cohnheim's areas.*

Fig. 43.—A diagram of a sarcomere. (After Sharpey-Schafer.) A. In a moderately extended condition. B. In a contracted condition.



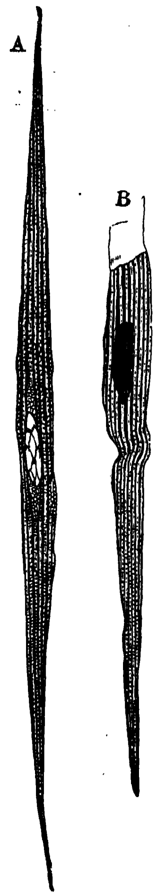
H. Line of Hensen. *k, k.* Membranes of Krause. S.E. Sarcous element.

When the sarcostyles are separated by suitable methods it becomes evident that each exhibits alternate dim and clear portions, with Dobie's and Hensen's lines, and that the striped appearance of the fibre is due to the apposition of the corresponding segments of the fibrils of which it is composed.

Sir E. Sharpey-Schafer worked out the minute anatomy of muscular fibres, particularly in the wing-muscles of insects, which are peculiarly adapted for this purpose on account of the relatively large size of the sarcostyles and the ease with which they can be separated, and the description given below is based on his work.

A sarcostyle may be said to be made up of successive portions, each of which is termed a *sarcomere*. The sarcomere is situated between two membranes of Krause, and consists of (1) a central dark part, which forms a portion of the dark band of the whole fibre, and (2) a clear area at either end, each forming, with the corresponding clear part of the adjacent sarcomere, the light band of the fibril. The central dark segment really consists of two parts, and when the fibre is stretched these two parts become separated from each other at the line of Hensen (fig. 43, A). The clear areas are well marked in the extended sarcostyle, but in the contracted sarcostyle they are small or altogether absent (fig. 43, B).

FIG. 44.—Muscle fibres from the small intestine. (From Quain's Elements of Anatomy, vol. ii. pt. i., Microscopic Anatomy, by Sir Edward Sharpey-Schafer.)



A. Complete cell. B. Broken cell showing delicate external layer.

The central dim portion, or *sarcous element*, does not lie free in the sarcomere, for when the sarcostyle is stretched, very fine lines, which are probably septa, may be seen running through the clear portion from the sarcous element to the membrane of Krause.

Sharpey-Schafer explains these phenomena in the following way. He considers that each dim segment contains a number of longitudinal channels, which open into the clear part towards the membrane of Krause but are closed at the line of Hensen. When the muscular fibre contracts the clear part of the muscular substance passes into these channels or tubes, and is therefore hidden from sight, but at the same time it swells up the sarcous element and widens and shortens the sarcomere. When, on the contrary, the fibre is stretched, this clear substance is driven out of the tubes and collects between the sarcous element and the membrane of Krause, and gives the appearance of the light part between these two structures; by this means it elongates and narrows the sarcomere.

Sharpey-Schafer has shown that, if this view be correct, it harmonises the contraction of muscle with the amœboid action of protoplasm. In an amœboid cell there is, according to one view of the structure of protoplasm, a framework of spongioplasm, enclosing in its meshes a clear substance, termed hyaloplasm. Under stimulation the hyaloplasm passes into the pores of the spongioplasm; without stimulation it tends to pass out, as in the formation of pseudopodia. In muscle there is the same thing, viz. a framework of spongioplasm—the substance of the dim segment; and this encloses a clear hyaloplasm—the clear substance of the sarcomere. During contraction of the muscle—i.e. under stimulation—this clear substance passes into the pores of the spongioplasm; while during extension of the muscle—i.e. when there is no stimulation—it tends to pass out of the spongioplasm. In this way the contraction is brought about; under stimulation the protoplasmic material (the clear substance of the sarcomere) recedes into the sarcous element, causing the sarcomere to widen out and shorten. The contraction of the muscle is merely the sum total of this widening out and shortening of these bodies.

Vessels and nerves of striped muscle.—The *capillaries* of striped muscle are very abundant, and form a sort of rectangular network, the branches of which run longitudinally in the endomysium between the muscular fibres, and are joined at short intervals by transverse anastomosing branches. In the red muscles of the rabbit dilatations occur on the transverse branches of the capillary network. The larger vascular channels (arteries and veins) are found only in the perimysium, between the muscular fasciculi. *Nerves* are profusely distributed to striped muscle. Their mode of termination is described in the chapter on Neurology. *Lymph vessels* do not occur in striped muscle, though they have been found in tendons and in the sheaths of the muscles.

According to John Irvine Hunter, vertebrate muscle, like that of the invertebrates, consists of two kinds of fibres, i.e. those connected with active contraction, and those responsible for the maintenance of tonic contraction. The former are the ordinary striped muscle fibres innervated by ordinary medullated motor fibres. The latter consist of thin, red fibres, rich in sarcoplasm, and with a non-medullated sympathetic nerve-supply. Though adequate

proof has been adduced for the double innervation of striped muscle, no unequivocal experimental evidence has been advanced in favour of the regulation of muscle-tone by sympathetic nerves.

The **unstriped, plain, or involuntary muscle** is found in the following situations—in the lower half of the œsophagus and the whole of the remainder of the gastro-intestinal tube; in the trachea and bronchi; in the gall-bladder and bile-duct; in the large ducts of the salivary and pancreatic glands; in the calyces of the kidney, the ureter, including its pelvis, the bladder, and urethra; in the female sexual organs—viz. the ovary, the uterine tube, the uterus (enormously developed in pregnancy), the vagina, the broad ligament, and the corpora cavernosa of the clitoris; in the male sexual organs—viz. the dartos of the scrotum, the vas deferens and epididymis, the seminal vesicle, the prostate and the corpora cavernosa and corpus spongiosum of the penis; in the capsule and trabeculæ of the spleen; in the mucous membranes, forming the muscularis mucosæ; in the skin, forming the arrectores pilorum, and also in the sweat-glands; in the mammary glands; in the arteries, veins, and lymph vessels; in the iris and ciliary muscle.

FIG. 45.—Anastomosing muscular fibres of the heart seen in a longitudinal section. On the right the limits of the separate cells with their nuclei are exhibited somewhat diagrammatically. (Schweigger-Seidel.)

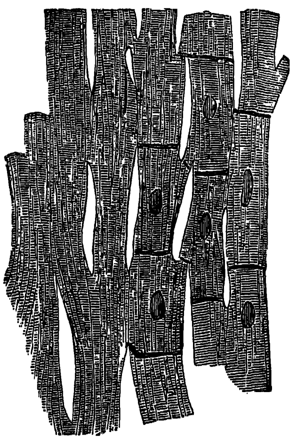


FIG. 46.—Cardiac muscle, stained with hæmatoxylin and eosin. (Human.)

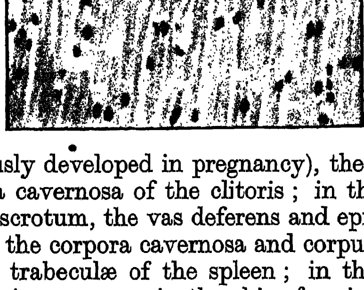

FIG. 47.—Purkinje's fibres from the sheep's heart. × 250.

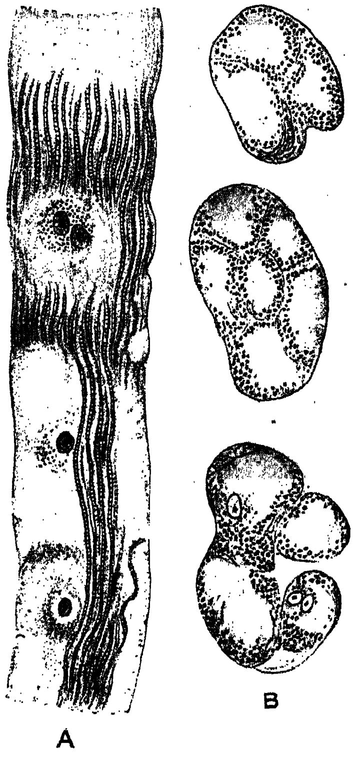


A. In longitudinal section.
B. In transverse section.

Unstriped or plain muscle is made up of spindle-shaped cells (fig. 44), collected into bundles and held together by a cement-substance. These bundles are further aggregated into larger fasciculi, or sheets, bound together by areolar tissue.

The cells are elongated, spindle-shaped, and nucleated, and are of various sizes, averaging from 40μ to 80μ in length, and 6μ to 7μ in breadth. On trans-

verse section they are more or less polyhedral in shape, from mutual pressure. Each presents a faint longitudinal striation and consists of an elastic cell-wall containing the contractile substance, and an oval or rod-like nucleus. A centriole lies close to the nucleus. The fibres are attached to one another by a certain amount of interstitial cement-substance which reduces nitrate of silver, but in some regions, e.g. the muscular coat of the intestines, the muscle-cells are also connected by ' bridges ' similar to those which occur in the prickle cells of the epidermis.

Sheets of smooth muscle frequently exhibit rhythmical contractions, which are more sluggish than the contractions of striped muscle and in many cases travel along the sheet in the form of waves. Such waves are well marked in the wall of the intestine. Contraction is often excited by a mechanical stimulus; for example, distension of the urinary bladder or of the rectum excites the appropriate reflex of evacuation.

The cardiac muscular tissue.—The fibres of the heart differ very remarkably from those of other striped muscles. They are striated both transversely and longitudinally, but the striation is finer as compared with that of striped muscle. The tissue consists of a branched syncytium in which there is no clear, cellular definition. The apparent cell boundaries (fig. 46) are now generally believed to be due to localised bands of contraction or to fragmentation during preparation of the specimen. The nuclei, which are oval in outline and central in position (fig. 45), occur at regular intervals. The connective tissue between the bundles of fibres is much less than in ordinary striped muscle, and no sarcolemma has been proved to exist.

Purkinje's fibres (fig. 47).—Between the endocardium and the ordinary cardiac muscle peculiar fibres known as *Purkinje's fibres* are found imbedded in a small amount of connective tissue. They are associated with the terminal distributions of the atrioventricular bundle. In man the fibres are no larger in size than the cardiac cells but differ from them in several ways. In longitudinal section they are quadrilateral in shape, being about twice as long as they are broad. The central portion of each fibre contains one or more nuclei and is made up of granular protoplasm, with no indication of striation, while elsewhere in the fibre transverse striations are conspicuous (fig. 691). The fibres are intimately connected with each other, possess no definite sarcolemma, and do not branch. They form a considerable portion of the moderator band in the heart of the sheep.

The **atrioventricular bundle** (see chapter on Angiology) is composed of cells which differ from ordinary cardiac muscle-cells in being more spindle-shaped. They are, moreover, more loosely arranged and have a richer vascular supply than the rest of the cardiac muscle.

Development of muscle-fibres.—Voluntary muscular fibres are developed from the mesoderm, the embryonic cells of which elongate, show multiplication of nuclei, and eventually become striated; the striation is first obvious at the side of the fibre, spreads around the circumference, and ultimately extends to the centre. The nuclei, at first situated centrally, gradually pass out to assume their final position immediately beneath the sarcolemma. In the case of involuntary muscle the mesodermal cell assumes a pointed shape at the extremities and becomes flattened, the nucleus also lengthening out to its permanent rod-like form.

NERVOUS TISSUE

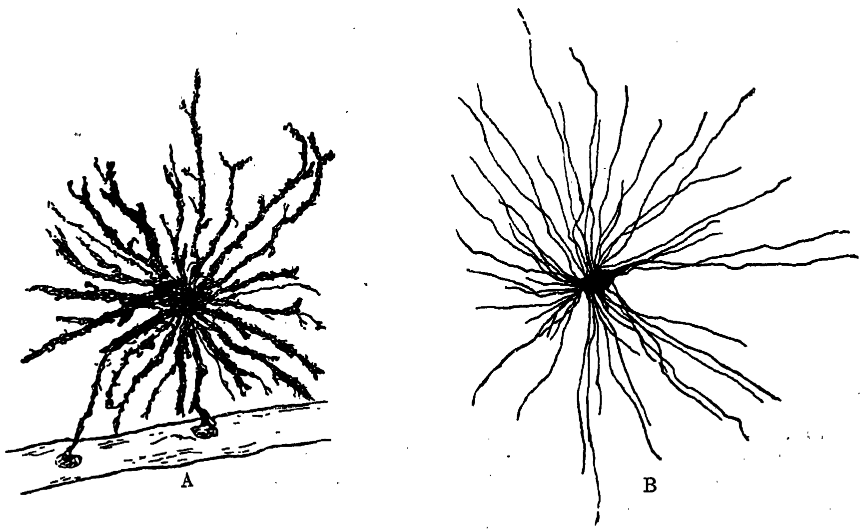
Nervous tissue is specialised for the inauguration, propagation and reception of nerve impulses, and its high degree of specialisation is indicated by the fact that, like muscle tissue, it has lost the power of reproduction. The nervous tissues of the body comprise the brain, the spinal cord, the cranial, spinal, and sympathetic nerves, and the ganglia connected with them.

The nervous tissues are composed of *nerve-cells* and their various processes, together with a supporting tissue called *neuroglia*, which, however, is found only in the brain and spinal cord. Certain long processes of the nerve-cells are of special importance, and it is convenient to consider them apart from the cells; they are known as *axons* or *axis-cylinder processes*, and together with their covering sheaths they form the *nerve-fibres*.

To the naked eye certain portions of the brain and spinal cord appear grey and others white, when freshly cut sections are examined. The *grey matter* is composed largely of nerve-cells, while the *white matter* contains only their long processes, the nerve-fibres. It is in the former that nervous impressions are received, stored, and transformed into efferent impulses, and by the latter that they are conducted. Hence the grey matter forms the essential constituent of all the ganglionic centres, both those in the isolated ganglia and those aggregated in the brain and spinal cord; while the white matter forms the bulk of the commissural portions of the nerve-centres and the peripheral nerves.

Neuroglia is the peculiar variety of ectodermal tissue which binds together the true nervous constituents of the brain and spinal cord. It consists of cells and fibres, and may be regarded as a special variety of connective tissue, found only in association with true nervous tissue. Some of the cells (spider-cells) are stellate in shape, with ill-defined cell-bodies. Their fine processes become neuroglia fibres and extend radially and unbranched (fig. 48 B), among the

FIG. 48.—Neuroglia-cells of the brain shown by Golgi's method. (After Andriezen.) (From Sir E. Sharpey-Schafer's Essentials of Histology.)



A. Arborescent cell with branched processes. B. Spider-cell with unbranched processes.

nerve cells and fibres which they aid in supporting. Other cells (arborescent cells) give off processes which branch repeatedly (fig. 48, A). Some of the fibres start from the epithelial cells lining the ventricles of the brain and central canal of the spinal cord, and pass through the nervous tissue, branching repeatedly, to end in slight enlargements on the pia mater. Thus, neuroglia is evidently a connective tissue in function, but it is not so in development; it is ectodermal in origin, whereas all true connective tissues are mesodermal.

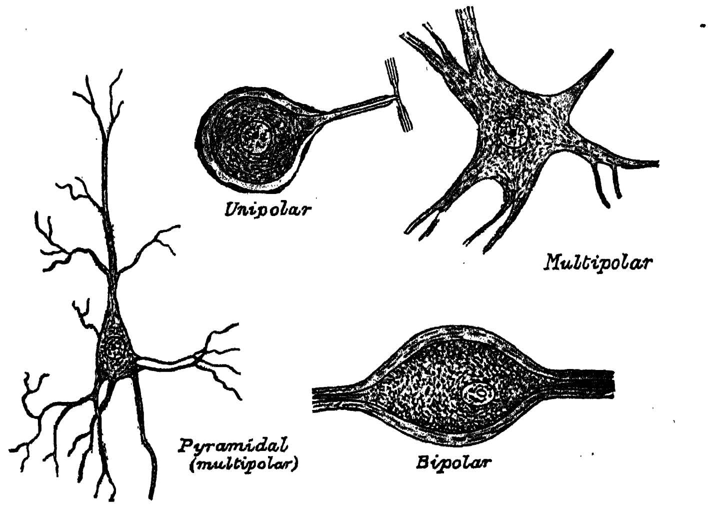
Nerve-cells (fig. 49) are largely aggregated in the grey substance of the brain and spinal cord, but smaller collections of these cells also form the swellings, called *ganglia,* seen on many nerves. These latter are found chiefly upon the spinal and cranial nerve-roots and in connexion with the sympathetic nerves.

Nerve-cells vary in shape and size, and have one or more processes. A typical nerve-cell from the cerebral cortex possesses a number of processes. Of these one, and only one, acts as a transmitter to convey nerve impulses away from the cell. It is termed the *axon* or *axis-cylinder process,* and it has a characteristic structure, to be described later. The other processes are all receptors, and convey nerve impulses to the cell; they are termed *dendrites* and they differ from the axon in structure as well as in other ways. Usually the axon is a long process, which gives off one or two collaterals but does not branch freely until it approaches its termination. The dendrites, on the other hand, are usually short and are restricted to the immediate vicinity of the cell-body. They branch freely, sometimes producing the most intricate patterns

(fig. 52) and end in minute twigs. Such nerve-cells are termed *multipolar*, and they abound in the grey matter of the brain and spinal cord and in the ganglia of the sympathetic system.

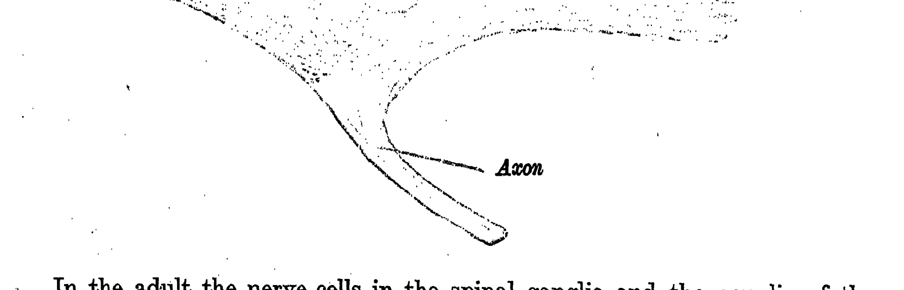
All nerve-cells, however, are not multipolar. The nerve-cells in the retina and in the spiral and vestibular ganglia of the eighth cranial nerve are *bi-polar*

FIG. 49.—Various forms of nerve-cells.



(fig. 49). One process enters the cell from the periphery and functions as a dendrite : the other leaves the cell to enter the brain and functions as the axon. Structurally, however, both are axons. Bipolar cells are found throughout life in the spinal ganglia of fishes, and they occur in the same situation in the human embryo. The condition of bi-polarity therefore may be regarded justifiably as primitive.

FIG. 50.—A motor nerve-cell from the anterior horn of the spinal cord of an ox, stained with methylene blue. × 500. The spindle-shaped Nissl's granules are shown. The dendrites and axon are broken off close to the cell.



In the adult the nerve-cells in the spinal ganglia and the ganglia of the cranial nerves (apart from the eighth) are *unipolar*, and the condition is brought about in the fœtus by the approximation and fusion of the proximal parts of the two processes above-mentioned. The single process of these unipolar cells, after a short course from the cell-body, divides in a T-shaped manner (fig. 49) into two processes. Of these one runs towards the periphery and, as it con-

ducts impulses towards the cell, functions as a dendrite ; the other enters the central nervous system and, as it conducts impulses away from the cell, functions as an axon. Structurally, however, the functional dendrite of a unipolar cell is indistinguishable from the axon.

The body of the nerve-cell is known as the *cyton*. In fixed and stained preparations it consists of a finely fibrillated protoplasmic material in which there are occasionally patches of a deeper tint, caused by the aggregation of

Fig. 51.—A pyramidal cell from the cerebral cortex of a mouse. Golgi method. (After Ramón y Cajal.)

a. Axon. *b*. Collateral. *c* and *d*. Dendrites.

pigment-granules at the sides of the nucleus, as in the substantia nigra and locus cœruleus of the brain. The protoplasm also contains peculiar angular masses of granules which stain deeply with basic dyes such as methylene blue ; these are known as *Nissl's spindles* (fig. 50). These bodies extend into the dendritic processes but not into the axon, and they disappear (*chromatolysis*) during fatigue or after section of the nerve-fibre connected with the cell. They are supposed to represent a store of nervous energy, and in various mental diseases are deficient or absent. The nucleus is, as a rule, a large, well-defined body, with a relatively small amount of chromatin, and contains a well-marked nucleolus. The small clear area at the point of exit of the axon is termed the *cone of origin*.

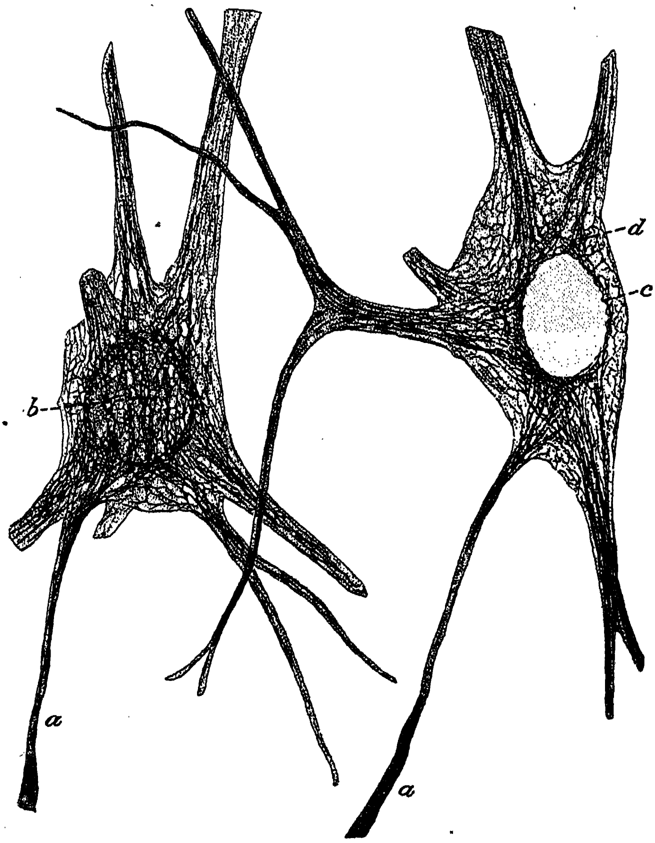
In addition to the protoplasmic network described above, each nerve-cell may be shown to have delicate neurofibrils running through its substance

(fig. 53); these fibrils are continuous with the fibrils of the axon, and are believed to convey nerve-impulses. A *pericellular network* of fine branching fibres is a characteristic feature of many nerve-cells.

Mott and Marinesco have shown that, when living nerve-cells are examined by the dark ground illumination method, neither Nissl's bodies nor fibrils of any kind can be seen. The constancy of the occurrence of both these structures in fixed preparations, however, indicates that they represent something specific in the living cell.

Nerve-fibres are found universally in the peripheral nerves, and in the white matter of the brain and spinal cord. They are of two kinds—viz. *medullated* or *white* fibres, and *non-medullated* or *grey* fibres.

FIG. 53.—Nerve-cells of a kitten, showing neurofibrils. (Ramón y Cajal.)



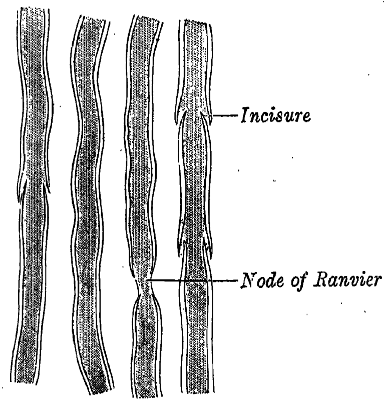
a. Axon. *b.* Cyton. *c.* Nucleus. *d.* Neurofibrils.

The *medullated fibres* form the white matter of the brain and spinal cord, and also the greater part of every cranial and spinal nerve, and give to these structures their opaque, white colour. When perfectly fresh they appear to be homogeneous; but soon after removal from the body each fibre, when examined by transmitted light, presents a double outline or contour, as if consisting of two parts (fig. 54). The central portion is the *axon*; it is surrounded by a sheath of fatty material, staining black with osmic acid, named the *white substance of Schwann* or *medullary sheath*, which gives to the fibre its double contour; and the whole is enclosed in a delicate membrane, termed the *neurolemma, primitive sheath*, or *nucleated sheath of Schwann* (fig. 55). Medullated nerve-fibres vary in dimeter from 2μ to 16μ.

The *axon* is the essential part of the nerve-fibre, and is always present; the medullary sheath and the neurolemma are occasionally absent, especially at the origin and termination of the nerve-fibre. The axon undergoes no interruption from its origin in the nerve-centre to its termination, and must be regarded

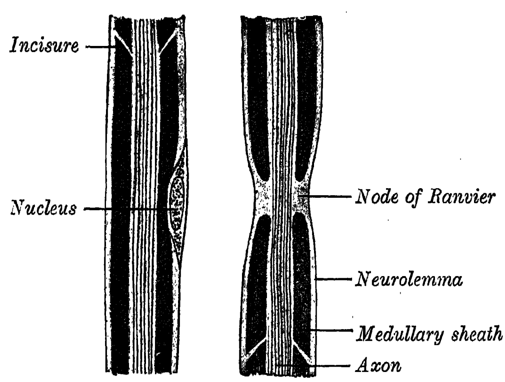
as a direct prolongation of a nerve-cell. Nerve-fibres in the white matter of the brain and spinal cord give off twigs known as *collaterals*. These arise from the main fibre at right angles to its course and run into the grey matter, where they terminate by arborisation. The axon constitutes about one-half or one-third of the nerve-fibre, being greater in proportion in the fibres of the central nervous system than in those of the peripheral nerves. It is quite transparent, and is therefore indistinguishable in a perfectly fresh and natural state of the nerve. It is made up of exceedingly fine fibrils (figs. 55 and 56), which stain darkly with gold chloride, and at its termination may be seen to break up into these fibrils. The axon is said by some to be enveloped in a special reticular sheath, which separates it from the medullary sheath, and is composed of a substance called *neurokeratin*. The more common opinion is that this network or reticulum is contained in the white substance of Schwann, and by some it is believed to be produced by the action of the reagents employed to show it.

Fig. 54.—Medullated nerve-fibres. × 350.



The *medullary sheath* or *white substance of Schwann* (fig. 55) is regarded as being a fatty material in a fluid state, which insulates and protects, or possibly supplies nutriment to, the essential part of the nerve—the axon. As a general rule its thickness is proportional to the size of the axon, and is such that it

Fig. 55.—A diagram of longitudinal sections of medullated nerve-fibres. Osmic acid.



forms about half of the total area of the cross-section of the fibre. Its continuity is interrupted at intervals of about 1 mm., giving to the fibre the appearance of constriction at these points ; these are known as the *nodes of Ranvier* (figs. 54 and 55). The portion of nerve-fibre between two nodes is called an *internodal segment*. The neurolemma or primitive sheath is not interrupted at the nodes, but passes over them as a continuous membrane. Some observers, however, believe that the neurolemma of one internodal segment is connected with that of the adjacent segment at the node by cement-substance. If the fibre be treated with silver nitrate the reagent penetrates the neurolemma at the nodes, and, on exposure to light, reduction takes place, giving rise to the appearance of black crosses (*Ranvier's crosses*) on the axon. Transverse lines, termed *Fromann's lines* (fig. 57), also may be seen beyond the nodes ; their significance is not understood. In addition to these interruptions, oblique clefts or *incisures* may be seen in the medullary sheath, subdividing it into irregular

portions, which are termed *medullary segments*, or *segments of Lantermann* (figs. 54 and 55) ; there is reason to believe that these clefts are artificially produced in the preparation of the specimens. Medullated nerve-fibres, when examined in the fresh condition, frequently present a beaded or varicose appearance, due to manipulation and pressure, which cause the oily matter to collect into drops ; in consequence of the extreme delicacy of the primitive sheath even slight pressure will cause the transudation of the fatty matter, which collects as drops of oil outside the sheath.

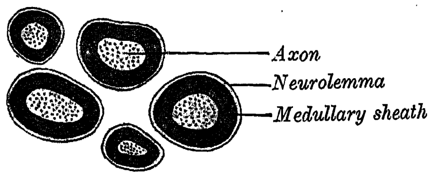


Fig. 56.—Transverse sections through medullated nerve-fibres. Osmic acid.

The *neurolemma* or *primitive sheath* is a delicate, structureless membrane ; here and there beneath it, and situated in depressions in the white substance of Schwann, are nuclei, each surrounded by a small amount of protoplasm. The nuclei are oval and somewhat flattened, and one is generally found in the middle of each internode. *The primitive sheath is absent from the medullated fibres of the brain and spinal cord.*

Wallerian Degeneration.—When nerve-fibres are cut across, the central ends of the fibres degenerate as far as the first node of Ranvier ; but the peripheral ends degenerate simultaneously throughout their whole length. The medullary sheath of each fibre becomes broken down, forming droplets of fatty substance, and the axon undergoes fragmentation. The nuclei of the primitive sheath proliferate, and finally absorption of the axons and fatty substance occurs. If the cut ends of the nerve be sutured together,

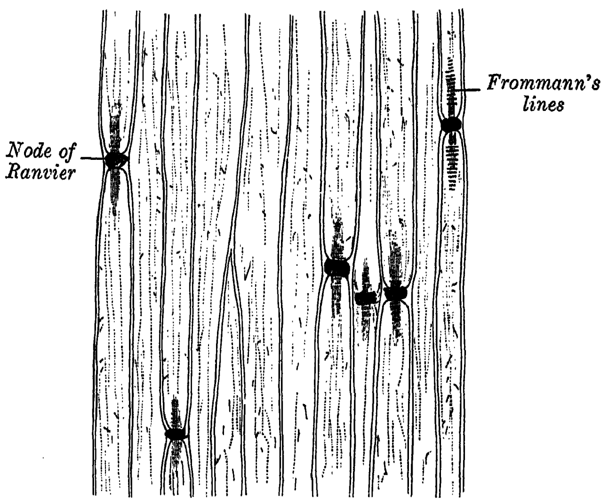

Fig. 57.—Medullated nerve-fibres stained with silver nitrate.

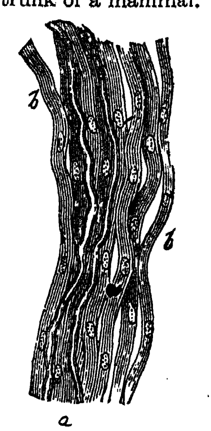

Fig. 58.—A small branch from the sympathetic trunk of a mammal.

a. Two small medullated nerve-fibres among a number of non-medullated nerve-fibres, *b*.

regeneration of the nerve-fibres takes place by the downgrowth of axons from the central end of the nerve. At one time it was believed that the regeneration was peripheral in origin, but this has been disproved, the proliferated nuclei in the peripheral portions taking part merely in the formation of the so-called scaffolding along which the new axons pass. Regeneration of the peripheral end of a cut nerve-fibre occurs only when the fibre possesses a primitive sheath. As a result the medullated fibres of the brain and spinal cord cannot regenerate after they have been severed.

Non-medullated fibres.—Most of the fibres of the sympathetic system, and some of the cerebrospinal, consist of the *grey* or *gelatinous* nerve-fibres—*fibres of Remak* (fig. 58). Each of these consists of an axon to which nuclei are applied at intervals. These nuclei are believed to be in connexion with a delicate sheath corresponding with the neurolemma of the medullated nerve-fibre. In external appearance the non-medullated nerve-fibres are semitransparent and grey or yellowish-grey. The individual fibres vary in size, generally averaging about half the size of the medullated fibres.

EMBRYOLOGY

INTRODUCTION

THE series of changes which constitutes the development of the human body commences when the female germ-cell, or ovum, is fertilised by a male germ-cell, or spermatozoön, and terminates when the adult condition is reached. Embryology deals with the changes which occur prior to the birth of the child.

Two processes, intimately associated with each other although essentially distinct, are responsible for the transformation of the single-celled ovum into the complex form of the newly born child. These processes are (1) *growth* and (2) *differentiation*. Growth, with certain exceptions to be noted later, involves increase in size brought about by cell division and is dependent on the ingestion of a sufficient quantity of the appropriate type of nourishment. The process of growth is not a simple one, for in certain situations it must be accompanied by a process of absorption, which is just as much an indication of growth activity as increase of size. For example, as the mandible increases in size, the anterior part of its ramus is constantly being remodelled by a process of absorption, while the opposite phenomenon of bone deposition is occurring along its posterior border.

Differentiation is the process whereby a group of cells assumes certain special characteristics which enable them to carry out some particular function. It was long believed that all the stimuli which lead groups of cells to undergo differentiation were inherent in the cells themselves and were directly due to an hereditary factor, but this view requires considerable modification in the light of recent experimental work. The earliest cells derived from the fertilised ovum are totipotent, i.e. any one of them may go on to form a complete embryo, but, as development proceeds and the first signs of differentiation appear, the potency of the cells concerned in the differentiation becomes reduced and limited. Before a group of cells can become differentiated along certain lines, it must not only possess the requisite potency but it must also receive a determining stimulus, and this stimulus is usually provided by its environment. Recent experimental work has shown that, so long as their differentiation has not been carried too far, cells which normally give rise to a particular tissue or organ can be influenced to differentiate into quite different structures if they are brought into a different environment, e.g. contact with a group of cells to which they bear no relation normally. Under normal conditions the ectoderm on the surface of the head which overlies the developing optic vesicle undergoes a series of changes and gives rise to the lens. If the optic vesicle is transplanted into the tissues of the abdominal wall, the lens fails to develop in its normal situation, but the ectoderm under which the transplanted vesicle lies will form a lens in the ordinary way. Spemann, working on amphibian larvæ, transplanted portions of the dorsal lip of the blastopore into an undifferentiated region of another embryo. As a result the transplant and the tissues of the host interacted on one another in such a way that a secondary, incomplete embryo formed in the tissues of the host. This, and other experiments of a similar nature, demonstrate the latent potencies of undifferentiated cells and the organising power of the cells situated in the dorsal lip of the blastopore.

Many tissues of the adult body retain their potencies to a large extent and are capable of taking on new characters when an appropriate stimulus is received, always provided that their cells are still able to reproduce themselves. Such processes frequently occur in the formation of tumours and in other pathological conditions. They serve to demonstrate that the individual cells do not possess any inherent tendency to take on special characters but that their future depends on their potencies and their environment.

Differentiation is the result of the activities of certain *growth organisers*, such as the dorsal lip of the blastopore, but it would appear that the latter are unable to control the growth after a certain stage has been reached. For example, a portion of an optic vesicle, if transplanted, may continue to grow

and may give rise to a complete vesicle, independently of the environment in which it may be placed. If it fails to behave in this way, the transplant dies and is absorbed. The regulation and control of the extent of growth processes are apparently effected by the hormones secreted by the ductless glands, but nothing is known of the way in which they exercise their influence.

The importance of embryology.—To the student of medicine the study of human embryology is of great practical value, for it renders intelligible many of the facts of human anatomy which are otherwise meaningless or anomalous. In its early stages the body of the embryo exhibits an almost perfect symmetry, which, owing to a variety of causes, becomes considerably obscured in certain regions of the body in the adult. The normal processes of development supply not only the reasons for these differences but also the explanations of those departures from the normal which constitute congenital abnormalities or defects.

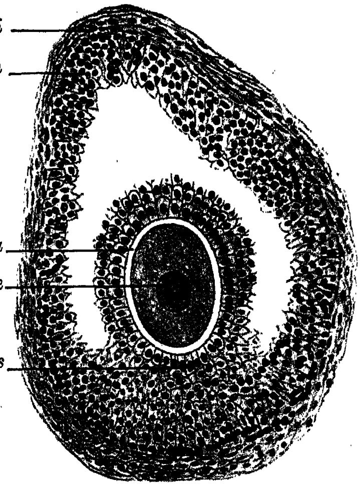
In addition to its value as an aid to the interpretation of human anatomy, embryology possesses importance on account of the evidence which it provides regarding the phylogeny of man. The changes which any embryo undergoes in the course of its development repeat—often, it is true, in a very abridged form—the changes which occurred in the embryos of its ancestral forms. The embryos of all vertebrates exhibit a stage in which gill-arches and clefts are present in the neck region. In fishes the cleft membranes break down and the gills develop and persist as essential functional structures in the adult form. In all air breathing vertebrates this stage, although transient, nevertheless occurs, but, in the human embryo, the cleft membranes never break down. In many cases the constituent parts of the arches become modified and adapted for new uses, a remarkable and noteworthy fact to which reference will be made repeatedly in the following pages.

Having regard to the main purpose of this work, it is impossible, in the space available in this chapter, to describe or illustrate fully all the changes which occur during the development of the human body. Only the principal facts are given, and the student is referred for further details to one or other of the text-books * on embryology.

THE OVUM

The ova develop in the ovary, which is the sexual gland of the female. The primitive sex cells are differentiated at a very early stage of development (p. 192) and by their repeated division give rise to a number of smaller cells, termed *oögonia*. After a time the oögonium ceases to divide and passes through a resting phase. It has now become an *ovum* or *primary oöcyte*, and the changes which it subsequently undergoes constitute the maturation or ripening of the ovum.

Fig. 59.—A section through an ovarian follicle of a cat. ×50.



Human ova vary from about 117μ† to 142μ in diameter, according to their stage of development. They are contained within the vesicular (Graafian) follicles of the ovaries; as a rule each follicle contains one ovum, but sometimes two

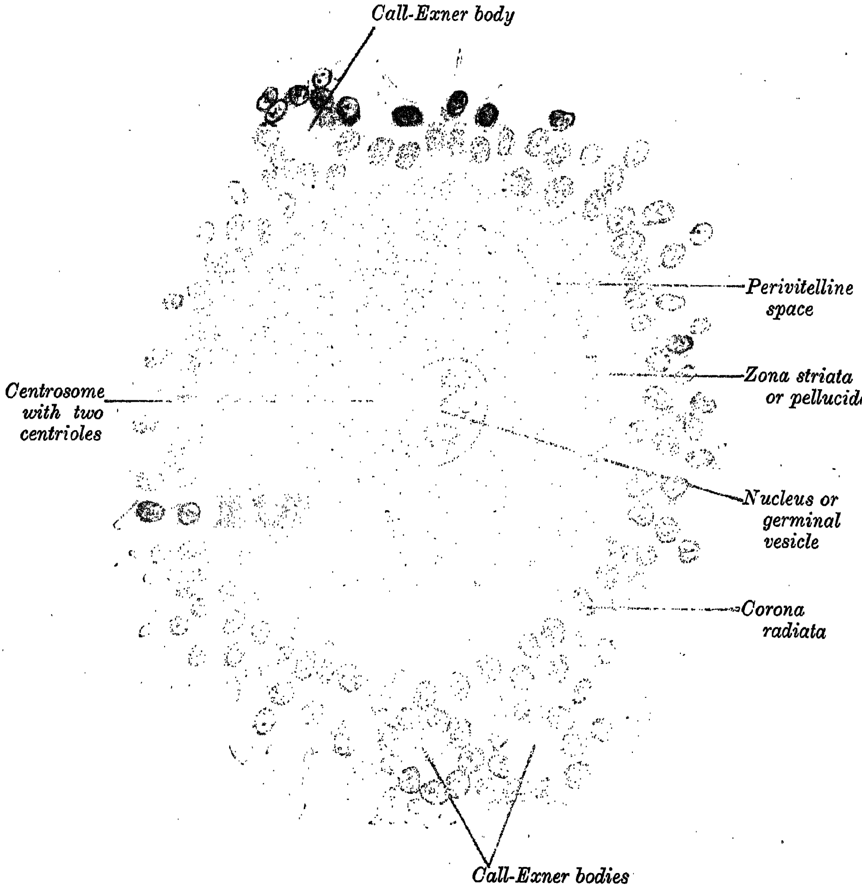
† μ = ·001 mm.

or more are present. Each ovum is at first invested by a single layer of cubical cells, which by multiplication form several layers. At a later stage a cavity filled with fluid appears amongst the cells, and gradually splits them into two strata, an inner (cumulus ovaricus) and an outer (stratum granulosum); but at one spot the strata remain in continuity. The stratum granulosum is enveloped by a sheath (theca folliculi) derived from the stroma of the ovary * (fig. 59). By the enlargement and subsequent rupture of a follicle at the surface of the ovary, an ovum, surrounded by the cells of the cumulus, is liberated and enters the uterine tube, through which it is conveyed to the cavity of the uterus. Unless the ovum is fertilised it is discharged from the uterus, but if

FIG. 60.—A human ovum stained with Mallory's aniline blue. ×600. Drawn from a specimen lent by Professor Arthur Thomson, University of Oxford.



fertilisation takes place it is retained there and is developed into a child, which is born at the end of ten lunar months of twenty-eight days or nine calendar months.

Although the ovum (fig. 60) is very much larger than the ordinary cell, it resembles it closely in structure and general appearance, but distinctive names are given to its several parts; thus, the cell-substance is known as the *yolk* or *oöplasm*, the nucleus as the *germinal vesicle*, and the nucleolus as the *germinal spot*. The ovum has a thick, transparent envelope named the *zona striata* or *zona pellucida*, and then the ovum is liberated from the vesicular follicle, several layers of cells, derived from those of the cumulus ovaricus, adhere to the outer surface of the zona pellucida, and collectively constitute the *corona radiata*.

It should be stated that a radical selective elimination occurs in human ova during the late stages of the growth of the follicles. Only one ovum is shed from each ovary in each menstrual cycle, but in the same period a large number

* For further particulars, see description of the ovary under Splanchnology.

(5-20), although developing normally for a time, subsequently show atretic changes and become degenerated.*

The **yolk** comprises (1) *cytoplasm* similar to that of the ordinary animal cell (p. 1), and frequently termed the *formative yolk*; (2) *deutoplasm* or *nutritive yolk*, which consists of fatty droplets containing lecithin—a phospholipin closely allied to and found with the animal fats.† In the mammalian ovum the deutoplasm is extremely small in amount, and nourishes the embryo in the early stages of its development only, whereas in the egg of the bird there is sufficient to supply the chick with nutriment throughout the whole period of incubation. The mode of distribution of the deutoplasm within the egg varies in different animals; in some it is almost uniformly dispersed throughout the cytoplasm; in others it is centrally placed and surrounded by the cytoplasm; and in others it is accumulated at the lower pole of the ovum, while the cytoplasm occupies the upper pole. A *centrosome* and *centrioles* are sometimes present and lie in the immediate neighbourhood of the nucleus; they are absent, however, in the mature ovum (p. 47).

The **nucleus** or **germinal vesicle** is a large spherical body which usually occupies an eccentric position in the yolk. Its structure is that of an ordinary cell-nucleus, viz. it consists of a reticulum or karyomitome the meshes of which are filled with karyoplasm. Connected with, or imbedded in, the reticulum there are a number of chromatin masses or chromosomes, which may present the appearance of a skein or may assume the form of rods or loops. The nucleus is enclosed by a delicate nuclear membrane, and contains in its interior a well-defined nucleolus or germinal spot.

THE COVERINGS OF THE OVUM

The **zona pellucida** or **zona striata** (fig. 60) is a thick membrane, which, under the higher powers of the microscope, is seen to be radially striated. Between it and the cytoplasm of the ovum there is a narrow *perivitelline space*, filled with fluid, in which the polar bodies are seen lying after their extrusion from the ovum. Thomson ‡ describes the zona pellucida as consisting of (*a*) an inner, homogeneous layer which is derived from the ovum, and (*b*) an outer, fibrillar layer formed by the felting of the basal fibres of the innermost cells of the corona radiata. He is also of opinion that there is distinct evidence of a *vitelline membrane* within the zona pellucida.

The **corona radiata** (fig. 60) consists of two or three strata of radially arranged cells. These consist of the cells of the cumulus ovaricus, which adhere to the outer surface of the zona pellucida when the ovum is set free from the vesicular follicle. The cells of the innermost layer are columnar in shape, and send delicate processes through the zona pellucida, thus giving the latter a striated appearance.

THE MATURATION OF THE OVUM

Before an ovum or primary oöcyte can be fertilised, it must undergo a process of *maturation* or *ripening*. This consists of a preliminary stage of growth during which the ovum increases greatly in size, followed first by a heterotypical or reduction division and then by a homotypical division. The whole process has been carefully studied in the ova of many of the lower animals and the following description is based on these investigations.

During the stage of growth, changes occur both in the nucleus and in the cytoplasm. The nuclear changes affect chiefly its chromatin content. The chromosomes become prominent and stain deeply with basic dyes. They unite with one another in pairs, usually in their long axes, so that their number is reduced by half, each however representing a double chromosome. This process is termed the *conjugation of the chromosomes*, and it would appear to be

* Edgar Allen, J. P. Pratt, Q. U. Newell and L. J. Bland, *American Journal of Anatomy*, vol. 46, No. 1.

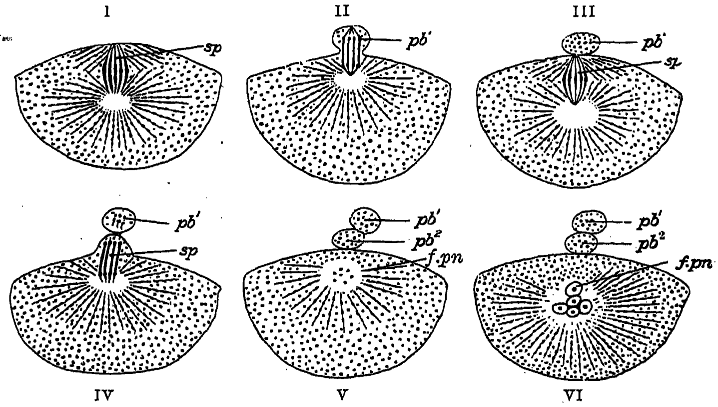
† Arthur Robinson (*Proceedings of the Anatomical Society of Great Britain and Ireland*, 1925, p. 109) has shown that unsaturated fat, demonstrable by osmic acid, is practically absent from human ova, and from the ova of rats and mice, but is present in large amount in the ova of dogs and ferrets, where it forms the greater part of the volume of the ova.

‡ Professor Arthur Thomson, *Journal of Anatomy*, vol. liii. 1919.

an essential preliminary to the ensuing heterotypical division. As already stated (p. 2) the number of chromosomes found in the nucleus is constant for all the cells in an animal of any given species, and in man the number is probably forty-eight. This applies not only to the somatic cells but to the oögonia and the primary oöcytes also. In the latter two of the chromosomes are believed to possess distinguishing features and are known as the x-chromosomes. The conjugation process reduces the number of chromosomes in the human primary oöcyte to twenty-four, one of which is formed by the union of the two x-chromosomes with each other.

The changes in the cytoplasm which mark the period of growth result in a great increase in the size of the cell. Its metabolic processes become extremely active, and a store of nourishment is accumulated which is necessary for the supply of the ovum during the early stages of its development. The essential feature of the metabolic activity is the *formation of deutoplasm*, but at the same time the amount of protoplasm increases, and the mitochondria become much more numerous.

FIG. 61.—The formation of the polar bodies in Asterias glacialis. (Slightly modified from Hertwig.)



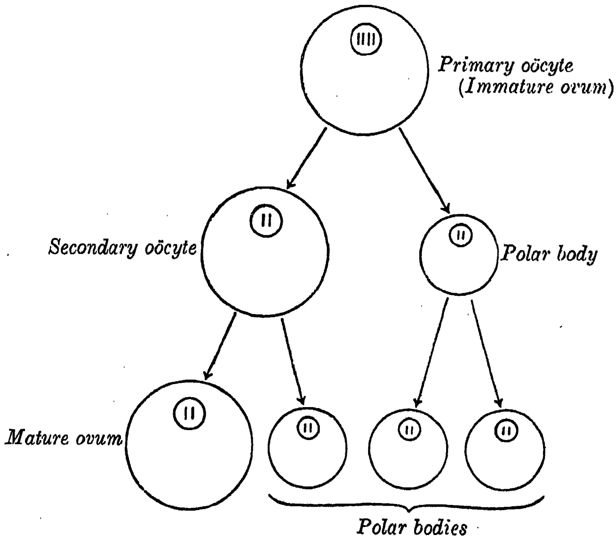
In fig. I the polar spindle (*sp*) has advanced to the surface of the egg. In fig. II a small elevation (pb^1) is formed which receives half of the spindle. In fig. III the elevation is constricted off, forming the first polar body (pb^1), and a second spindle is formed. In fig. IV is seen a second elevation which in fig. V has been constricted off as the second polar body (pb^2). Out of the remainder of the spindle (*f.pn* in fig. VI) the female pronucleus is developed.

Having passed through this period of growth, the ovum is now ready to undergo heterotypical division. Near its upper pole the double chromosomes arrange themselves in an equatorial plate with reference to the spindle, which is placed radially. The chromosomes divide and one half of them pass centrally, while the other half pass outwards, forming a projection at the upper pole of the ovum, which becomes separated off to form the *first polar body*. The division of the cytoplasm, unlike the division of the nucleus, is unequal, and the polar body only carries with it a small part of the cytoplasmic content of the ovum. Following this reductional division the nucleus of the larger cell, which is now a *secondary oöcyte*, is not reconstituted before the cell again divides. Its chromosomes rearrange themselves in an equatorial plate at the upper pole of the cell, and undergo homotypical division so that a *second polar body* is formed. The larger cell, which has lost but little of its cytoplasm, is now a *mature ovum* and lies within the zona pellucida, together with the two polar bodies, or three, if the first has succeeded in dividing, as it does in some species. The chromosomes of the mature ovum lose their identity during the resting stage prior to fertilisation and form a reticulum, constituting the *female pronucleus*. The mature ovum is characterised (1) by the number of its chromosomes, which is just one-half of the typical number for the somatic cells of the species, (2) by its great size and the large amount of cytoplasm relative to the size of the nucleus, and (3) by the presence of the deutoplasm. The sequence of heterotypical and homotypical divisions which is characteristic of the maturation of the sex cells, is termed meiosis.*

* Different authors employ the term 'meiosis' with varying shades of meaning, but it always implies a reduction in the number of chromosomes.

In most vertebrates the heterotypical division occurs before the ovum or primary oöcyte is liberated from the vesicular (Graafian) follicle, and the homotypical division after a spermatozoön has penetrated the zona pellucida. Thomson * has submitted evidence to show that in man both polar bodies are

FIG. 62.—A diagram showing the reduction in number of the chromosomes during the maturation of the ovum. The first division is heterotypical, the second homotypical.



extruded before the ovum is liberated from the follicle ; in other words, the process of maturation is completed before the ovum has been subjected to the influence of a spermatozoön. Additional evidence in favour of this view has been adduced recently as the result of the investigation of fresh material obtained at operations.†

THE SPERMATOZOÖN

The spermatozoa or male germ-cells are developed in the testes and are present in enormous numbers in the seminal fluid. Each consists of a small but greatly modified cell, and possesses a head, which represents the nucleus, a neck, a body or connecting piece, and a tail (fig. 63).

The **head** is ovoid or elliptical, but flattened, so that when viewed in profile it is pear-shaped. A layer of modified protoplasm, named the *head-cap*, covers its anterior two-thirds, and ends in front in a sharp edge.

The **neck** is less constricted in the human spermatozoön than in the sparmatozoa of some of the lower animals. The *anterior centriole* is situated at the junction of the head and neck, and behind it there is a band of homogeneous substance.

The **body** or **connecting piece** is rod-like, and is limited behind by a *terminal disc* or *ring*. The *posterior centriole* is placed at the junction of the body and neck, and from it an *axial filament*, surrounded by a sheath, runs through the body and tail. In the body the sheath of the axial filament is encircled by a *spiral thread*, which is enclosed in an envelope containing chondriosomes or mitochondria granules, and termed the *mitochondrial sheath*.

The **tail** consists of the axial thread or filament, surrounded by a thin protoplasmic sheath ; the terminal portion or *end-piece* of the tail is composed of the axial filament only.

Krause gives the length of the human spermatozoön as between 52μ and 62μ, the head measuring 4μ to 5μ, the connecting piece 6μ, and the tail from 41μ to 52μ.

By virtue of their tails, which act as propellers, the spermatozoa are capable of free movement, and ascend from the vagina into the cavity of the uterus, and from the latter into the uterine tube ; if placed in favourable surroundings

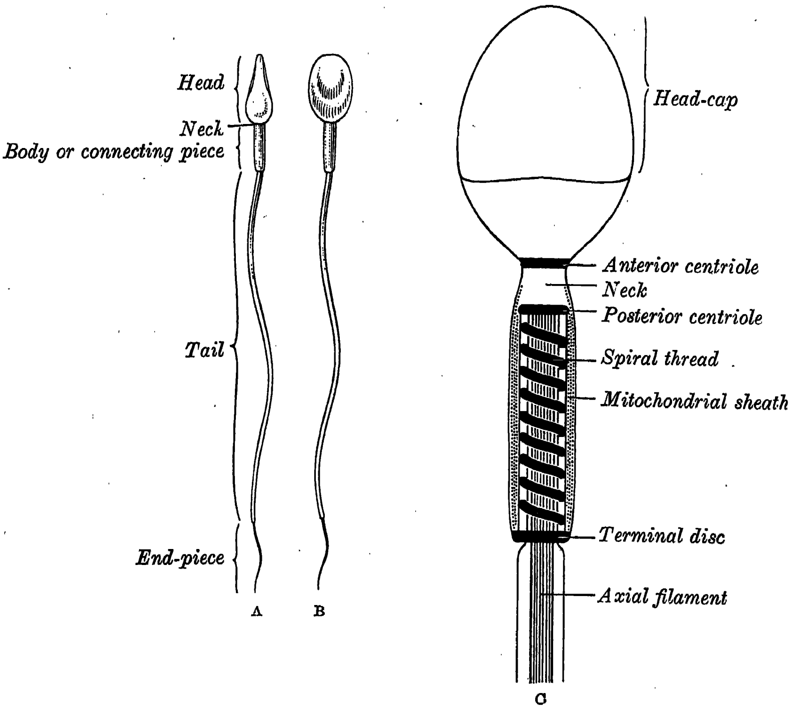
* *Loc. cit.* † Edgar Allen and others. *Loc. cit.*

(e.g. in the female passages) they will retain their vitality and fertilising power for several days.

The spermatozoa are developed from the primary germ-cells (p. 192) imbedded in the testes, and the stages of their development are very similar to those of the maturation of the ovum. The primary germ-cells undergo division and produce a number of cells termed *spermatogonia*.

After a number of mitoses the spermatogonia enter on a resting phase and gradually change, without further division, into *primary spermatocytes*. During this period the cell body enlarges, the mitochondria increase in number, and

Fig. 63.—A human spermatozoön, highly magnified. A. Profile view. B. Surface view. (After Retzius.) C. A diagrammatic representation of the head, neck and connecting piece, more highly magnified. (Modified from Meves.)

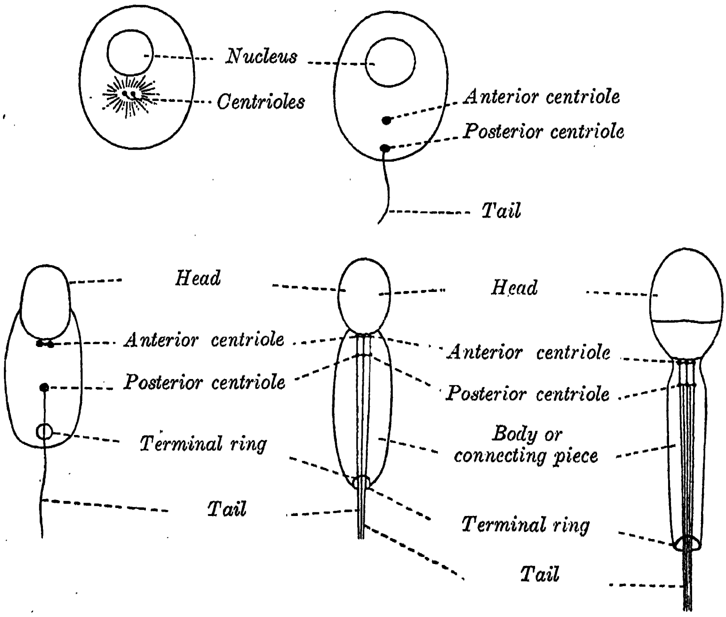


the centrosome, previously difficult to identify, becomes easy to recognise. The nuclear changes, which are of a very complicated character, result in a process of conjugation of the chromosomes, whereby their number is reduced to one-half. The chromosomes of the spermatogonia include two sex chromosomes, one of which, the x-chromosome, is identical with the sex chromosomes of the oögonia ; the other is very diminutive and is termed the y-chromosome. During conjugation the x- and the y-chromosomes become mated. It should be stated that many authorities deny the existence of a y-chromosome in man, and believe that during conjugation the x-chromosome does not mate.

The primary spermatocyte now proceeds to divide by a heterotypical mitosis into two apparently equal *secondary spermatocytes*, each of which possesses one-half of the number of chromosomes which is typical for the species. The only difference between them involves the sex chromosomes. When division occurs, the mated x- and y-chromosomes separate and pass to opposite poles of the spindle, so that one becomes included in one secondary spermatocyte, and the other in the other. After a brief resting phase each secondary spermatocyte divides, by a process of homotypical mitosis, into two *spermatids*. Division affects the x- and y-chromosomes as well as the others, and of the four spermatids which result from the division of each primary spermatocyte, two possess x-chromosomes and two possess y-chromosomes, while all four contain half of the number of chromosomes which is typical for the species.

Interesting changes occur during the conversion of the spermatid into the spermatozoön (fig. 64). At first the two centrioles lie side by side, but they soon alter their positions so that one comes to be placed deeper than the other; the deeper one forms the anterior centriole of the neck. The axial filament grows out from the superficial centriole, which divides into an anterior and a posterior part. The anterior part forms the posterior centriole of the neck, while the posterior part, which is ring-like, migrates to the distal end

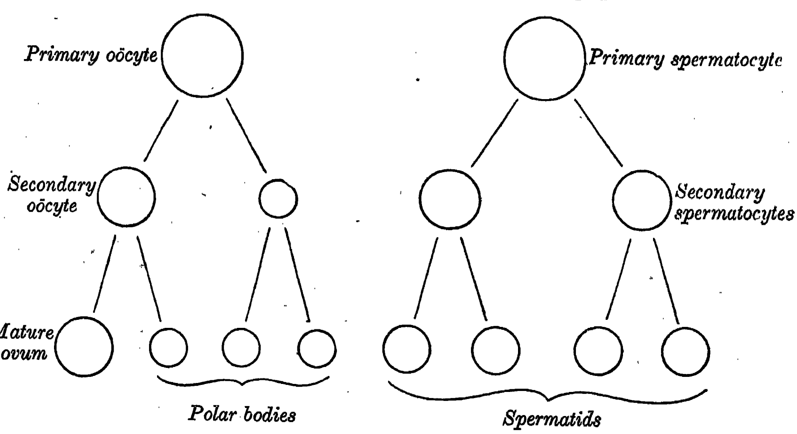
FIG. 64.—The transformation of a spermatid into a spermatozoön. Diagrammatic. (Modified from Meves.)



of the connecting piece or body and there forms the terminal disc or ring, through which the axial filament passes. The nucleus of the spermatid forms the head of the spermatozoön, and the cytoplasm, the investing sheath of the body and tail.

On comparing the development of the spermatozoön with the maturation of the ovum or primary oöcyte (fig. 65) it will be observed that the primary spermatocyte gives rise to two secondary spermatocytes, and the primary

FIG. 65.—A scheme showing the analogies in the process of maturation of the ovum and the development of the spermatids (young spermatozoa).



oöcyte to the secondary oöcyte and the first polar body; the two secondary spermatocytes give origin to four spermatozoa, and the secondary oöcyte and first polar body to four cells, the mature ovum and three polar bodies. In the development of the spermatozoön, and in the maturation of the ovum, there is

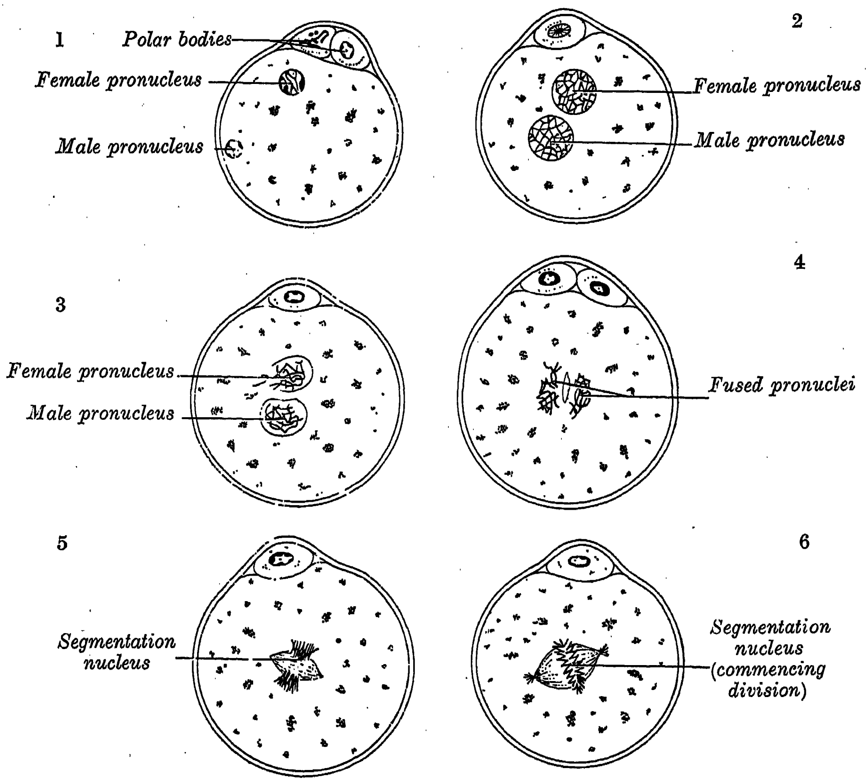
a reduction of the nuclear chromosomes to one-half of those present in the parent cell, and in each case the reduction is preceded by a process of conjugation of the chromosomes. But here the similarity ends, for it must be noted that the four spermatozoa are of equal size, and each is capable of fertilising a mature ovum, whereas the three polar bodies are much smaller than the mature ovum, are incapable of further development, and may be regarded as abortive ova.

THE FERTILISATION OF THE OVUM

Fertilisation consists of the union of a spermatozoön with a mature ovum (fig. 66). Nothing is known as to the fertilisation of the human ovum, but the various stages of the process have been studied in other mammals, and from the knowledge so obtained it is believed that fertilisation of the human ovum takes place in the lateral or ampullary part of the uterine tube.

A spermatozoön pierces the zona pellucida and enters the mature ovum, the point of entry being closed at once to prevent the admission of other spermatozoa. If the ovum has not thrown off its second polar body, it does so immediately after the entry of the spermatozoön. At the same time the

FIG. 66.—The process of fertilisation in the ovum of a mouse. (After Sobotta.)



latter sheds its tail, whilst its head and body become altered to form the *male pronucleus* and two centrosomes. The male pronucleus increases in size by absorbing fluid from the ovum, and there develops in its immediate neighbourhood a radial arrangement of the granules of cytoplasm, which has been termed the *aster of fertilisation*.

At the time of the entry of the spermatozoön, the ovum has laid up such a store of nutriment that there would appear to be danger of its dying from autointoxication. The contact of the spermatozoön has a striking effect. A wave of contraction passes over the ovum from its upper pole and a quantity

of deutoplasm is extruded from the cell and comes to lie between it and the zona pellucida. This process is termed *deutoplasmolysis*. It appears to have a beneficial effect on the ovum, freeing its cytoplasm of waste products and enabling it more easily to orientate itself within the zona pellucida. The process effects an alteration in the polarity of the ovum, for the two pronuclei approach each other in the centre of the cell or even at what was previously the lower pole.

The two pronuclei fuse with each other and give rise to the *segmentation nucleus*. This step is the essential feature of fertilisation. The nucleus so formed now possesses the number of chromosomes which is typical for the species, and one-half of them has been derived from the ovum and one-half from the spermatozoön. Following the fusion of the pronuclei the aster of fertilisation disappears, and the centrosomes of the spermatozoön separate from one another and proceed to opposite poles of the segmentation nucleus. The chromatin network breaks down and the chromosomes arrange themselves in an equatorial plane in the spindle formed between the two centrosomes. They then divide and retreat from the equator in opposite directions. Intense activity of the cytoplasm is apparent at this stage and results in the segmentation of the ovum into two daughter cells which are nearly equal in size. The next stage, viz. the segmentation of the ovum, has now begun.

Applied Anatomy.—Sometimes the fertilised ovum is arrested in the uterine tube, and undergoes development there, giving rise to a *tubal pregnancy*; or it may fall into the abdominal cavity and produce an *abdominal pregnancy*; occasionally it is not expelled from the vesicular follicle when the latter ruptures, but is fertilised within the follicle and produces what is known as an *ovarian pregnancy*. Under normal conditions only one spermatozoön enters the yolk and takes part in the process of fertilisation.

The rôle of the chromosomes.*—According to recent researches the mature ovum contains within itself all the materials essential for the formation of a new being, and in the lower forms at least may produce such, when its potential energy is converted into free energy by suitable mechanical or physico-chemical means. Loeb and others have been able to imitate the process of fertilisation in sea-urchins, frogs, etc., by altering the osmotic pressure of the unfertilised ovum.

* Consult *The Organism as a Whole*, by Jacques Loeb; *The Physical Basis of Heredity*, by Morgan; and *The Mechanism and Physiology of Sex Determination*, by Goldschmidt, translated by Dakin.

Reference has already been made to the fact that the spermatozoa, in equal numbers, contain either an x- or a y-chromosome, and that the mature ovum contains one x-chromosome. If an ovum be fertilised by a spermatozoön containing an x-chromosome, the cells of the embryo will each contain two x-chromosomes and the embryo will be female, but if an ovum is fertilised by a spermatozoön containing a y-chromosome, the cells of the embryo will each contain one x- and one y-chromosome and its sex will be male.

This, however, is not the only factor involved in the determination of sex. The theory advanced is that the chromosomes contain materials which initiate and control, by chemical means, the processes that lead to the development of the various tissues and their individual peculiarities. The establishment of a sex-difference is therefore, in the first instance, dependent on a specialised chromosome, but the development of the sexual features results from the presence of specialised chemical substances in the chromosomes.

The ova of certain animals contain a variable amount of pigment which, as the result of fertilisation, undergoes rearrangement in a very regular manner so as to form a crescentic area, intermediate in tint between the darkly pigmented area and the lighter polar area. This has been termed the "grey crescent." Its central, deeper portion controls the growth of the head and exerts an influence over the horns of the crescent, which are responsible for the formation of the right and left halves of the trunk and the corresponding limbs.* The polarity of the fertilised ovum is therefore fixed at a very early stage, and it would appear that, in many animals at least, the plane of bilateral symmetry is determined by the line of entry of the spermatozoön. Nevertheless it must be remembered that the cells derived from the ovum by its early segmentations are totipotent. Consequently a fertilised ovum may later divide into two equal parts, each of which may go on to form a complete embryo (*uniovular twins*), although under normal conditions it will only give rise to a single embryo.

THE SEGMENTATION OF THE FERTILISED OVUM

The early stages in the development of the human ovum have not yet been seen, but from what is known to occur in other mammals it may be regarded as certain that the process of segmentation starts immediately after fertilisation, i.e. while the ovum is in the uterine tube. The nucleus exhibits the usual changes, and these are succeeded by division of the fertilised ovum into two cells of nearly equal size. The process is repeated again and again, so that the two cells are succeeded by four, eight, sixteen, thirty-two, and so on, with the result that a mass of cells is formed, and to this mass the term *morula* is applied (fig. 67). During these changes the intense activity of the cytoplasm of the cells is evidenced by the constant streaming of their contained granules. The individual cells do not remain motionless but restlessly alter their positions relative to one another and reorientate themselves within the zona pellucida in order to maintain the bilateral symmetry of the ovum.

Before segmentation occurs the amount of cytoplasm in the fertilised ovum is great out of all proportion to the size of the nucleus, and the initial divisions which result in the formation of the morula have the effect of reducing the disproportion until the cytoplasm bears to the nucleus the average relationship which obtains in the average somatic cells of the species. As soon as this stage is reached the zona pellucida must disappear, for the continued process of segmentation thereafter results in an increase in the size of the ovum as a whole.

The process of differentiation, which plays such an important part in the formation of the embryo, commences in the cells of the morula. Its outermost layer constitutes the *trophoblast*, and the cells in its interior differentiate into a closely packed *inner cell mass* or *formative mass*, and a loosely arranged *primary mesoderm* † (fig. 71).

The cells of the trophoblast subsequently differentiate into an inner cellular layer, which is termed the *cytotrophoblast*, and an outer syncytial layer termed the *plasmodial trophoblast*, in which growth is so active that the nuclear divisions

* Brachet, A., *Quarterly Review of Biology*, 1927.

† It would be more accurate to term this tissue mesenchyme (see p. 62).

are not accompanied by divisions of the cytoplasm, and there is no cellular definition. The plasmodial trophoblast exerts a histolytic action on the uterine mucosa, and not only effects the imbedding of the ovum in the maternal tissues but also, at a slightly later stage, opens up the channels by means of which the developing embryo is enabled to draw nourishment from the maternal blood.

While these changes are occurring in the trophoblast, the inner cell mass

FIG. 68.—A section through the blastodermic vesicle of Vespertilio murinus. (After van Beneden.)

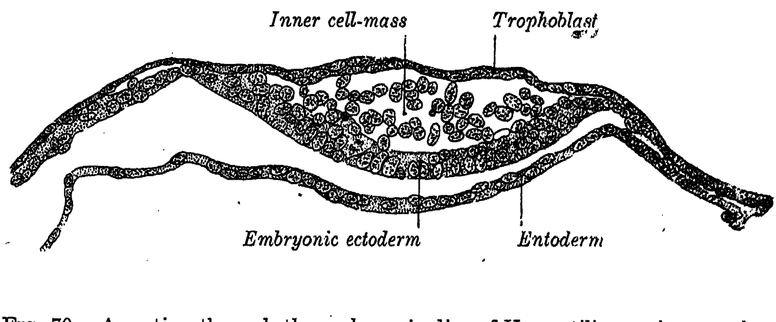

FIG. 70.—A section through the embryonic disc of Vespertilio murinus to show the formation of the amniotic cavity. (After van Beneden.)

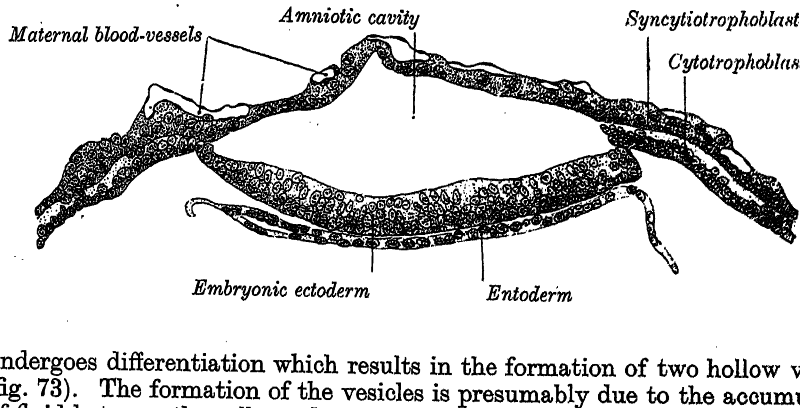

undergoes differentiation which results in the formation of two hollow vesicles (fig. 73). The formation of the vesicles is presumably due to the accumulation of fluid between the cells, and as it increases in amount the cells arrange themselves in a surrounding wall. Of the two vesicles so formed, one remains in close contact with the trophoblast and constitutes the *ectodermal* or *amnio-*

embryonic vesicle. The other is placed more centrally and is at first the smaller of the two. It constitutes the *entodermal vesicle,* and is often referred to as the *archenteron* or *yolk sac.**

While differentiation is occurring in the trophoblast and in the inner cell mass, changes are taking place in the primary mesenchyme. The fluid in which its constituent cells are floating tends to collect centrally and the cells become relegated to the periphery, where they eventually form a layer on the inner surface of the cytotrophoblast and on the outer surfaces of the entodermal and ectodermal vesicles. In this way a cavity, filled with a fluid rich in albuminous material, comes to surround the vesicles almost completely. It is termed the *magma cavity,* and it subsequently forms the extra-embryonic cœlom (figs. 73, 90). Its wall, which consists of trophoblast lined with primary mesenchyme, constitutes the *chorion.*

Concomitant with the changes which have just been described, and which transform the morula into a *blastocyst,* the ovum is gradually carried along the uterine tube by the action of the cilia of its lining epithelium. It is uncertain

FIG. 71.—A diagram showing the differentiation of the inner cell-mass.

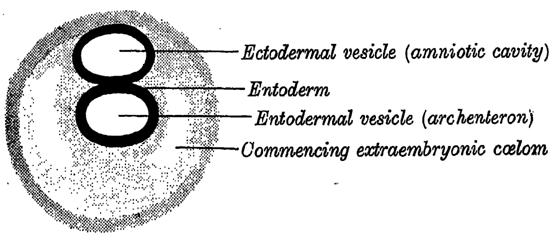

FIG. 73.—A diagram showing the completion of the extra-embryonic cœlom and the formation of the connecting stalk.

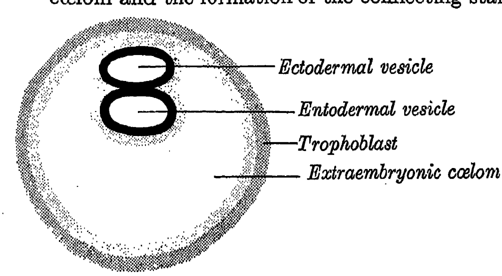


how long an interval elapses between the fertilisation of the ovum and its arrival in the uterus. † The passage along the tube probably covers a period of not less than three and not more than seven or eight days and this interval allows the uterine mucous membrane to prepare itself for the reception of the fertilised ovum (p. 78). It is probable that the ovum retains its zona pellucida until it leaves the uterine tube, and it is believed that it remains within the uterus for a short time before it becomes imbedded. During this interval the trophoblast undergoes differentiation, and the imbedding is effected owing to the histolytic action of the plasmodial trophoblast on the uterine mucosa, by means of which the ovum literally burrows its way into the wall of the uterus.

One of the earliest human ova yet obtained for examination was described by Professors Bryce and Teacher in 1908. It had already reached the stage

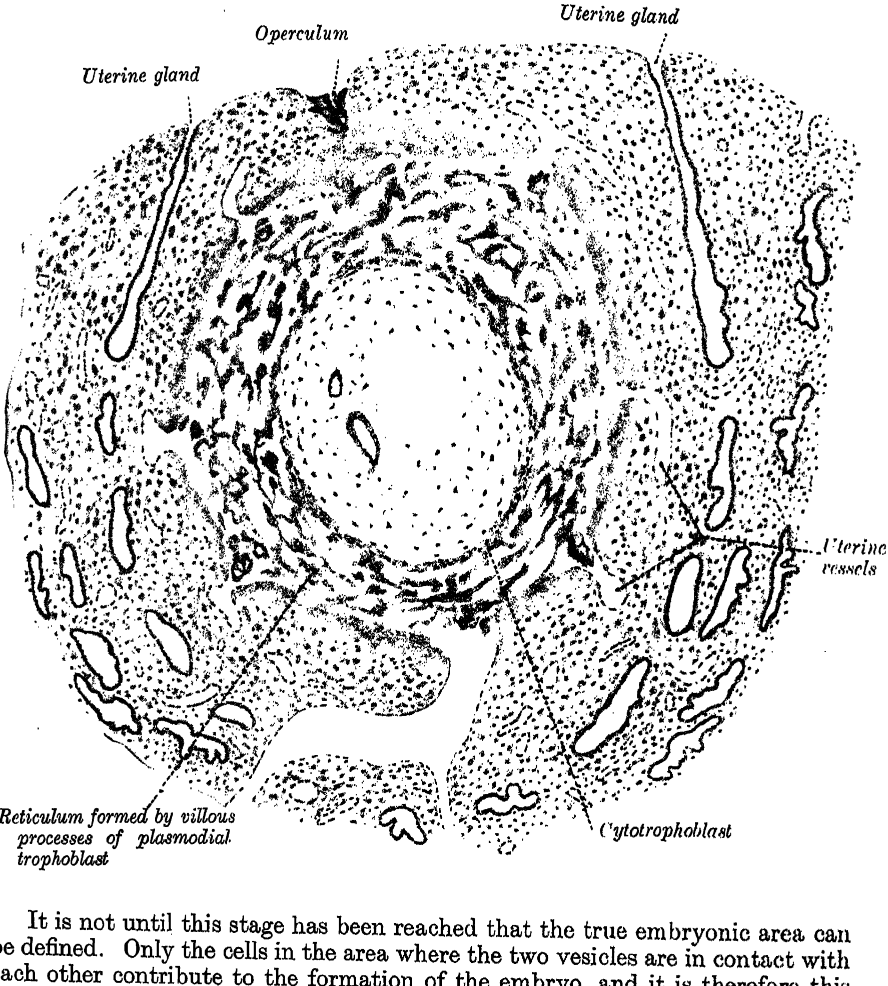
* H. Stieve (*Zeitschrift für Mikroskopisch-Anatomische Forschung,* Bd. 40, 1936) holds that the yolk-sac does not arise in this way. In the Werner ovum, which he claims represents an earlier stage of development than the Teacher-Bryce ovum described on this page, the entoderm is represented only by a simple plate of cells closely applied to the ventral aspect of the amnio-embryonic vesicle, which is already present. In Stieve's view the yolk-sac is formed by an extension of the peripheral cells of this plate into the magma cavity, a portion of which is surrounded and shut off in the process.

In this connexion consult a paper by P. N. B. Odgers in the *Journal of Anatomy,* vol. lxxi. 1937.

† G. W. Corner, *Contributions to Embryology,* vol. xiii. 1921.

which has just been outlined, and its age has been estimated at 13-14 days. The ovum (fig. 74) was imbedded in the uterine wall, where villous processes of the plasmodial trophoblast formed an actively growing reticulum. The interior of the blastocyst contained an ectodermal vesicle, connected to the trophoblast by a short stalk not seen in the figure, and an entodermal vesicle, imbedded in a loose bed of primary mesenchyme. The magma cavity was present in an early stage of formation. Owing to shrinkage during fixation the ectodermal and the entodermal vesicles were no longer in contact with each other but were some little distance apart.

FIG. 74.—Section of early human embryo (Teacher-Bryce I.) with decidua and implantation cavity. From Bryce's "Observations on the Early Development of the Human Embryo," *Transactions of the Royal Society of Edinburgh*, 1924.

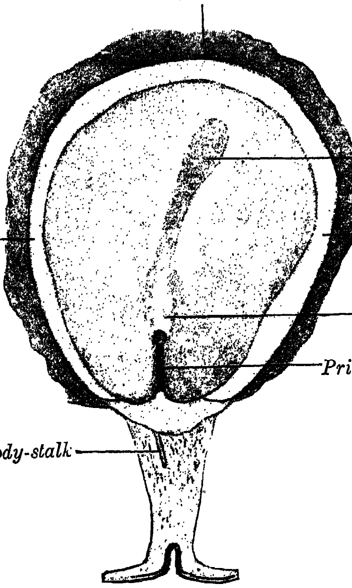


It is not until this stage has been reached that the true embryonic area can be defined. Only the cells in the area where the two vesicles are in contact with each other contribute to the formation of the embryo, and it is therefore this contact region which is termed the *embryonic area* or *shield*. It is noteworthy that of the thousands of cells derived from the ovum at this stage only a relatively small number take part in the formation of the embryo, while the vast majority form its covering and nourishing membranes and certain other extra-embryonic structures to be noted later. The ectodermal cells of the embryonic area are columnar in type and are marked off from the entoderm by a limiting membrane. By the third week they form three or four interlocking rows of cells (fig. 77). The ectodermal cells of the amnion are flatter and more elongated and form only a single stratum. The entodermal cells of the embryonic area are flattened, but those lining the rest of the entodermal vesicle or yolk-sac

vary in appearance and patches of cubical or low columnar cells are found, especially on the caudal wall. Except in certain situations to be noted later, the entoderm never forms more than a single layer of cells.

There are, however, two other features of the embryo at this time which deserve mention. The presence of a short stalk connecting the amniotic or ectodermal vesicle to the trophoblast has already been noticed. This stalk, which consists of primary mesenchyme, contains in its interior a duct which communicates with the amniotic cavity but ends blindly near the trophoblast. A somewhat similar stalk has been found in some specimens

FIG. 75.—An embryo of Hylobates concolor. Dorsal aspect, with the amnion laid open. (After Selenka.) (From Quain's Elements of Anatomy, vol. i., Embryology.)



extending from the entodermal vesicle into a strand of primary mesenchyme which connects the vesicle to the trophoblast. These two ducts are both transient features, but they have a very different significance.

In the reptilia, and in many mammals, the amnion arises as a fold around the embryonic area which soon closes in to form a vesicle. The amniotic duct may be regarded as an indication of the abridgment of this process in the human embryo, in which, as has already been seen, the amnion arises as a cavity within the inner cell mass. The duct of the entodermal vesicle or yolk-sac has quite a different significance. In many mammals the entodermal vesicle is much larger and occupies nearly the whole interior of the blastocyst, and the presence of the duct in the human embryo may be regarded as evidence that the primates evolved from a stock in which the entodermal vesicle was a much larger organ.

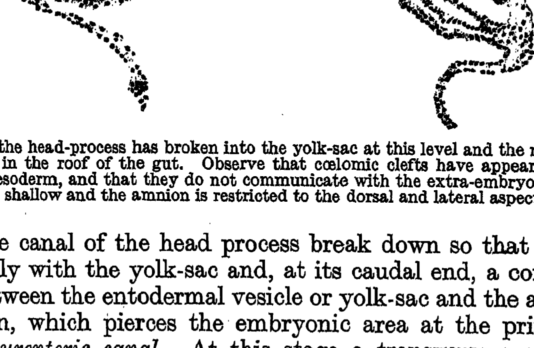
The differentiation of the embryonic area.—The embryonic area shows no distinguishing features in its earliest stages. At first nearly circular, its outline rapidly alters and becomes oval, indicating the long axis of the body. The oval area becomes pear-shaped, and in the median plane of its narrower portion there appears a localised opacity, which soon elongates to form a linear opacity, termed the *primitive streak* (fig. 75). It must be remembered that in the early stages of development the living tissues are translucent, but any localised thickening due to cellular proliferation naturally interferes with the translucency and causes a localised opacity. The presence of the primitive streak indicates that rapid growth is occurring throughout its site. At the headward end of the primitive streak an area of exceptionally active growth develops and forms a knob-like thickening which is termed the *primitive node*. At the caudal end of the embryonic area the ectoderm and entoderm are very intimately related over a limited region which subsequently forms the *cloacal membrane*.

From the primitive node a rod-like process of cells grows headwards in the median plane and separates the ectoderm of the embryonic area from the subjacent roof of the entodermal vesicle (fig. 96). This is termed the *head process*, and it is the forerunner of the skeletal axis of the body. The solid rod of cells becomes canaliculised (fig. 76) and at its caudal end the canal breaks through on to the ectodermal surface at the primitive node. The entodermal cells lying ventral to the head process disappear, and the head process is then a constituent part of the roof of the yolk-sac in the median plane. The cells forming

Fig. 76.—Transverse section of the tail-fold of a human embryo, about 19 days old (Embryo: Bryce-McIntyre). From Bryce's "Observations on the Early Development of the Human Embryo," *Transactions of the Royal Society of Edinburgh*, 1924.

The canaliculised head-process lies in the roof of the hind-gut. The primitive streak and groove lie on the ventral aspect of the tail-fold. Observe that the secondary mesoderm is continuous ventrally with the primitive streak, and that the tail-fold is lying within the amniotic cavity.

Fig. 77.—Transverse section of a human embryo, about 19 days old (Embryo: Bryce-McIntyre). From Bryce's "Observations on the Early Development of the Human Embryo," *Transactions of the Royal Society of Edinburgh*, 1924.



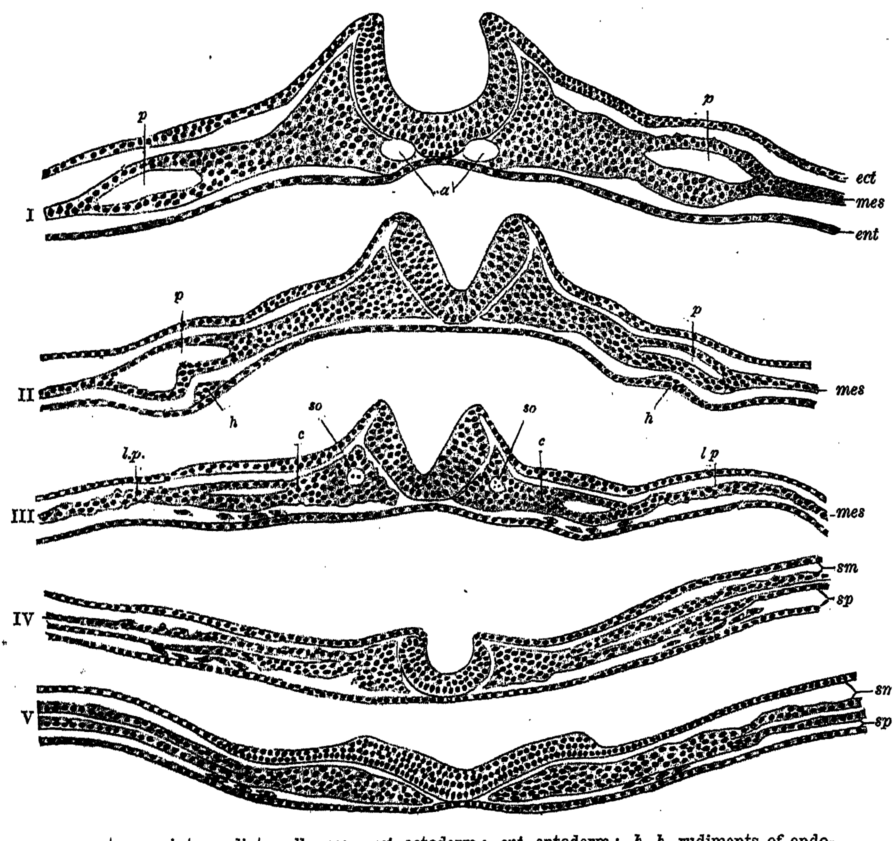
The canal of the head-process has broken into the yolk-sac at this level and the notochordal plate is incorporated in the roof of the gut. Observe that cœlomic clefts have appeared in the lateral plates of the mesoderm, and that they do not communicate with the extra-embryonic cœlom. The neural groove is shallow and the amnion is restricted to the dorsal and lateral aspects of the embryo.

the floor of the canal of the head process break down so that the canal communicates freely with the yolk-sac and, at its caudal end, a communication is established between the entodermal vesicle or yolk-sac and the amniotic cavity. This connexion, which pierces the embryonic area at the primitive node, is termed the *neurenteric canal*. At this stage a transverse section across the embryonic area shows that, in the median plane, the roof of the entodermal vesicle is formed by the cells of the head process (fig. 77), and this intercalation extends forwards to the region which will subsequently form the pharynx. Later, these cells of the head process become excalated out from the entoderm

and form the *notochord*, the roof of the entodermal vesicle being repaired by the fusion of the adjoining entodermal cells. Subsequently the cells of the notochord develop around them a homogeneous sheath, and the continued proliferation of the cells within the sheath results in the formation of a solid but flexible rod, which becomes surrounded by the mesenchyme of the primitive or membranous vertebral column (p. 83).

FIG. 78.—A series of transverse section through the embryo of a dog. (After Bonnet.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

Section I is the most anterior. In V the neural plate is spread out nearly flat. The series shows the uprising of the neural folds to form the neural canal.



a, aortæ; *c*, intermediate cell-mass; *ect*, ectoderm; *ent*, entoderm; *h*, *h*, rudiments of endothelial heart-tubes. In III, IV, and V the scattered cells represented between the entoderm and splanchnic layer of mesoderm are the vasoformative cells which give origin in front, according to Bonnet, to the heart tubes *h*; *l.p.*, lateral plate still undivided in I, II, and III; in IV and V split into somatic (*sm*) and splanchnic (*sp*) layers of mesoderm; *mes*, mesoderm; *p*, pericardium; *so*, primitive segment.

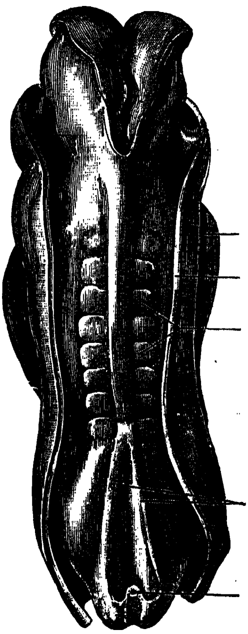
During the earlier part of this period another important change occurs which affects nearly the whole of the embryonic area. From the sides of the primitive streak there is an intensely active cell growth. These cells spread laterally and forwards until they extend over the whole embryonic area *with the exception of the median plane*. They insinuate themselves between the ectoderm and the underlying entoderm and constitute a third constituent layer, which is termed the *secondary mesoderm* (fig. 76). At the extreme cephalic end of the area the secondary mesoderm does cross the median plane, constituting what has been termed the '*pericardial bar.*'

The primitive streak is not the only source of secondary mesoderm. Cephalic to the headward end of the head process, the entoderm in the roof of the yolk-sac becomes thickened and gives rise to a plate of large, vesiculous cells which has been termed the *prochordal plate*. This plate contributes secondary mesoderm to the head region, and the cranial end of the head process gives origin

to two lateral mesodermal bands, which may be regarded as representing the gastral mesoderm * (p. 65).

In the wider cephalic end of the oval embryonic area the ectoderm thickens to form a curved ridge, the lateral limits of which extend caudally until they pass beyond the primitive node. This second thickening constitutes the *medullary plate*, from which by far the greater part of the central nervous system is

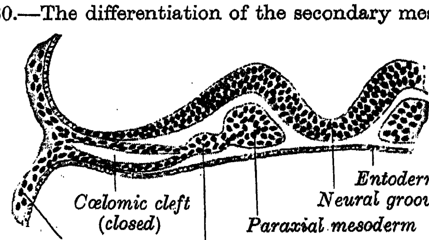
FIG. 79.—A human embryo, 2·1 mm. long. Dorsal aspect. (From a model by Eternod.)



developed. The raised ridges constitute the *neural folds*, and the median groove which separates them is the *neural groove.*

As the embryonic area increases in length the neural folds deepen at the anterior end of the area and the walls of the groove become expanded (fig. 78). This enlargement is the first sign of brain formation. It is not a continuous enlargement, however, for two transverse constrictions indicate a subdivision

FIG. 80.—The differentiation of the secondary mesoderm.



into three parts, viz. the *prosencephalon* or *fore-brain*, the *mesencephalon* or *mid-brain*, and the *rhombencephalon* or *hind-brain*. Between the fore-brain and the pericardial bar of mesoderm the ectoderm and entoderm come into contact over a small area, forming the *buccopharyngeal membrane* (fig. 174). As the neural groove deepens, its dorsal edges come into contact with each other and fuse to convert the groove into a somewhat slit-like canal. Fusion occurs first in the region of the hind-brain (fig. 79) and extends both headwards and tailwards, until only a small opening is left at each end. These openings are termed

* J. P. Hill and J. Florian, *Journal of Anatomy*, vol. lxv. 1931.

the anterior and posterior *neuropores* ; both close towards the end of the fourth week. The cells which connect the fused dorsal edges of the neural groove to the overlying ectoderm constitute the *neural crest epithelium* (fig. 139), the history of which will be considered in a subsequent section (p. 108).

The fusion of the dorsal lips of the neural groove in the region of the brain results in the formation of the three *primary cerebral vesicles.* The walls of these vesicles become thickened and develop into the nervous tissue and neuroglia of the brain, and the cavities are modified to form the ventricles of the brain. The remainder of the tube forms the spinal cord, its cavity persisting as the central canal.

Throughout the region of the notochord the secondary mesoderm arranges itself in (1) a thickened medial portion which lies immediately lateral to the neural groove and is termed the *paraxial mesoderm* (fig. 80), (2) a narrower portion, termed the *intermediate cell mass,* situated to its lateral side and directly continuous with it, and (3) a flattened lateral portion, continuous medially with (2), which extends over the surface of the embryonic area to its periphery, where it becomes continuous with the primary mesenchyme on the outer surfaces of the ectodermal and entodermal vesicles. This portion is termed the *lateral plate.*

The appearance of the secondary or intra-embryonic mesoderm completes the first stage of differentiation in the embryonic area. The embryo now consists of an outer, protective layer, the ectoderm, an inner nutritive layer, the entoderm, and an intermediate layer, the mesoderm, which is available primarily as a muscle-forming layer. It is clear from their history and their early differentiation that these layers are of considerable significance, but too much stress must not be laid on their independence from one another. In other words, the differentiation reached at this stage has not gone so far as to leave the constituent cells of the three layers with potencies so limited that complete divergence is assured for the future. The potencies of the individual cell layers are reduced from the totipotent condition found at an earlier period, but not to such an extent that the potencies of the cells of one layer are entirely different from those of the two remaining layers.

Broadly stated, however, the three layers in the human embryo contribute to the formation of systems and organs which show distinct functional differences.

The **ectoderm** consists of columnar cells, which, however, become somewhat flattened or cubical, especially towards the periphery of the embryonic area. It gives origin to : (1) the skin and the lining cells of the glands which open on it, and its appendages, the hair and nails ; (2) practically the whole of the nervous system, including the cranial and spinal ganglia, the sympathetic ganglia and the posterior lobe of the hypophysis cerebri ; (3) the chromaffin organs ; (4) the anterior lobe of the hypophysis cerebri ; (5) the epithelium of the cornea, conjunctiva and lacrimal glands ; (6) the lens ; (7) the plain muscle of the iris ; (8) the neuro-epithelium of the sense-organs ; (9) the epithelium lining the nose and the paranasal sinuses, the roof of the mouth, the gums, and the cheeks ; (10) the salivary glands and the enamel of the teeth ; and (11) the lower part of the anal canal.

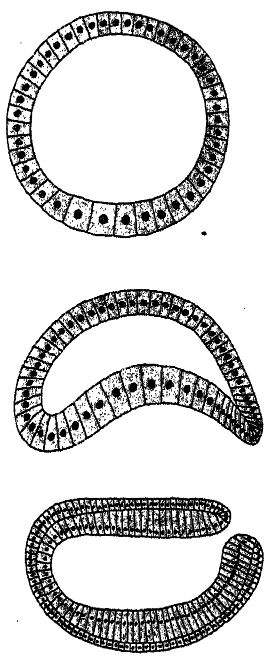
The **entoderm** consists at first of flattened cells, which subsequently become columnar. It gives origin to : (1) the epithelial lining of the whole of the alimentary canal, with the exception of those portions already ascribed to the ectoderm ; (2) the lining cells of all the glands which open into the alimentary canal, including the liver and the pancreas, but excluding the salivary glands ; (3) the epithelium lining the pharyngo-tympanic tube and the tympanic cavity ; (4) the epithelium of the thyroid and parathyroid glands and the thymus ; (5) the lining epithelium of the larynx, trachea and the smaller air passages, including the alveoli and the air-sacs ; (6) the epithelium of most of the urinary bladder and the adjoining part of the urethra ; (7) the epithelium of the prostate.

The **mesoderm** gives origin to the remaining organs and tissues of the body. These include : (*a*) all the connective tissues, including bone and cartilage, i.e. the whole skeletal system, and the blood ; (2) the teeth, with the exception of the enamel ; (3) the whole musculature of the body, both striated and unstriated,

with the exception of the musculature of the iris ; (4) the blood-vascular and lymphatic systems ; (5) the urogenital system, with the exception of most of the urinary bladder, prostate and urethra ; (6) the cortex of the suprarenal glands and the endothelial linings of the pericardial, pleural and peritoneal cavities.

It should be observed that the cells of the mesoderm are very soon differentiated into those which subsequently retain their close-packed cellular character (*mesoderm proper*) and those which form a loose tissue with a fluid matrix (*mesenchyme*). Thus the muscles and urogenital organs are mesodermal while the connective tissues are mesenchymatous, and on account of the fluid character of the matrix their cellular elements are able to alter their position by active migration (p. 83). The term *mesothelium* is sometimes applied to epithelial cells of mesodermal origin, such as the secretory epithelium of the kidney, the cortical cells of the suprarenal glands, and the endothelium lining the serous cavities.

FIG. 81.—Three stages in the development of amphioxus (after Hatschek.)



A

B

C

A. Spherical blastoderm. The cells at the lower pole are larger than those at the upper pole.
B. Invagination of the lower pole to form a gastrula.
C. Longitudinal section through the embryo at a slightly later stage. Gastrulation is completed and the primitive alimentary canal communicates with the exterior through the blastopore, which lies at the caudal end of the flattened dorsal surface of the embryo.

It may prove helpful at this point to compare the early history of the human ovum with that of other vertebrata and lower chordata. The ovum of amphioxus contains only a small amount of deutoplasm and, when fertilised, it segments first into two cells of equal size, the line of cleavage corresponding to the plane of bilateral symmetry. The second and third divisions, both in planes at right angles to the first, result in the formation of eight cells, of which the four at the upper pole are slightly smaller than the four at the lower pole. The egg continues to divide and eventually forms a hollow sphere or *blastula*, the larger cells still being situated at its lower pole. Even in the ovum it is possible to identify the material that is destined to give rise to the cells of the mesoderm, and its history has been investigated recently.* In the fully formed blastula entodermal, ectodermal and mesodermal areas can be identified. The entodermal cells are the largest, and the mesodermal are the smallest and are somewhat spherical in shape. At this stage the ectodermal cells along the anterior border of the entoderm are already undergoing differentiation and a '*chordal plate*' can be recognised. The hollow blastula becomes invaginated, and the chordal plate and the mesoderm are involved in this process in addition to the entoderm. As a result of this invagination the segmentation cavity of the blastula becomes crescentic (fig. 81, B), and is finally obliterated (fig. 81, C). The ovum has now been converted into a hollow cup-like mass or *gastrula*, the walls of which are two cells thick and enclose a cavity, termed the *archenteron*. This cavity communicates with the exterior through an orifice, which is termed the *blastopore*. The inner layer of the gastrula consists principally of entoderm, but its dorsal wall is formed in the median plane by the chordal plate and on each side by the mesoderm. In the succeeding growth changes the embryo becomes elongated and flattened along its dorsal aspect. At the same time the lips of the blastopore are approximated and the opening, much reduced in size, comes to lie at the caudal end of the flattened dorsal surface. While gastrulation is in progress, the cells in the region of the dorsal lip of the blastopore undergo rapid proliferation, which results in the formation and elongation of the dorsal surface of the embryo. Subsequent to the closure of the blastopore continued activity in this region is responsible for the further growth of the embryo in its long axis.

A median groove forms on the ventral aspect of the chordal plate in the roof of the

* E. G. Conklin, "The Embryology of Amphioxus," *Journal of Morphology*, vol. 54, Dec. 1932.

archenteron (fig. 82, I), and it becomes closed off from the cavity to form a rod of cells, which occupies the median plane between the neural tube and the archenteron (fig. 82, II). This rod forms the notochord and it remains for some time in continuity with the entoderm at its cephalic end. At the same time two parallel grooves form in the mesoderm on each side of the chordal plate (fig. 82, I), and become shut off from the archenteric cavity in such a way as to form two columns, which become constricted at intervals to give rise to the mesodermic somites (fig. 82, II). While these changes are in progress the entoderm extends

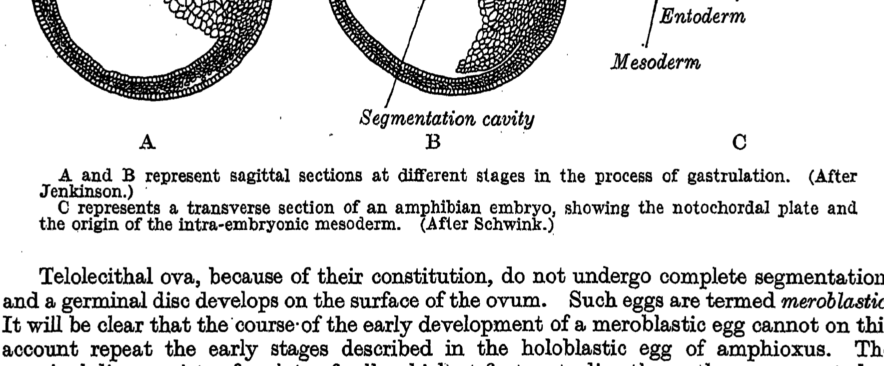
dorsally on each side and forms a new roof for the archenteron, from which the chordal plate and the mesoderm have now been excluded. The mesoderm extends ventrally between the ectoderm and the entoderm, and its contained clefts constitute the cœlom (fig. 82, III).

It has been seen that the fertilised ovum of amphioxus undergoes complete segmentation, and such eggs are termed *holoblastic*. This condition is by no means general and is dependent on the quantity of deutoplasm in the ovum. The egg of amphioxus contains a relatively small amount of deutoplasm, and is termed *microlecithal*, but the eggs of fishes, reptiles, and birds contain a much larger quantity, being termed *lecithal* or *telolecithal*.

FIG. 83.—Early development of the fertilised egg of an amphibian.



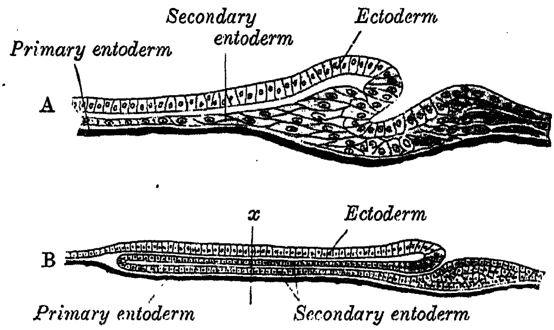
A and B represent sagittal sections at different stages in the process of gastrulation. (After Jenkinson.)

C represents a transverse section of an amphibian embryo, showing the notochordal plate and the origin of the intra-embryonic mesoderm. (After Schwink.)

Telolecithal ova, because of their constitution, do not undergo complete segmentation, and a germinal disc develops on the surface of the ovum. Such eggs are termed *meroblastic*. It will be clear that the course of the early development of a meroblastic egg cannot on this account repeat the early stages described in the holoblastic egg of amphioxus. The germinal disc consists of a plate of cells which at first rests directly on the unsegmented or incompletely segmented yolk. Soon a segmentation cavity appears which separates the smaller embryonic cells from the larger cells of the yolk mass on which it rests (fig. 83).

While this is occurring in the amphian egg a curved groove appears at the caudal margin of the disc, and its raised lip constitutes a region of intensely active growth. The groove deepens and the cells which form its roof constitute the entoderm. The formation of this groove and the active growth of entoderm from its margin constitutes a modified process of gastrulation and the raised lip constitutes the dorsal lip of what is actually a blastopore. It is, however, impossible for the large and incompletely divided cells of the yolk mass to be invaginated, and to compensate for this the ectodermal cells of the germinal disc grow over the surface of the yolk until they completely envelop it. This extension of the ectoderm over the yolk corresponds partly to the process of gastrulation and partly to the closing in

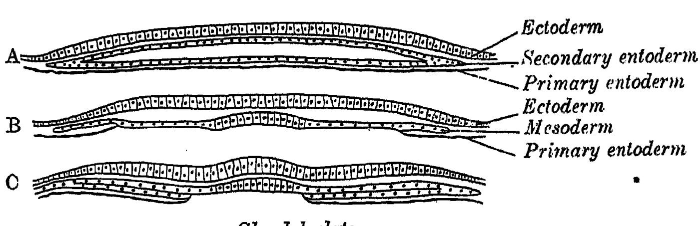
FIG. 84.—Sagittal sections through a reptilian egg (after Will).



A shows the formation of a depression at the caudal end of the embryonic disc.
B shows the invagination of the secondary entoderm.

of the blastopore, which is left as a small opening at the caudal end of the embryo, and is subsequently closed. The forward growth of the entoderm outlines the digestive cavity and its roof is formed by a ' chordal plate ' which subsequently becomes constricted off and forms the notochord. Before this occurs, however, this plate, while still a constituent part of the enteric roof, gives off from each side a mass of cells which grow ventrally in the interval between the ectoderm and the entoderm. They form the intra-embryonic mesoderm and split into two layers to enclose a cœlomic cavity. As the blastopore narrows a ring of mesoderm is found surrounding it, and the headward portion of this ring is continuous with the caudal end of the mesoderm of the chordal plate and may be regarded as being derived from it. The closure of the blastopore converts this ring into a solid mass, which adopts a median position and a linear outline. Its cells are indistinguishable from

FIG. 85.—Diagrammatic transverse sections of a reptilian embryo, showing the notochordal plate and the formation of the intra-embryonic mesoderm.



A represents a transverse section made at *X* in fig. 84, B. The tubular invagination of the secondary entoderm is seen between the ectoderm and the primary entoderm.
In *B* the adjoining portions of the primary and secondary entoderm have broken down, and the notochordal plate is seen in the roof of the primitive gut.
In *C* the primary entoderm is closing in on the notochordal plate and the intra-embryonic mesoderm is extending laterally on each side.

the covering ectoderm and the underlying entoderm, and they constitute the *primitive streak.*

Further modifications are found in the early development of the reptilian egg. As the ectoderm of the germinal disc grows over the surface of the yolk, a pit-like depression appears at the caudal end of the disc. This depression, however, does not behave in the same manner as in the amphibian egg, for the cells in its raised border differentiate into a superficial layer, the ectoderm, and an underlying mass of scattered cells, the deepest layer of which differentiates to form the primary entoderm of the roof of the digestive cavity. In the floor of the depression, which constitutes the primitive streak, it is not possible to dis-

tinguish the individual layers from one another. At the next stage the depression deepens and a groove extends headwards over the embryonic area between the ectoderm and the primary entoderm. This invagination forms a relatively wide, flattened tube, lined by *secondary entoderm*, which corresponds to the chordal plate and the mesoderm in amphioxus. The primary entoderm in the roof of the digestive cavity and the floor of this secondary invagination break down so that the roof of the gut comes to be formed by the secondary entoderm in the roof of the invagination (fig. 85). The cells in the median plane of this new roof can now be identified as a 'chordal plate,' and the primary entoderm grows medially again towards this area. As it does so the lateral part of the secondary entoderm becomes shut out from the gut and lies as a solid plate between the primary entoderm and the ectoderm. It is now recognisable as a part of the intra-embryonic mesoderm and is continuous caudally with the cells of the primitive streak. Subsequently it loses its connexion with the chordal plate, which becomes excalated from the gut as the notochord.

If the earlier stages of the development of the human ovum be re-examined in the light of this summary it will be found that they recapitulate these changes, although the process has been so abbreviated as to obscure the resemblance. The whole of the holoblastic egg of amphioxus gives rise to the embryo. The human egg is also holoblastic, but the fact that only a small proportion of the cells to which it gives origin actually contribute to the formation of the embryo indicates that its holoblastic character is secondary and that it has evolved from an ancestral meroblastic stock. It is therefore necessary to compare it with the reptilian egg in the first place. The primitive node, which is a centre of intensely active growth in the embryos of birds and mammals, is pierced by the neurenteric canal. The node itself corresponds to the dorsal lip of the reptilian blastopore and the neurenteric canal to the blastopore itself. The notochord arises from the chordal plate, which forms the median part of the roof of the digestive cavity in amphioxus and in amphibians. In reptilia, however, it is derived from the secondary entoderm which arises as an outgrowth from the primitive streak, and secondarily becomes incorporated in the roof of the digestive cavity. Its origin in man is very similar to its origin in reptilia, although it arises as a solid rod, which later becomes canaliculised and associated with the roof of the gut, being temporarily included in it. The origin of the intra-embryonic mesoderm is closely allied to the origin of the notochord. In amphioxus it is involved in the process of gastrulation and lies in the dorsilateral wall of the archenteron in continuity with the chordal plate on the one hand and with the entoderm on the other (fig. 82, I); in amphibia it is an outgrowth from the sides of the chordal plate (gastral mesoderm), but at its caudal end it emerges into the primitive streak (prostomial mesoderm), a structure which can only occur in meroblastic ova. In reptilia the double origin of the mesoderm is again found, and in man the secondary (intra-embryonic) mesoderm, although mainly derived from the primitive streak, receives a contribution from the prochordal plate (p. 60)

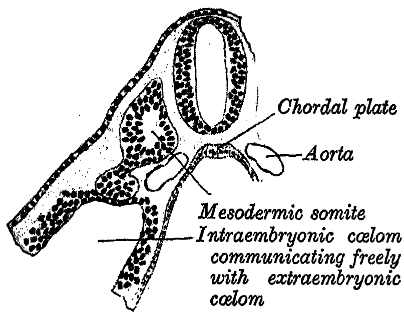
THE SEGMENTATION OF THE MESODERM AND THE FORMATION OF THE INTRA-EMBRYONIC CŒLOM

In the embryos of all vertebrate animals the intra-embryonic mesoderm becomes incompletely subdivided by a longitudinal groove into a *paraxial portion* and a *lateral plate*, on each side of the median plane. The mesoderm in the floor of the groove which connects these two portions is termed the *intermediate cell mass*, or *nephrogenic cord* (fig. 80). Soon after the appearance of this longitudinal groove the paraxial mesoderm becomes subdivided into a series of cubical blocks by a series of transverse grooves. This process is termed the *segmentation of the mesoderm*, and the blocks of paraxial mesoderm so formed are known as *mesodermic somites*, *primitive segments* or *metameres*. Commencing at the end of the third or the beginning of the fourth week in the region of the hind-brain the process extends in a caudal direction, additional somites being laid down as the embryo grows in length, until some thirty-five or more pairs are present (fig. 133). In the human embryo it is only the paraxial mesoderm which is actually segmented, but in view of the obviously segmental arrangement of the nerves of the spinal cord and their distribution, it is reasonable to suppose that the segmentation of the other structures is only obscured. The whole process may be regarded as evidence that the invertebrate ancestor of all vertebrate animals showed clear signs of its segmental origin.

Each mesodermic somite at first contains a central cavity termed the *myocoel*, which is soon filled by a core of spindle-shaped or fusiform cells. The cells occupying the dorsilateral portion of the somite constitute the *myotome*, and

they are destined to give rise to a *muscle plate*, from which all the striated musculature of the segment is derived (p. 102). The cells occupying the ventrimedial portion of the somite are more loosely arranged and fusiform in shape. They constitute the *sclerotome* and give rise to the *scleratogenous tissue* from which the axial skeleton is ultimately derived (p. 83).

Fig. 86.—Cross-section through the body of a human embryo at the end of the fourth week, to show the arrangement of the mesoderm. Diagrammatic.



While the segmentation of the mesoderm is proceeding, a number of clefts appear in the lateral plate on each side. These clefts soon run into one another, and they extend headwards into the pericardial area (p. 59), where a cavity has already been formed. In this way the lateral plate becomes divided into a *somatic* and a *splanchnic layer* (fig. 80). The somatic layer, with its covering of ectoderm, constitutes the *somatopleure*, and the splanchnic layer, with the underlying entoderm, constitutes the *splanchnopleure*. The cavity which they include is termed the *intra-embryonic cœlom*, and from it the pericardial, pleural and peritoneal cavities are subsequently developed. Around the periphery of the embryonic area the somatopleure and the splanchnopleure are continuous, at first, both with each

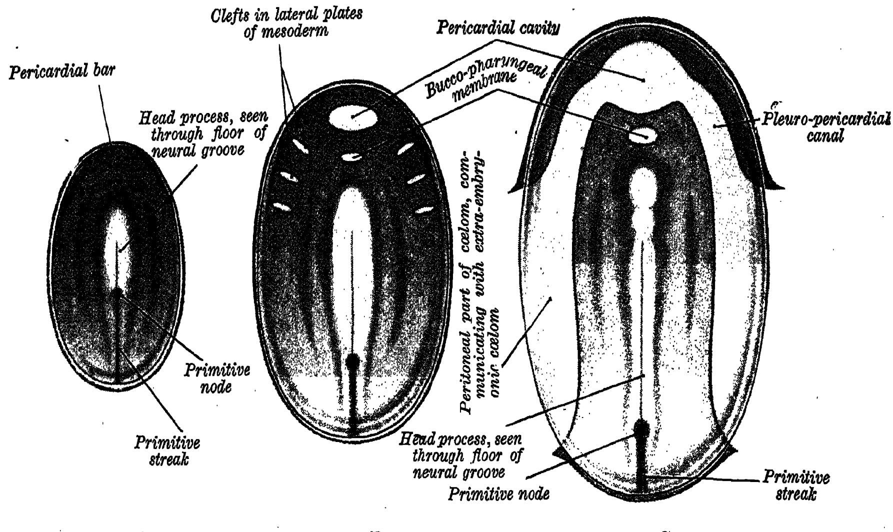
other and with the primary mesenchyme (fig. 80). Soon, however, the cleft extends beyond the embryonic area, the continuity between the somatopleure and the splanchnopleure is broken, and the intra-embryonic cœlom is thrown into free communication with the extra-embryonic cœlom. This process does not affect the pericardial area or the regions immediately adjoining it on either side; the latter constitute the pleuropericardial canals (fig. 88, C).

FIG. 88.—Diagram illustrating the formation of the cœlom.

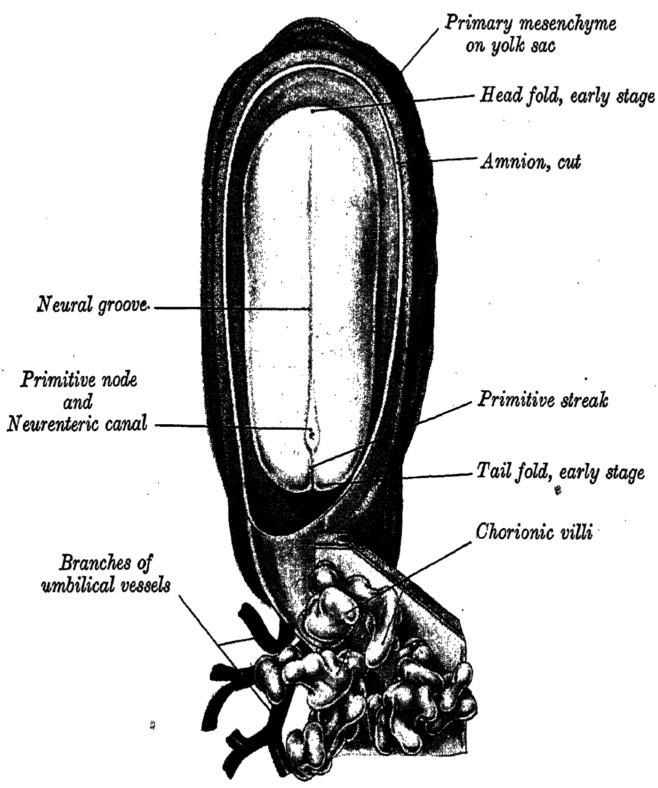


In A the secondary mesoderm (shown in blue) extends over the embryonic area and becomes continuous with the primary mesenchyme around the periphery. The median area, shown in yellow, represents the floor of the neural groove and is devoid of secondary mesoderm.

In B the pericardial cavity has appeared at the head end of the embryonic area and a series of clefts is present in the lateral plate on each side.

In C the clefts have extended and run into one another and into the pericardial cavity. In the caudal part of the area the clefts have broken through into the extra-embryonic cœlom.

FIG. 89.—Dorsal view of a human embryo, 1·3 mm. long. (From a model by Eternod.)



THE FORMATION OF THE EMBRYO

The formation of the head and tail folds.—Hitherto we have been dealing with a disc-like embryonic area, but at the end of the third week of its development the embryo begins to assume its definitive shape. The immediate cause of this alteration is the difference in the rate at which adjoining areas are growing. The rate of growth in the periphery of the embryonic area fails to keep pace with the rate of growth in the embryonic area, and, as the embryo is increasing more rapidly in its long axis, its cephalic and caudal extremities tend to bulge forwards and tailwards and so project beyond the limits of the area (figs. 93, A, and 95). In this way a *head-fold* is developed at the cephalic extremity and a *tail-fold* at the caudal extremity of the embryonic area. At the same time right and left *lateral folds* develop, and the extension of these four folds gradually constricts off the embryo from the yolk sac and gives it its characteristic shape.

Fig. 90.—A diagram showing one of the earliest observed stages of the human ovum.

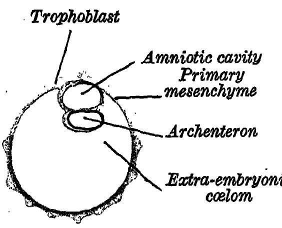


Fig. 91.—A diagram illustrating the early formation of the allanto-enteric diverticulum and the definition of the connecting stalk.

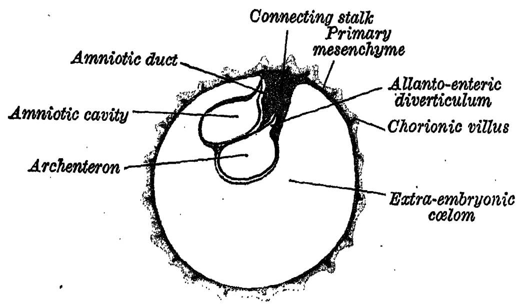

Fig. 92.—A diagram showing a later stage of the development of the human embryo. Observe that the heart occupies the most anterior part of the embryonic area and is separated from the prosencephalon by the buccopharyngeal membrane.

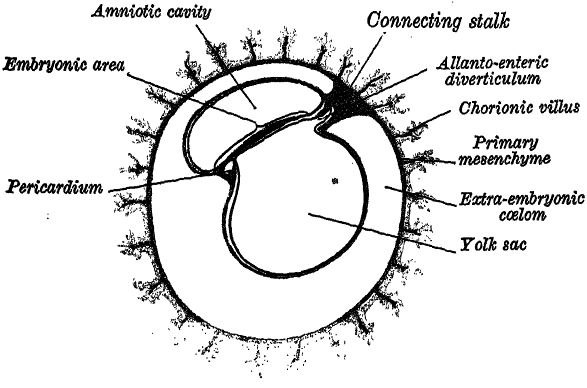

As a result of the formation of the head-fold, the prosencephalon, which was hitherto separated from the cephalic extremity of the embryonic area by the buccopharyngeal membrane and the pericardial area, comes to lie at the cephalic extremity of the embryo (figs. 93, A, 94). This alteration in position of

the fore-brain is accompanied by a corresponding alteration in the relative positions of the buccopharyngeal membrane and the pericardial area (figs. 172 and 174). The former now lies on the ventral surface and is situated at the bottom of a depression, which constitutes the primitive mouth or *stomodæum*. On its cephalic side the stomodæum is bounded by the projecting fore-brain and on its caudal side by the pericardial area. The latter has not only altered its

FIG. 93A.—A diagram showing the formation of the head- and tail-folds, the expansion of the amnion, and the delimitation of the umbilicus.

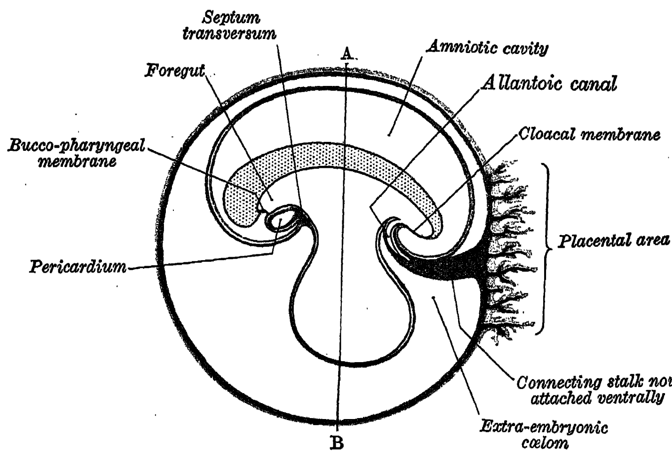

FIG. 93B.—A diagram showing a transverse section along the line AB in Fig. 93A. Observe that the intra-embryonic cœlom communicates freely with the extra-embryonic cœlom.

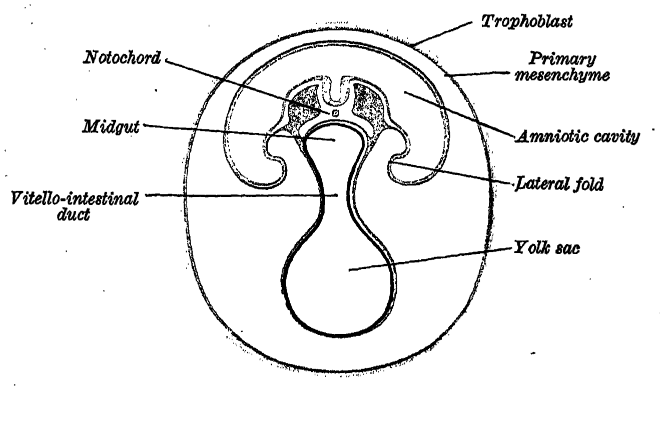


position relative to the cephalic extremity of the embryo but has also undergone a reversal of its surfaces, as will be pointed out later.

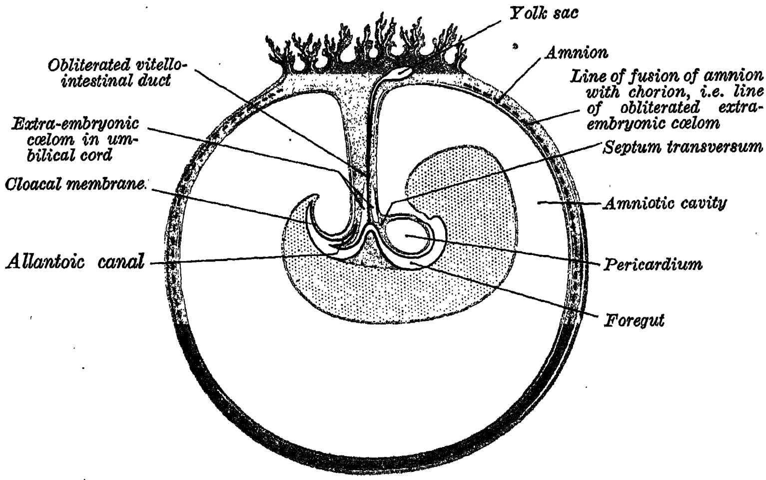
In addition to these alterations the head-fold results in the inclusion within it of a portion of the entodermal vesicle. This included portion is termed the *fore-gut* and it is placed between the buccopharyngeal membrane and the pericardium, on its ventral aspect, and the hind-brain, dorsally (fig. 94). It communicates at its caudal end with the midgut through an opening often termed the *anterior intestinal portal*.

The ventral bend of the head-fold produces a well-marked flexure in the brain at the site of the mesencephalon, termed the *cephalic flexure*.

Prior to the formation of the tail-fold the embryonic area is anchored to the trophoblast by a stalk of primary mesenchyme, covered on one aspect by

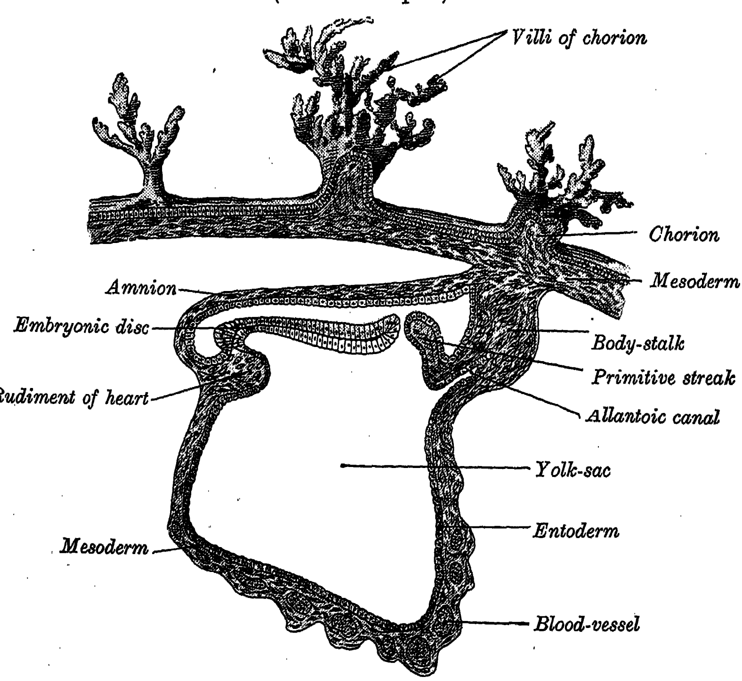
the epithelium of the amnion (fig. 92). This connexion, which is termed the *connecting stalk*, serves to conduct blood-vessels to the embryo from the chorion and vice-versa. The formation of the tail-fold carries the connecting stalk round

Fig. 94.—A diagram illustrating a later stage in the development of the umbilical cord.



on to the ventral aspect of the embryo, so that it now assumes the permanent position of the umbilical cord. It will be remembered that the stalk was connected to the embryo at the caudal end of the primitive streak, and, in

Fig. 95.—A sagittal section through the embryo which is represented in fig. 89. (After Graf Spee.)



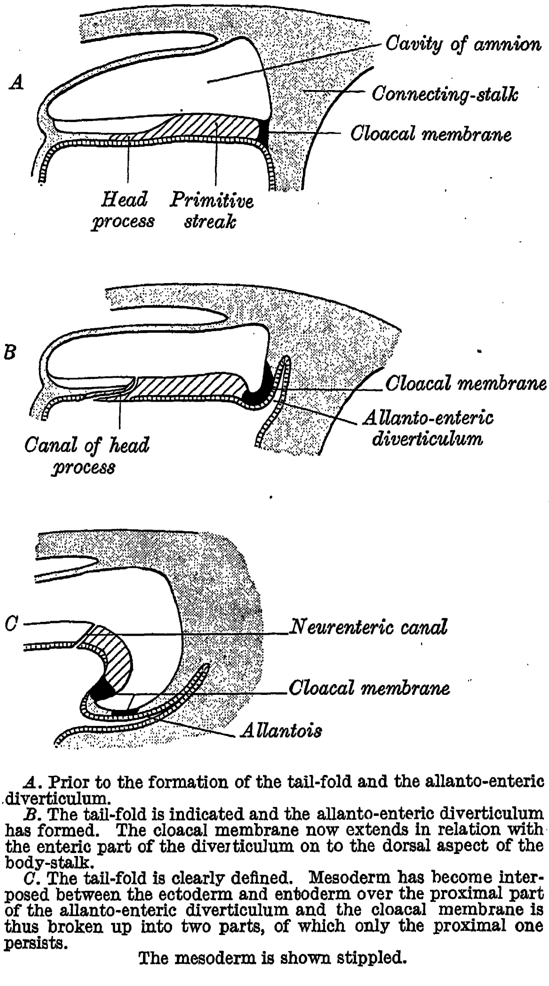
consequence of the formation of the tail-fold, the primitive streak like the connecting stalk extends round on to the ventral aspect of the embryo, traversing the region which will become the perineum.

Just as a portion of the entodermal vesicle is included within the head-fold

to form the fore-gut, so a corresponding portion is included within the tail-fold to form the *hind-gut.* But the similarity between these two included portions goes further. A portion of the entoderm in the floor or ventral wall of the fore-gut comes into direct contact with the ectoderm over an area which is termed the buccopharyngeal membrane. This membrane soon disappears and the communication of the gut with the exterior through the mouth is thus established. In the region of the hind-gut a similar relationship exists. Even before the tail-fold is defined, the ectoderm and entoderm come into contact with each other over a limited area at the caudal end of the embryonic area, forming the *cloacal membrane* (fig. 96, *A*). As will be described later, this membrane subsequently breaks down in two places to form the urogenital and anal orifices, which therefore lie in the line of the primitive streak.

Prior to the formation of the tail-fold a diverticulum arises from the dorsi-caudal portion of the archenteron and grows into the mesenchyme of the connecting stalk (fig. 91). This outgrowth constitutes the *allanto-enteric diverticulum* (fig. 96, *B*). As the tail-fold becomes defined the proximal part of the diverticulum becomes incorporated in the hind-gut, and its distal portion persists as the allantoic canal or *allantois* (p. 73), which then communicates directly with the ventral surface of the hind-gut. The portion of the hind-gut which lies caudal to this communication forms the *entodermal cloaca* (p. 171). As the tail-fold is formed, the cloacal membrane comes to lie in the ventral wall of the hind-gut but it extends also on to the adjoining dorsal aspect of the connecting stalk, where it is associated with the enteric portion of the allanto-enteric diverticulum (fig. 96, *B*). Even before the latter is incorporated in the hind-gut, the cloacal membrane becomes interrupted and shortened by the interposition of mesenchyme between the entoderm of the diverticulum and the ectoderm of the body-stalk * (fig. 96, *C*).

Fig. 96.—Three stages in the development of the cloacal membrane. (J. Florian.)



A. Prior to the formation of the tail-fold and the allanto-enteric diverticulum.
B. The tail-fold is indicated and the allanto-enteric diverticulum has formed. The cloacal membrane now extends in relation with the enteric part of the diverticulum on to the dorsal aspect of the body-stalk.
C. The tail-fold is clearly defined. Mesoderm has become interposed between the ectoderm and entoderm over the proximal part of the allanto-enteric diverticulum and the cloacal membrane is thus broken up into two parts, of which only the proximal one persists.

The mesoderm is shown stippled.

Between the head- and the tail-folds the embryo becomes constricted off by right and left lateral folds. The intervening dorsal portion of the entodermal vesicle, which these folds threaten to cut off, and later succeed in separating from the remainder of the vesicle, constitutes the *mid-gut.* At first the mid-gut communicates freely on its ventral surface with the rest of the entodermal vesicle, but the continued growth of the folds results in a narrowing of the connexion, which becomes drawn out as the *vitello-intestinal duct* (figs. 93,

* J. Florian, *Journal of Anatomy,* vol. lxiv. July, 1930.

94). The remainder of the vesicle remains extra-embryonic and constitutes the *yolk-sac* or *umbilical vesicle*. The subsequent history of the duct and the vesicle will be dealt with later (pp. 168, 173).

The nutrition of the embryo.—In the early stages of development the cells of the ovum derive their nourishment from the store laid up within the cell body of the primary oöcyte. It is probable that this nourishment is at first maintained in a highly concentrated form and is subsequently liberated in a more dilute form, readily available for absorption, in the magma cavity of the blastocyst, and also, possibly, in the entodermal vesicle. In addition, it has been suggested that the blastocyst derives nourishment from the uterine glands and, during the process of imbedding, from the portion of the uterine wall which has been destroyed. Owing, however, to the relatively small amount of yolk contained in the human ovum, it is essential that some other source of food-supply should be rendered available at an early stage. The maternal circulation is selected, but it can only function as a source of supply when it is brought into close, though indirect, contact with the embryonic circulation. On this account, the formation of angioblastic tissue is very precocious in the human embryo.

The work of van der Stricht, Sabin and others makes it highly probable that the earliest angioblastic tissue is formed in the deepest part of the mesenchyme covering the entodermal vesicle or yolk-sac. About the same time, or slightly later, angioblastic tissue can be recognised in the connecting stalk and in the primary mesenchyme of the chorion, and a little later it appears also in the embryonic area. Tissue spaces form in the angioblast and the cells which line these spaces take on the characters of typical, flattened endothelial cells, and adjoining spaces run into one another and form a capillary plexus. While the spaces are in process of formation small, localised groups of mesodermal cells project into their interior and become cut off to form blood islets. The constituent cells of these islets become modified to form the blood corpuscles (p. 133).

The vessels formed in the chorion soon establish an intimate relationship with the maternal circulation (p. 77). The vessels which develop in the embryonic area form two longitudinal channels, which, at their headward ends, project into the dorsal wall of the pericardium. They are the rudimentary right and left dorsal aortæ, and at their cephalic ends, after curving ventrally on the lateral wall of the pharynx to reach the cephalic end of the pericardium, they fuse to form a primitive tubular heart. At the caudal end of the embryo they traverse the connecting stalk as the rudimentary umbilical arteries and break up into capillaries in the chorion. The venules from the chorion converge on the stalk where they form the right and left umbilical veins, which run headwards in the somatopleure, close to the margin of the embryonic area, to reach the heart.

It will be remembered that the pericardial cavity never communicates directly with the extra-embryonic cœlom, and at its cephalic limit the somatopleure and splanchnopleure become continuous (fig. 172). With the formation of the head-fold the surfaces of the pericardium are reversed, and the original cephalic limit comes to lie in intimate relation with the wall of the fore-gut at the ventral border of the anterior intestinal portal (fig. 174). As the floor (caudal limit) of the pericardium deepens ventridorsally, the mesenchyme between it and the gut forms a sheet which is termed the *septum transversum*. This structure later plays an important part in the development of the diaphragm ; at this stage it is bounded on its headward surface by the pericardium and on its caudal surface by the fore-gut, and on its lateral surfaces it is limited by the pleuropericardial canals, which connect the pericardium with the peritoneal cavity. The umbilical and body-wall veins, which run in the somatopleure, and the vitelline veins, which run in the splanchnopleure, meet one another in the septum transversum and so gain the venous end of the heart.

In this way there is established the circulation, through the vessels and tissues of the embryo, of blood which has derived oxygen and nutriment from the maternal circulation.

THE FŒTAL MEMBRANES AND THE PLACENTA

The **allantois** (figs. 91, 96).—The allanto-enteric diverticulum arises early in the third week as a solid, entodermal outgrowth from the dorsi-caudal part of the entodermal vesicle and grows into the primary mesenchyme of the connecting stalk. It soon becomes canaliculised and when the hind-gut is developed, the proximal (enteric) part of the diverticulum is incorporated in its ventral wall and the distal (allantoic) portion is carried ventrally to open into the ventral aspect of the cloaca or terminal part of the hind-gut. The allantoic diverticulum is lined with entoderm and is surrounded by the mesenchyme of the connecting stalk, in which the umbilical vessels develop at a slightly later stage.*

The **amnion** is a membranous sac which surrounds and protects the embryo ; it is developed in reptiles, birds, and mammals, but not in amphibia or fishes.

In the human embryo the earliest stages of the formation of the amnion have not been observed ; in the youngest embryo which has been studied † the amnion was already present as a closed sac, and, as indicated on page 54, it appears as a cavity in the ectodermal part of the inner cell-mass. This cavity is roofed in by a stratum of flattened ectodermal cells termed the *amniotic ectoderm,* and its floor consists of the prismatic ectoderm of the embryonic disc —the continuity between the roof and floor being established at the margin of the embryonic disc. On the outside the amniotic ectoderm is covered with a thin layer of primary mesenchyme which is continuous, round the margins of the embryonic disc, both with the primary mesenchyme covering the entodermal vesicle and with the intra-embryonic mesoderm. Through the medium of the connecting stalk it is continuous also with the mesenchyme lining the chorion (fig. 92).

Fluid, termed *liquor amnii,* appears within the amniotic cavity and increases steadily in amount, so that the sac gradually expands and encroaches on the cavity of the extra-embryonic cœlom (fig. 94) ; this expansion continues until the extra-embryonic cœlom is obliterated entirely, except for a small portion which is included within the umbilical cord. The liquor amnii increases in quantity up to the sixth or seventh month of pregnancy, and then diminishes somewhat ; at the end of pregnancy it amounts to 1 litre. It allows of the free movements of the fœtus during the later stages of pregnancy, and also diminishes the risk to the fœtus of injury from without. It contains less than two per cent. of solids, consisting of urea and other extractives, inorganic salts, a small amount of protein, and frequently a trace of sugar.

The **connecting stalk** and the **umbilical cord.**—The connecting stalk (figs. 92, 93, 94) is a mass of primary mesenchyme which at first connects the tail-end of the embryonic area with the chorion. Its proximal part surrounds the allanto-enteric diverticulum and it is traversed by the umbilical vessels. Its dorsal surface is covered with the amnion and its ventral surface is bounded by the extra-embryonic cœlom. As a result of the folding of the embryo and the distension of the amnion the connecting stalk comes to lie on the ventral surface of the embryo,

* In reptiles, birds, and many mammals the allantoic diverticulum expands into a vesicle which projects into the extra-embryonic cœlom and forms a vascular organ to which the term *allantois* should be restricted. In the bird it projects to the right side of the embryo, and, gradually expanding, spreads over the dorsal surface of the embryo as a flattened sac between the amnion and the serosa, and ultimately surrounds the yolk. Its outer wall becomes applied to, and fuses with, the serosa which lies immediately inside the shell membrane. Blood is carried to the allantoic sac by the two allantoic or umbilical arteries, which are continuous with the primitive aortæ, and after circulating through the allantoic capillaries, is returned to the primitive heart by the two umbilical veins. In this way the allantoic circulation, which is of the utmost importance in connexion with the respiration and nutrition of the chick, is established. Oxygen is taken from, and carbonic acid is given up to the atmosphere through the egg-shell, and nutritive materials are at the same time absorbed by the blood from the yolk. With the formation of the amnion the embryo is, in most animals, separated entirely from the chorion, and is not united to the chorion again until the allantoic mesenchyme spreads over and becomes applied to its inner surface ; but the human embryo, as was pointed out by His, is never wholly separated from the chorion, its tail-end being from the first connected with the chorion by means of a thick band of mesenchyme, named the *connecting stalk.*

† H. Stieve, *loc. cit.*, p. 55.

and its mesenchyme approaches that of the yolk-sac and vitello-intestinal duct (fig. 93).

As a consequence of the continued expansion of the amnion the extra-embryonic cœlom is obliterated to a very large extent (fig. 94), and the only part of it which remains surrounds the elongated vitello-intestinal duct, and

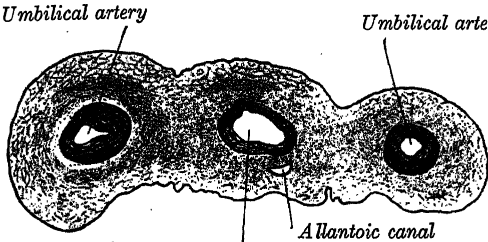
FIG. 97.—A fœtus of about eight weeks, enclosed in the amnion. Magnified a little over 2 diameters. Drawn from stereoscopic photographs lent by Prof. A. Thomson, Oxford.

still communicates freely with the intra-embryonic cœlom. The mesenchyme-covered surfaces of the head, tail and lateral folds of the amnion converge on the region of the connecting stalk and the vitello-intestinal duct, and the umbilical cord is formed as they meet one another (figs. 92, 94). The cord consists of an outer covering of amniotic ectoderm, containing in its interior the vitello-intestinal duct and the yolk-sac or umbilical vesicle, partially invested by the remains of the extra-embryonic cœlom and all imbedded in a mass of primary mesenchyme, contributed in part by the head and the lateral folds but, to a much greater extent, by the connecting stalk. The umbilical cord, therefore, incorporates within itself the connecting stalk and its contained umbilical vessels and the allantoic canal. The part of the extra-embryonic cœlom included in the umbilical cord acts as the sac for the normal umbilical hernia which characterises the embryo between the sixth and the tenth weeks (p. 168). After the disappearance of this hernia the remains of the extra-embryonic cœlom normally become obliterated.

The umbilical cord becomes spirally twisted, owing, it is believed, to the unequal growth of the two umbilical arteries; it also increases in length so that at the end of pregnancy it is about 50 cm. long.

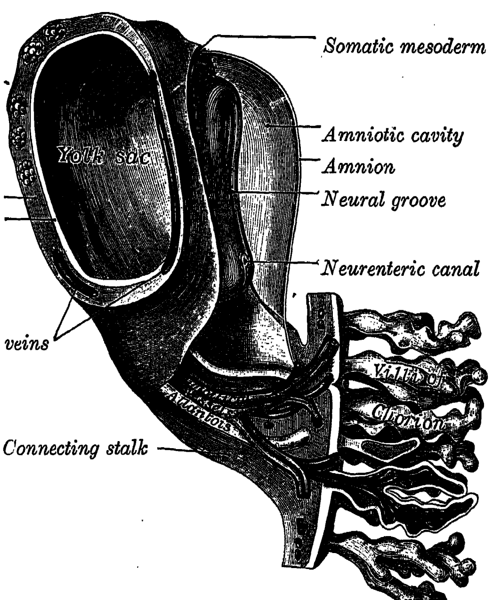
The implantation or imbedding of the fertilised ovum in the uterine wall.—As already stated (p. 51), fertilisation of the ovum is believed to occur in the lateral or ampullary end of the uterine tube, and is immediately followed by segmentation. The segmenting ovum is conveyed along the uterine tube to the cavity

FIG. 98.—A transverse section through the umbilical cord.



of the uterus by the action of the cilia of the epithelial lining of the tube, the journey occupying not less than three and not more than seven or eight days. By the time it reaches the uterus it possesses a well-developed trophoblast, which adheres like a parasite to the uterine mucous membrane, destroys the epithelium over the area of contact, and excavates for the ovum a cavity in the mucous membrane in which it becomes imbedded. In an ovum described

FIG. 99.—A human embryo, 1·3 mm. long. (From a model by Eternod.)



by Bryce and Teacher * the point of entrance of the ovum into the uterine mucous membrane was visible as a small gap closed by a mass of fibrin and leucocytes (fig. 74) ; in an ovum described by Peters † the opening was covered with a mushroom-shaped mass of fibrin and blood-clot, the narrow stalk of which plugged the aperture in the mucous membrane. It is believed that this operculum represents a portion of the plasmodial trophoblast of the ovum which is cut off by the decidua capsularis (*vide infra*).

* Contribution to the study of the early development and imbedding of the human ovum, 1908.

† *Die Einbettung des menschlichen Eies,* 1899.

The structure actively concerned in excavating the uterine mucous membrane is the plasmodial trophoblast. This increases rapidly in thickness, invades and digests the uterine tissues, and attacks the walls of the uterine (maternal)

Fig. 100.—Primary chorionic villi. Diagrammatic. (Modified from Bryce.)

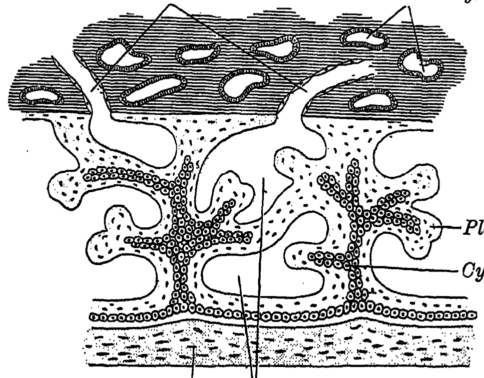


Fig. 101.—A secondary chorionic villus. Drawn from a microphotograph.

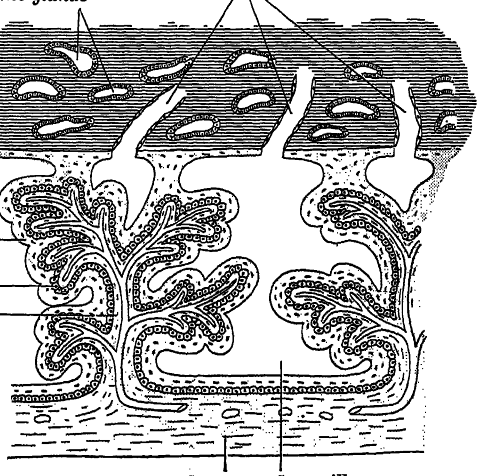
blood-vessels (fig. 74). This trophoblastic envelope soon becomes converted into a loose spongework, containing anastomosing spaces filled with maternal blood from the dilated uterine veins and capillaries, the walls of which have been partially destroyed. The strands of trophoblast which constitute the spongework are termed *primary villi.** The blood spaces expand to form what is ultimately known as the *intervillous space*. The inner wall of this space is formed by the chorion and its outer wall is formed by a shell of trophoblast (fig. 101). The primary villi become replaced by *secondary villi*, which contain

* The classification of the villi adopted here is that suggested by H. Stieve, *loc. cit.* p. 55.

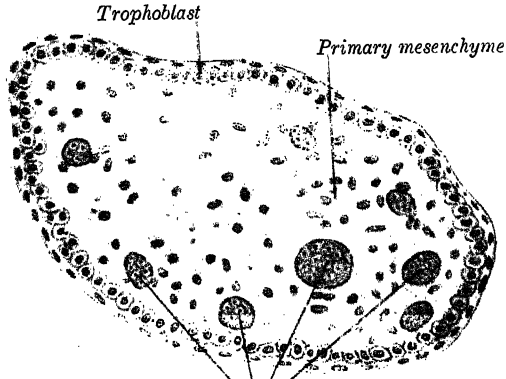
an inner core of primary mesenchyme derived from and continuous with the mesenchyme of the chorion. This core is covered by a single layer of cytotrophoblast, which in turn is covered by a layer of plasmodial trophoblast. The

FIG. 102.—Tertiary chorionic villi. Diagrammatic. (Modified from Bryce.)



secondary villi give off numerous branches and at their outer ends their cytotrophoblast becomes continuous with the cytotrophoblast of the trophoblastic shell. The shell consists for the most part of cytotrophoblast, but it is covered on its

FIG. 103.—A transverse section of a tertiary chorionic villus.



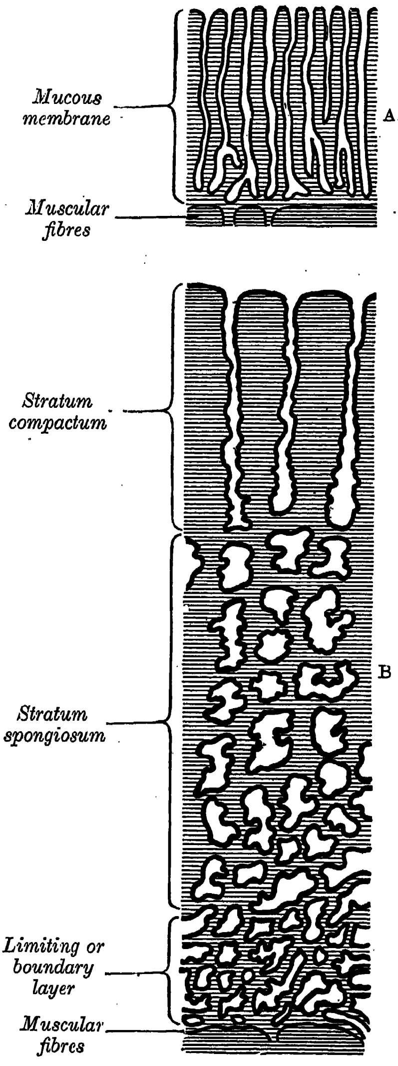
inner surface by plasmodium. As a result the blood-bathed walls of the intervillous space and of the villi are everywhere formed of plasmodial trophoblast. Finally, the secondary villi are converted into *tertiary villi* by the development within them of vascular spaces which soon become linked up with the radicles of the umbilical vessels. Through the walls of these villi and of their contained capillaries nutriment and oxygen pass to the fœtal circulation from the maternal blood in the intervillous space.

The plasmodial trophoblast which lines the intervillous space has been termed *resorptive trophoblast*,* as it is the medium by which nourishment is obtained for the ovum from the maternal circulation. Plasmodial trophoblast

* J. Florian, *Ergänzungsheft z. Anat. Anzeiger*, Bd. 66.

is found in other situations also, and especially around the periphery of the ovum where actively growing strands of plasmodium are responsible for the destruction of the uterine tissues. This variety is termed *proliferative trophoblast*, and its function is to enlarge the bed in which the ovum lies so as to provide for its increase in size. Wherever these strands of proliferative trophoblast break through the wall of a uterine blood-vessel and come into contact with the blood-stream, they tend to change their character and become transformed into the more passive resorptive variety.

FIG. 104.—Sections of the uterine mucous membrane; (A) of the non-pregnant uterus; (B) of the pregnant uterus. Diagrammatic. (Kundrat and Engelmann.)



The **decidua.** Before the fertilised ovum reaches the uterus, the mucous membrane of the body of the uterus undergoes important changes, and is then known as the *decidua*. The thickness and vascularity of the mucous membrane are greatly increased; its glands are elongated and their deeper portions are tortuous and dilated into irregular spaces. The interglandular tissue is increased in quantity; it contains a number of leucocytes, and is crowded with large round, oval, or polygonal cells, termed *decidual cells*. These changes are well advanced by the second month of pregnancy, when the mucous membrane consists of the following strata (fig. 104): (1) *stratum compactum*, next the free surface; in this the uterine glands are only slightly expanded, and are lined with columnar cells; (2) *stratum spongiosum*, where the uterine glands are greatly dilated and very tortuous, and are ultimately separated from one another by a small amount of interglandular tissue; for a time the cells lining the glands are cylindrical, but later they become flattened; (3) a thin *limiting or boundary layer*, next the uterine muscular fibres, containing the deepest parts of the uterine glands, which are not dilated, and are lined with cubical epithelium; it is from this epithelium that the epithelial lining of the uterus is regenerated after parturition.

After the ovum is imbedded distinctive names are applied to different portions of the decidua. The part which covers the ovum is named the *decidua capsularis*; the portion between the ovum and the uterine muscular wall is named the *decidua basalis*, and it is here that the placenta is subsequently developed; the part which lines the remainder of the body of the uterus is known as the *decidua parietalis* (fig. 106.).

Coincidently with the growth of the embryo, the decidua capsularis is thinned and distended (figs. 105, 106) and the space between it and the decidua parietalis is gradually obliterated. By the beginning of the third month of pregnancy the decidua capsularis and decidua parietalis are in contact; by the fifth month the decidua capsularis has practically disappeared, while during the succeeding months the decidua parietalis also atrophies, owing to the increased pressure. The glands of the stratum compactum are obliterated, and their epithelium is lost; in the stratum spongiosum the glands are compressed

and appear as slit-like fissures, and their epithelium undergoes degeneration ; in the limiting or boundary layer, however, the glandular epithelium retains a cubical form.

The **chorion** (figs. 89 to 94 and 100 to 102) consists of two layers : an outer of trophoblast, and an inner of primary mesenchyme. The trophoblast consists of an internal layer, termed the *cytotrophoblast*, and an external layer, termed the *plasmodial trophoblast*. As stated (p. 53), the trophoblast undergoes rapid proliferation and forms, on the surface of the chorion, a succession of processes which are known as the *primary*, *secondary* and *tertiary chorionic villi* (fig. 101). Blood is carried from the embryo to the chorion by the umbilical arteries, and after circulating through the capillaries of the chorionic villi, is returned to the embryo by the umbilical veins. Until about the end of the second month of pregnancy the entire chorion is covered with villi, which are almost uniform in size, and project into the decidua basalis and decidua capsularis (fig. 106). With the growth of the embryo and the expansion of the amniotic cavity the decidua capsularis is thinned and compressed, the circulation through it is gradually cut off, and the villi of the corresponding part of the chorion atrophy and disappear. This portion of the chorion becomes smooth (*chorion læve*) ; and, as it takes no share in the formation of the placenta, is sometimes named the non-

FIG. 105.—Diagram showing a young ovum imbedded in the uterine decidua near the fundus.

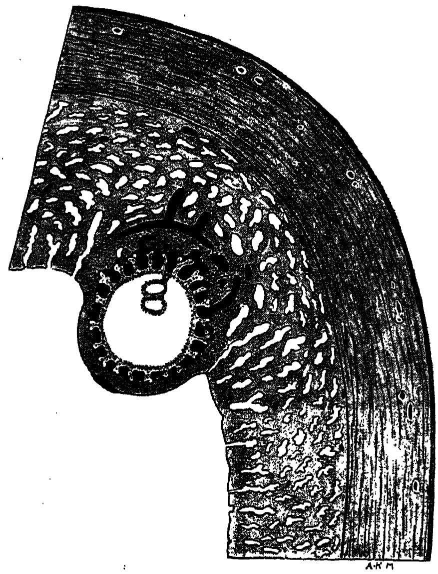


FIG. 106.—A sectional plan of the gravid uterus in the second month.

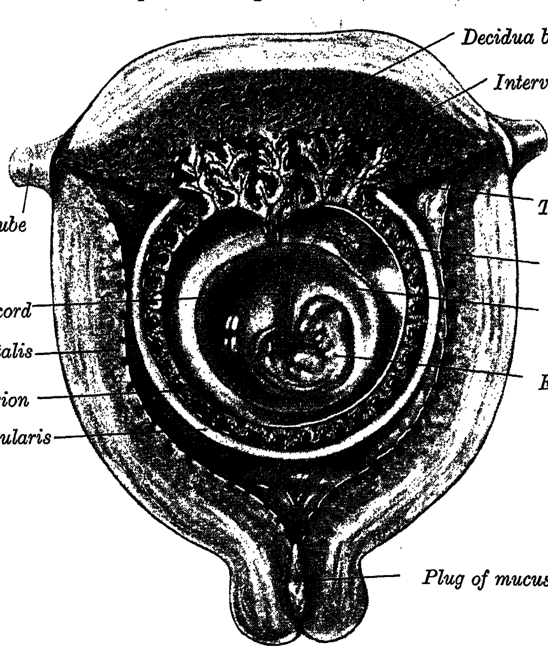
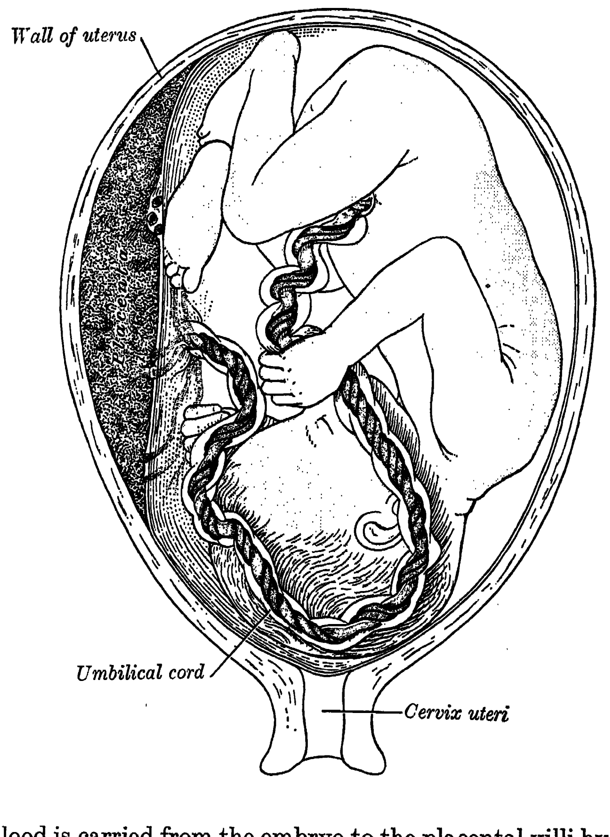


placental part of the chorion. On the other hand, the villi on that part of the chorion which is in contact with the decidua basalis increase greatly in size and complexity, and hence this part is named the *chorion frondosum* (figs. 93A, 94).

The **placenta** (figs. 106 to 108) connects the fœtus to the uterine wall, and is the organ by means of which the nutritive, respiratory, and excretory functions of the fœtus are carried on. It is composed of fœtal and maternal parts.

The *fœtal portion of the placenta* consists of the villi of the chorion frondosum, which branch repeatedly and increase enormously in size. The ends of some of the villi are anchored by columns of trophoblast to the walls of the intervillous space, but the majority hang free in the space. All are bathed in maternal blood, which is conveyed to and from the intervillous space by the uterine

Fig. 107.—A fœtus in utero, between the fifth and sixth months.

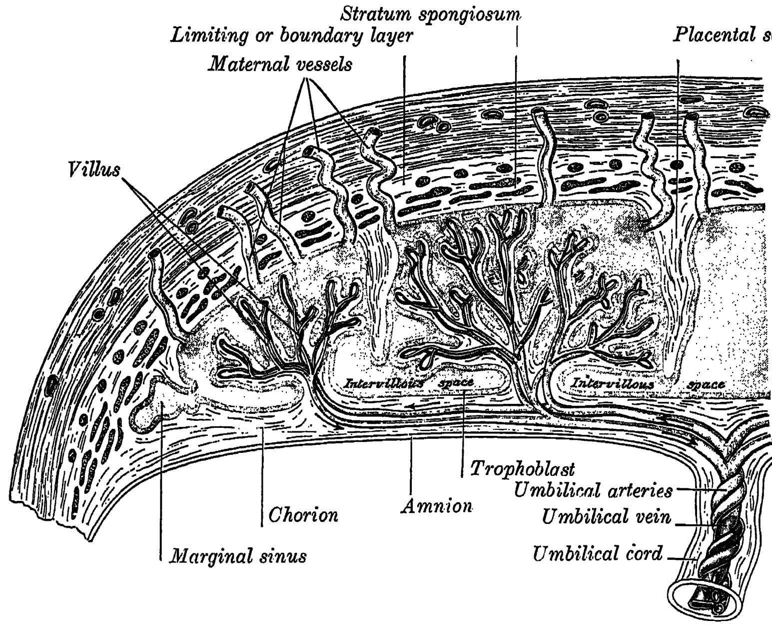


vessels. Blood is carried from the embryo to the placental villi by the umbilical arteries, and returned to the embryo by the umbilical veins. One or two branches of an artery enter each villus and there end in a capillary plexus, which is drained by one or two tributaries of the veins. The vessels of the villi are surrounded by a thin layer of mesenchyme, which is covered with the two strata of the trophoblast, the cytotrophoblast being in contact with the mesenchyme, and the plasmodial trophoblast in contact with the maternal blood (fig. 102); after the fifth month the two strata are replaced by a single layer of somewhat flattened cells.

The *maternal portion of the placenta* is formed by the decidua placentalis containing the intervillous space. As already explained (p. 76), this space is produced by the enlargement and intercommunication of the spaces in the trophoblast; it is therefore lined throughout with plasmodial trophoblast. The formation of the intervillous space involves the disappearance of the greater portion of the stratum compactum, but the deeper part of this layer persists and is condensed to form what is known as the *basal plate*; this constitutes the outer wall of the intervillous space, and consists of a stroma containing decidual

cells, portions of trophoblast and *fibrinoid substance*; the last appears to be derived in part from the trophoblast and in part from the maternal blood. The interval between the basal plate and the uterine muscular fibres is occupied by the stratum spongiosum and the limiting layer; through these and the basal plate the uterine arteries and veins pass to and from the intervillous space. Portions of the stratum compactum persist as pillars which project into the intervillous space, but these pillars do not extend as far as the chorion, except in the marginal part of the placenta; later they form the *placental septa* which incompletely divide the placenta into lobes or *cotyledons*.

Fig. 108.—A scheme of the placental circulation.



Maternal blood is conveyed to the intervillous space by branches of the uterine arteries and carried away by tributaries of the uterine veins (figs. 107, 108). These vessels lose their muscular coats as they enter the basal plate, and in this plate consist of sinuous channels lined only with endothelium; these channels open into the intervillous space, the arteries ending near the placental septa and the veins beginning near the centres of the cotyledons. The endothelial lining of the uterine vessels ends where the vessels open into the intervillous space, the latter being lined throughout with plasmodial trophoblast. The circumferential part of the intervillous space consists of an irregular channel named the *marginal sinus* (fig. 108); this sinus partly encircles the placenta and communicates peripherally with the uterine veins, and centrally with the intervillous space; clusters of placental villi project into it.

The fœtal and maternal blood-currents do not intermingle, being separated from each other by the delicate walls of the villi. Nevertheless, the fœtal blood is able to absorb, through the walls of the villi, oxygen and nutritive materials from the maternal blood, and to give up to the latter its waste products. The blood, so purified, is carried back to the fœtus by the umbilical veins. It will thus be seen that the placenta not only establishes a mechanical connexion between the mother and the fœtus, but subserves for the latter the purposes of nutrition, respiration, and excretion. That the placenta possesses certain selective powers is evidenced by the fact that glucose is more plentiful in the maternal than in the fœtal blood; it is interesting to note also that the proportion of iron, lime and potash in the fœtus is increased during the last months of pregnancy. Further, there is evidence that the maternal leucocytes may

migrate into the fœtal blood, since leucocytes are much more numerous in the blood of the umbilical vein than in that of the umbilical arteries.

Applied Anatomy.—The placenta is usually attached near the fundus uteri, and its site corresponds with that at which the ovum is imbedded. It may, however, occupy a lower level, and in very rare cases occludes the internal orifice of the uterus, thus giving rise to the condition known as *placenta prævia.*

The *separation of the placenta.*—After the child is born, the placenta and membranes (the latter consisting of the amnion, the chorion læve and the superficial part of the decidua parietalis) are separated from the uterine wall and expelled as the *after-birth.* The separation takes place along the plane of the stratum spongiosum (fig. 108), and necessarily causes rupture of the uterine vessels. The orifices of the torn vessels are, however, closed by the firm contraction of the uterine muscular fibres, and thus *post-partum hæmorrhage* is prevented. After the separation of the placenta and membranes a thin layer of the stratum spongiosum is left as a lining to the uterus, but this layer subsequently undergoes degeneration, and is cast off. The mucous membrane, the glands and the epithelial lining of the uterus are regenerated from the limiting or boundary layer of the decidua (p. 78).

The expelled placenta is a discoid mass which has a weight of about 500 gm., a diameter of from 15 cm. to 20 cm., and an average thickness of about 3 cm., but the thickness rapidly diminishes near the circumference of the placenta, which is continuous with the membranes. Its uterine or outer surface is divided by a series of fissures into lobules or *cotyledons* which are imperfectly separated from one another by the placental septa. Its fœtal or inner surface is smooth, and is closely invested by the amnion. When looked at through the amnion, the chorion presents a mottled appearance, consisting of grey, purple, or yellowish areas. The umbilical cord is usually attached near the centre of the fœtal surface of the placenta, but may be inserted at any point between the centre and the margin; in some cases it is inserted into the membranes, i.e. the *velamentous* insertion. From the site of the attachment of the cord the larger branches of the umbilical vessels radiate under the amnion, the veins being deeper and larger than the arteries. Beneath the amnion, close to the cord, the remains of the vitello-intestinal duct and yolk-sac are sometimes seen, the former as an attenuated thread, the latter as a minute sac.

On section, the placenta presents a soft, spongy appearance, caused by the greatly branched villi; these are surrounded by a varying amount of maternal blood, which gives the structure its characteristic dark red colour.

THE DEVELOPMENT OF THE INDIVIDUAL SYSTEMS

The development of the embryo has already been traced to a stage at which the process of differentiation becomes so complicated that it is no longer possible to deal with the embryo as a whole. At this stage the embryo is only partly constricted off from the entodermal vesicle. The head- and tail-folds have formed, with the resultant enclosure of the fore-gut and the hind-gut. The projection caused by the fore-brain is now the cephalic end of the embryo, and the buccopharyngeal membrane and the pericardium lie caudal to it on the ventral aspect. The secondary mesoderm has differentiated to a certain extent, and its paraxial portion is undergoing segmentation with the resultant formation of mesodermic somites. The neural groove is in process of closure to form the neural tube and it is separated from the dorsal wall of the gut by the notochord. The earliest blood-vessels have been laid down and a primitive tubular heart is present in the pericardium. The chorionic circulation has been established and the embryo derives the nourishment which it requires from the maternal blood. The intra-embryonic cœlom consists of the pericardial cavity, from the dorsal aspect of which right and left pleuro-pericardial canals lead tailwards and, caudal to the septum transversum, communicate freely with the peritoneal cavity and with the extra-embryonic cœlom (fig. 88).

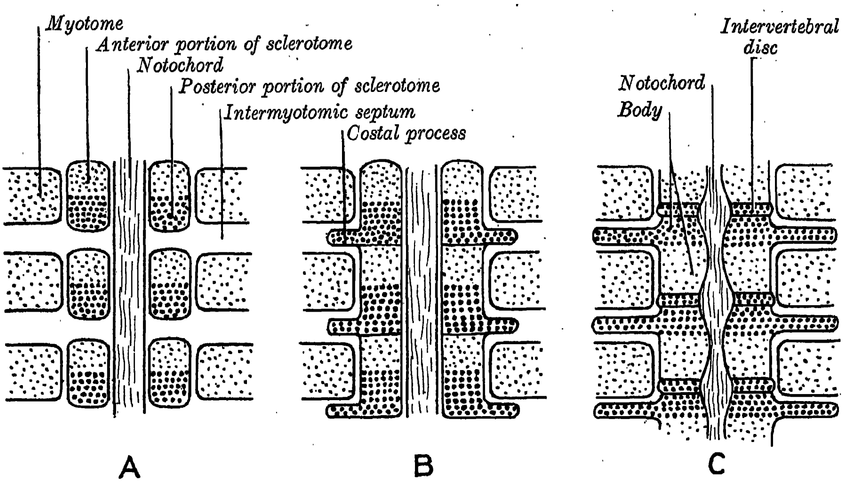
It is now necessary to deal with the development of the various systems and organs independently of one another, but, in the pages that follow, it will frequently be necessary to refer back to the stage which has just been summarised.

THE DEVELOPMENT OF THE SKELETAL SYSTEM

The skeleton is of mesodermal origin, and most of its parts pass through, first, a membranous or mesenchymal stage, and then a cartilaginous stage before they become ossified. In many instances the process of ossification follows immediately on the membranous stage, and the stage of chondrification is omitted.

The **vertebral column.**—Before it reaches its final condition the central axis of the body passes through no fewer than three preliminary stages. In the first place it is formed by the non-segmented notochord (p. 59), a flexible rod of cells enclosed within a stout membranous sheath. This structure, however, is not limited to the region in which the vertebral column is laid down, but extends into the region of the head as far as the caudal aspect of the hypophysis cerebri, and is subsequently incorporated in the basilar portion of the occipital bone and the posterior part of the body of the sphenoid.

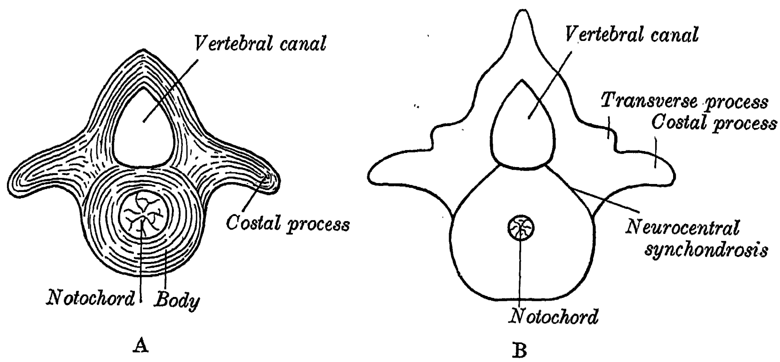
FIG. 109.—A scheme showing the manner in which each vertebral body is developed from portions of two adjacent segments.



The notochord acts as a framework around which the scleratogenous tissue derived from the sclerotomes (p. 66) builds up a *blastemal* or *mesenchymal vertebral column*, consisting of thirty-five or more segmental units, which are termed *protovertebræ*. Fusiform cells from the sclerotomes migrate ventrally and medially on each side and enclose the notochord in a mass of mesenchyme, which outlines the vertebral centrum (fig. 87). Coronal or sagittal sections passing through the blastemal column show that the cells are more closely packed together in the caudal half of each protovertebra and more loosely arranged in its cephalic half (fig. 109). From the darker, caudal portion of the protovertebra an extension grows dorsally on each side of the neural tube to outline the neural arch, and another extension grows laterally into the interval between the corresponding myotome and the one caudal to it, to outline the costal process. While these extensions are appearing, the darker caudal half of each protovertebral centrum fuses with the lighter, cephalic half of the one caudal to it. In this way the segmental protovertebræ give place to *blastemal vertebræ*, each of which is formed from portions of two adjoining segments and retains connexion with the lateral and dorsal outgrowths from its cephalic half.

As no further change in position occurs during the ensuing periods of chondrification and ossification, it follows that the intervertebral discs of the adult are segmental in origin, whereas the vertebral bodies comprise portions of two adjoining segments and the intersegmental tissue between. The intersegmental vessels, which lay opposite the intervals between the protovertebræ, now lie

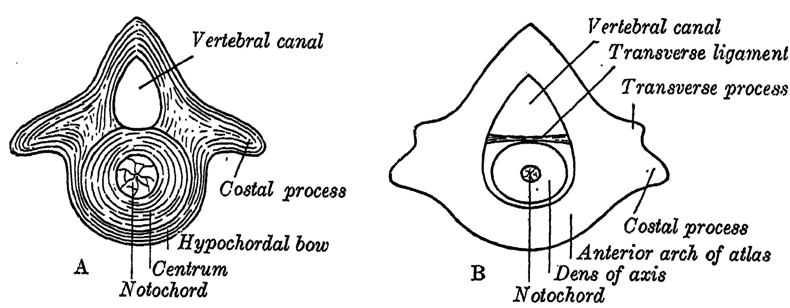
FIG. 110.—Diagrams showing (A) the blastemal and (B) the cartilaginous stages of a typical vertebra.



opposite the vertebræ, a topographical relationship which persists in the adult in the lumbar and lower thoracic regions.

The third stage in the development of the central axis of the body commences in the seventh week with the appearance of centres of *chondrification* in the blastemal vertebræ and their neural arches and proceeds to the formation of a *cartilaginous vertebral column.* Two centres of chondrification appear in the caudal half of each blastemal vertebra and fuse to form the cartilaginous *centrum.* Independent centres appear in each half of the neural arch and in each costal process. In the former chondrification extends forwards into the pedicles and backwards into the laminæ, but the two laminæ do not meet and fuse with one another until the fourth month of intra-uterine life. The centre

FIG. 111.—Diagrams showing the transformation of the hypochordal bow into the anterior arch of the atlas.



of chondrification in the costal process extends both laterally and medially and soon fuses temporarily with the centrum of the vertebra. This continuity does not last long and disappears as the costocentral joint becomes defined. Later, chondrification extends laterally from the neural arch to outline the transverse process, which lies dorsal to the costal process.

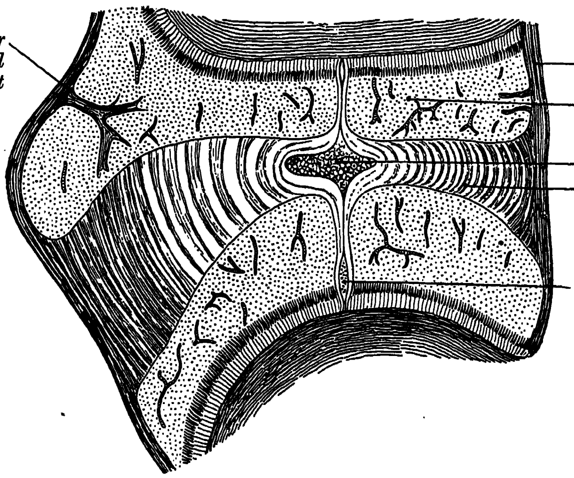
Special reference must be made to a structure which, although present in the *blastemal* period, only becomes recognisable as a separate entity subsequent to chondrification. This structure is named the **hypochordal bow.** It connects the vertebral ends of the two costal processes to each other across the ventral surface of the centrum (fig. 111), and, it should be observed, is only

found in connexion with the upper three or four cervical vertebræ. In the case of the atlas the hypochordal bow persists, and becomes ossified during the third year to form its anterior arch and the anterior ends of its lateral masses. In the cases of the succeeding vertebræ the hypochordal bow undergoes degeneration, and subsequently either disappears in its entirety or becomes incorporated in the anterior part of the centrum.

The notochord can still be identified traversing the centra of the cartilaginous column. Ultimately the portions within the centra atrophy and disappear, but the portions in the intervertebral discs are said to expand and persist throughout life as the central *nucleus pulposus* of each disc (p. 436).

Towards the end of the second month of intra-uterine life centres of *ossification* appear in the cartilaginous vertebræ, and the vertebral column enters on

FIG. 112.—A sagittal section through an intervertebral disc and the adjacent parts of two vertebræ of the embryo of a sheep. (Kölliker.)



its fourth and last stage, viz. that of ossification. The details of this process are described on p. 224.

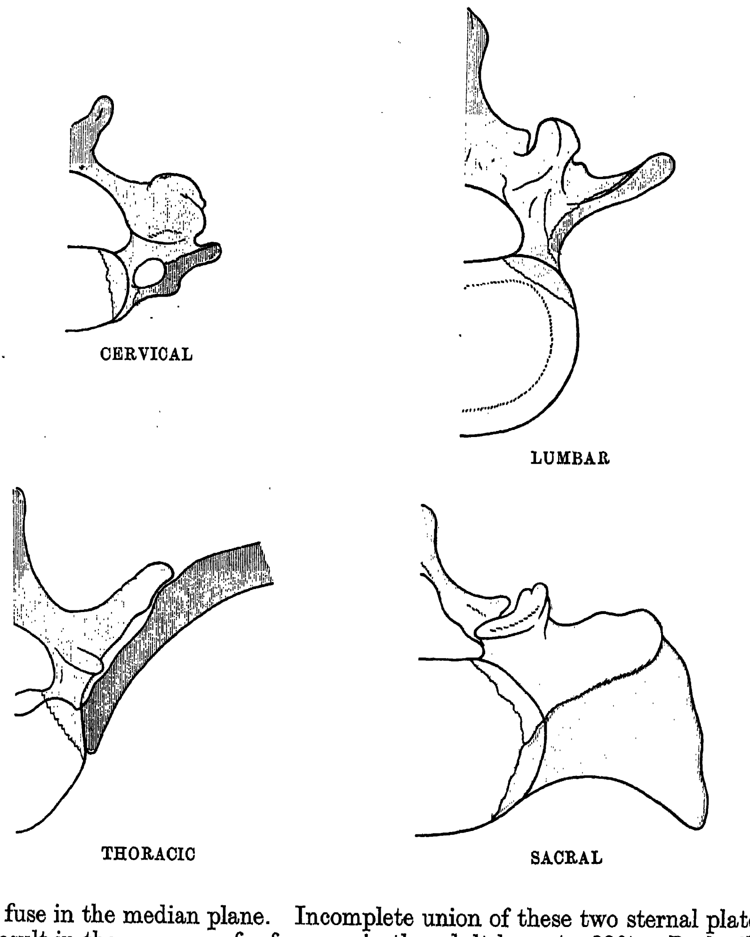
Applied Anatomy.—Occasionally the coalescence of the laminæ is not completed, and consequently a cleft is left in the arches of the vertebræ, through which a protrusion of the spinal membranes (dura mater and arachnoid), and generally of the spinal cord and pia mater, takes place, constituting the malformation known as *spina bifida*. This condition is most common in the lumbosacral region, but it may occur in the thoracic or cervical region, or the arches throughout the whole length of the canal may remain incomplete.

The ribs.—The ribs are formed from the costal processes of the primitive vertebral arches, the processes extending between the muscle-plates. In the *thoracic region* of the vertebral column the costal processes grow laterally to form a series of arches termed the *primitive costal arches*. The transverse process grows out behind the vertebral end of the costal process, and is at first connected to it by mesenchyme which is later differentiated to form the ligaments of the costotransverse joint; between the costal process and the tip of the transverse process the costotransverse joint is formed by absorption, while the proximal end of the costal process becomes separated from the neural arch by the development of the costocentral joint. In the *cervical vertebræ* (fig. 113) the transverse process forms the posterior boundary of the foramen transversarium, while the costal process, corresponding to the head and neck of the rib, remains in continuity with the body of the vertebra, and forms the anterior and lateral boundaries of this foramen. The distal portions of the primitive costal arches remain undeveloped; occasionally, however, the costal processes of the seventh cervical vertebra undergo greater development, and by the formation of costovertebral joints are separated off as cervical ribs. In the *lumbar vertebræ* the distal portions of the primitive costal arches fail; the proximal portions fuse

with the transverse processes to form the transverse process of descriptive anatomy. Occasionally a pair of movable ribs is developed in connexion with the first lumbar vertebra. In the *sacral vertebræ* costal processes are developed only in connexion with the upper three or four vertebræ; the processes of adjacent segments fuse with one another to form the anterior portions of the lateral masses of the sacrum. The *coccygeal vertebræ* are devoid of costal processes.

The **sternum**.—The ventral ends of the upper nine ribs become united to one another by a longitudinal bar termed the *sternal plate*, and the two sternal

Fig. 113.—Diagrams showing the portions of the adult vertebræ derived respectively from the centra (yellow), neural arches (pink), and costal processes (blue) of the embryonic vertebræ.



plates fuse in the median plane. Incomplete union of these two sternal plates may result in the presence of a foramen in the adult bone (p. 230). Both ribs and sternal plates consist at first of condensed mesenchyme, which later becomes chondrified. The eighth and ninth ribs lose their connexion with the sternum, and the portion so freed becomes the xiphoid process. This process of separation may be arrested too soon, and in this event the number of true ribs is increased to eight, or it may be carried too far and so cause a reduction in the number from seven to six. The ossification of the ribs and sternum is described on pp. 232 and 237.

The **skull**.—The bones of the cranium are developed in the mesenchyme which invests the cerebral vesicles, but, before the osseous stage is reached, the skull passes through, firstly, a blastemal or membranous stage, and, secondly, a cartilaginous stage. The chrondrocranium, which is formed in the second stage, is incomplete, and most of the cranial vault and portions of the base are not preformed in cartilage.

The membranous or blastemal skull.—At the end of the first month of intra-uterine life and the beginning of the second, the mesenchyme which surrounds the developing brain increases in thickness and forms localised masses which represent the earliest distinguishable elements of the skeleton of the head. These masses first become evident in the occipital region, where they form the *occipital plate,* which outlines the basilar part of the occipital bone. Two extensions grow laterally from each side of the plate, and their lateral extremities fuse with each other to complete a foramen around the hypoglossal nerve. At the same time the mesenchymal condensation extends forwards, dorsal to the pharynx, and reaches the rudiment of the hypophysis cerebri, thus outlining the clivus and dorsum sellæ of the sphenoid bone. Early in the second month it surrounds the duct of the hypophysis cerebri and extends between the right and left halves of the nasal cavity, where it forms the basis of the ethmoid bone and nasal septum.

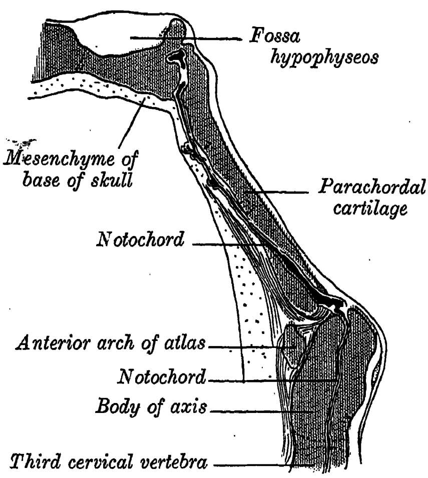


FIG. 114.—A sagittal section through the cephalic end of the notochord. (Keibel.)

The notochord traverses the occipital plate obliquely from its dorsal to its ventral surface and comes into intimate relation with the epithelium of the dorsal wall of the pharynx, with which it is for a time directly connected. It re-enters the base of the membranous skull and runs forward to terminate caudal to the hypophysis (fig. 114).

About the fifth week the two auditory vesicles (p. 130) become enclosed in mesenchymal capsules, each of which is soon differentiated into a dorsilateral part enveloping the semicircular ducts, and a ventrimedial part surrounding the cochlea; at the upper boundary between these two parts the facial nerve lies in a deep groove. The auditory capsules fuse with the lateral processes of the occipital plate, leaving a wide gap through which the internal jugular vein, and the glosso-pharyngeal, vagus and accessory nerves are transmitted.

At this stage the mesenchyme which surrounds the hypophyseal duct and forms the rudiment of the post-sphenoid part of the body of the sphenoid bone sends out a wing-like process on each side—the future greater wing. More anteriorly, from the central mesenchyme which is to form the interorbitonasal septum, processes extend laterally and indicate the sites of the lesser wings of the sphenoid bone, while condensations occur on each side of the nasal cavity and blend above with the mesenchymal septum.

The first indications of the vault of the skull are seen about the thirtieth day, and consist of plates of mesenchyme which appear at the sides of the head and gradually extend into the upper wall where they blend with one another; they also blend with the parts at the base of the cranium.

In the shark and dogfish this mesenchymal cranium undergoes complete chondrification and forms the cartilaginous skull or chondocranium of these animals. Chondrification takes place primarily in two regions: (*a*) the anterior or *prechordal* part is developed in front of the notochord and shows no regular division into primitive segments; (*b*) the posterior or *chordal* part of the base of the skull is developed from the mesenchyme which surrounds the notochord, and exhibits traces of four primitive segments separated from one another by the roots of the hypoglossal nerve.

In mammals the process of chondrification is limited to the base of the skull, including a region dorsal to the foramen magnum. Chondrification takes place primarily in three regions: (*a*) posterior, in relation to the notochord; (*b*) intermediate, in relation to the hypophysis; and (*c*) anterior, between the orbits and the nasal cavity. These parts may be named *chordal, hypophyseal,* and *interorbitonasal*; perhaps the last is identical with the trabeculæ cranii of the majority of vertebrates lower than mammals. It is uncertain what the hypophyseal part represents; when ossified it forms the post-sphenoid.

* In man chondrification of the skull (figs. 115, 116, 117) begins in the second month of intra-uterine life, and the first cartilaginous nuclei appear in the occipital plate, one on each side of the notochord. About the thirty-sixth day these two nuclei fuse anteriorly on the dorsal surface of the notochord, and later they fuse posteriorly on its ventral surface. Thus the notochord lies dorsal to the caudal part of the cartilaginous occipital plate, then

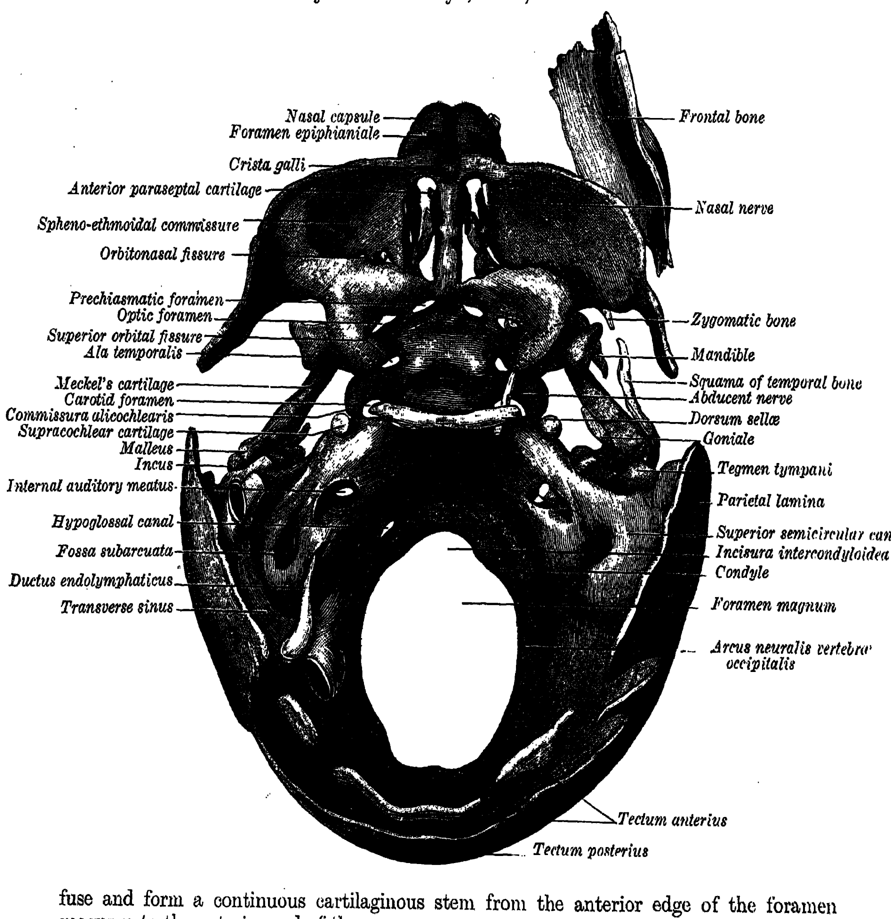
* The following description is mainly based on the researches of Professor E. Fawcett. The reader is referred for further details to the *Journal of Anatomy and Physiology,* volumes xlv., li., and lii., and to the *Proceedings of the Anatomical Society of Great Britain and Ireland,* 1916.

traverses the plate and lies ventral to it, and finally passes forwards in front of it and ends in the dorsal surface of the post-sphenoid cartilage (fig. 114).

The posterior part of the sphenoid cartilage chondrifies from two centres, one on each side of the developing hypophysis cerebri; these unite first behind the duct of the hypophysis and then in front of it, and in this way the craniopharnygeal canal, which transmits the hypophyseal diverticulum, is formed; this canal is usually obliterated at the third month, but may remain open.

The mesenchyme in front of the hypophysis cerebri undergoes independent chondrification; it speedily joins with the posterior end of the chondrifying interorbitonasal septum, and from these are subsequently developed the presphenoid part of the sphenoid bone and the bony (ethmoid) part of the nasal septum. All the above-mentioned parts ultimately

Fig. 115.—The chondrocranium of a human embryo of a crown-rump length of 27 mm. Superior aspect. (From a model prepared by Prof. Edward Fawcett and Gwladys Ruth Llewelyn, B.Sc.)



fuse and form a continuous cartilaginous stem from the anterior edge of the foramen magnum to the anterior end of the nose.

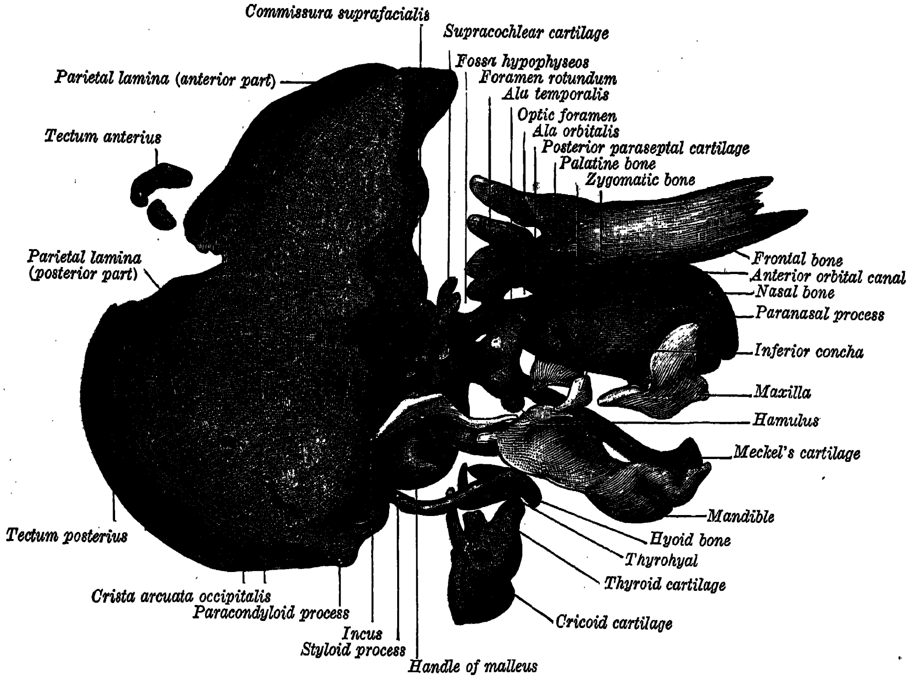
The auditory capsule next undergoes chondrification, the portion surrounding the semicircular ducts chondrifying before that enveloping the cochlea. A plate of cartilage is connected to the top of each auditory capsule by means of a cartilaginous commissure. At the third month this plate forms a considerable part of the side-wall of the cranium, and is separated by only a small interval from the hinder end of the lesser wing of the sphenoid bone. The distance between the two rapidly increases owing to the disappearance of the cartilage.

It is highly probable that the roof of the cranium in its typical human condition is formed by three tecta, which may be called the *tectum posterius*, *tectum intermedium*, and *tectum anterius*. The tectum posterius is the deepest, and when ossified forms the supra-occipital segment of the occipital bone. The tectum intermedium is very narrow and lies immediately in front of the tectum posterius; it soon disappears, and may not even form. The tectum anterius, which stretches between the two parietal plates, is a compound structure consisting of two lateral pieces, one on each side, and a median unpaired segment. Like the tectum intermedium, it soon disappears.

The greater wings of the sphenoid bone have separate cartilaginous nuclei; these fuse with the post-sphenoid cartilage and with two nuclei which connect the post-sphenoid cartilage and the corresponding greater wing with the anterior end of the cochlear capsule, lateral to the carotid artery. These nuclei form, on each side, the alar process, which later ossifies as the lingula. The cartilaginous greater wing is smaller than the lesser wing and only gives rise to the root of the pterygoid process and to that part of the bone which surrounds the maxillary division of the trigeminal nerve.

Between the greater wing and the auditory capsule a wide space lodges the trigeminal (semilunar) ganglion, and transmits the mandibular division of the trigeminal nerve and the

FIG. 116.—The chondrocranium shown in fig. 115. Lateral aspect.



middle meningeal artery. The backward growth of the alar process cuts off this space from the carotid canal, and at a later date the mandibular nerve and middle meningeal artery are surrounded by membrane bone. The space between the greater and lesser wings forms the superior orbital fissure.

A cartilaginous centre appears in the lesser wing, lateral to the optic nerve; it grows medially in front of the nerve and also behind it and fuses with the hinder part of the interorbitonasal septum and so forms the optic foramen. Ossification of the lesser wing begins just lateral to the optic foramen, but does not extend very far laterally; a considerable part of the cartilage disappears, and, owing to this, the size of the bony lesser wing is less than that of the greater wing.

The *nasal capsule* is situated in front of the lesser wings, and is well developed by the third month; it consists of a central part or septum, and two lateral parts.

The septum lies partly under the brain (subcerebral) and partly in front of the brain (precerebral); its lower margin is almost horizontal and is, for a time, free; its anterior border intervenes between the nares.

The lateral parts of the capsule are primarily suspended from the precerebral part of the septum; posteriorly, they are separated from the subcerebral part by the orbitonasal fissure, but later they become connected with it when the cartilaginous cribriform plate of the ethmoid bone develops. The lower edge of the lateral wall of the capsule is incurved to form the inferior nasal concha, which ossifies at the fifth month and becomes detached from the capsule. The posterior part of the lateral part of the capsule becomes ossified to form the ethmoidal labyrinth, and the middle and superior conchæ appear as ridges on its medial surface (fig. 117).

The floor of the cartilaginous nasal capsule is far from complete (fig. 117). The deficiency in the floor of the cartilaginous nares is continued backwards as the fissura rostroventralis. On each side of the free lower margin of the nasal septum there are two para-

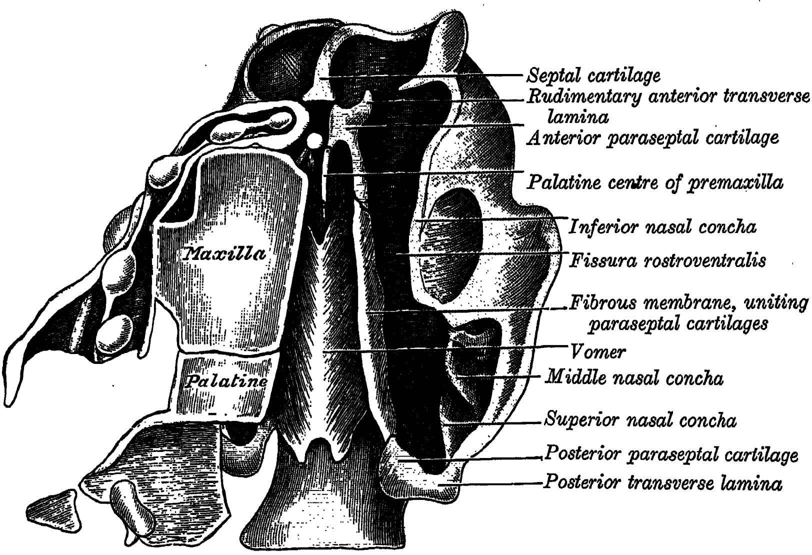
septal cartilages, connected to each other by a fibrous membrane, and represented in lower mammals by a single cartilaginous bar. The anterior paraseptal cartilage is closely related to the vomero-nasal organ; the posterior paraseptal cartilage is connected by a narrow transverse lamina to the postero-inferior corner of the lateral part of the capsule (fig. 117).

Part of the cartilaginous nasal capsule, as already stated, is ossified to form the ethmoid bone and the inferior nasal conchæ, but part remains cartilaginous as the septal and alar cartilages of the nose, and part is replaced by membrane bones.

The ventral surface of the chondrocranium is indirectly connected with the cartilages of the visceral arches, the fate of which is described below.

It will be observed from the accompanying figures that the stage of ossification commences before the chondrocranium has yet reached the height

FIG. 117.—The nasal capsule of a human embryo 65 mm. long. Ventral aspect. On the left side the floor of the capsule has been removed. (From a model by Professor Edward Fawcett.)



of its development. As the process of ossification extends the chondrocranium, after reaching its maximum extent, becomes rapidly reduced, but portions of it still persist at birth, and some are found in the adult skull. At birth the cartilage of the chondrocranium is present: (1) in the cartilages of the alæ and septum of the nose; (2) in the sphenoid bone (p. 294); (3) in the spheno-occipital (p. 426) and the petro-occipital joints (p. 426); and (4) in the foramen lacerum.

The bones of the vault of the skull are ossified in membrane, and are termed *dermal* or *covering bones*. They comprise the frontal and parietal bones, the upper part of the squama occipitalis (interparietal bone), and the squamous and tympanic parts of the temporal bones. Some of the dermal bones remain distinct throughout life (e.g. parietal and frontal), while others join with the bones of the chondrocranium (e.g. interparietal and squamous parts of temporals). The ossification of the bones of the skull is given with the description of the individual bones.

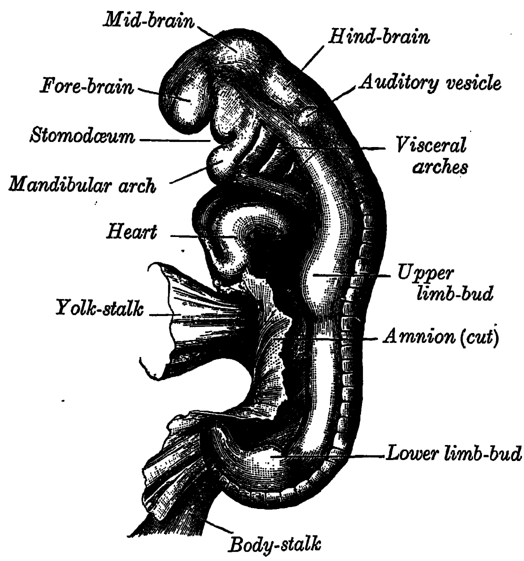
The development of the appendicular skeleton is dealt with on p. 101.

THE BRANCHIAL APPARATUS

After the formation of the head-fold the stomodæum, or primitive mouth, is bounded on its headward side by the forward projection of the fore-brain and on its caudal side by the pericardium. The lower part of the face and the

whole of the neck, which subsequently intervene between the mouth and the pericardium, owe their formation to the development of a series of six **visceral arches** which appear on the lateral aspect of the head in the region of the hind-brain. The first of these arches corresponds to the lower jaw of the fish, the second to the operculum or gill cover, and the remaining four to the branchial or gill arches. The mesenchyme on the lateral wall of the headward part of the fore-gut (lateral plate mesoderm) (p. 61) at first forms a thin sheet intervening between the ectoderm and the entoderm but, as growth proceeds, it proliferates and gives rise to a series of somewhat cylindrical processes which constitute the arches. At first the arches form rounded ridge-like projections in the overlying ectoderm and corresponding projections in the entodermal floor of the pharynx. These ridges are separated from one another by a series of furrows, where the surface ectoderm and the pharyngeal entoderm come into direct contact with one another. The ectodermal furrows are termed the **branchial** or **visceral clefts** and the entodermal furrows the **pharyngeal pouches.** At this stage the pharynx, which is wide at its cephalic end but rapidly narrows as it is traced caudally, is very shallow dorsi-ventrally. It possesses a wide roof and a wide floor, which meet on each side, so that there is no true lateral wall (fig. 119).

FIG. 118.—A human embryo, 4·2 mm. long. Left lateral aspect. (His.)



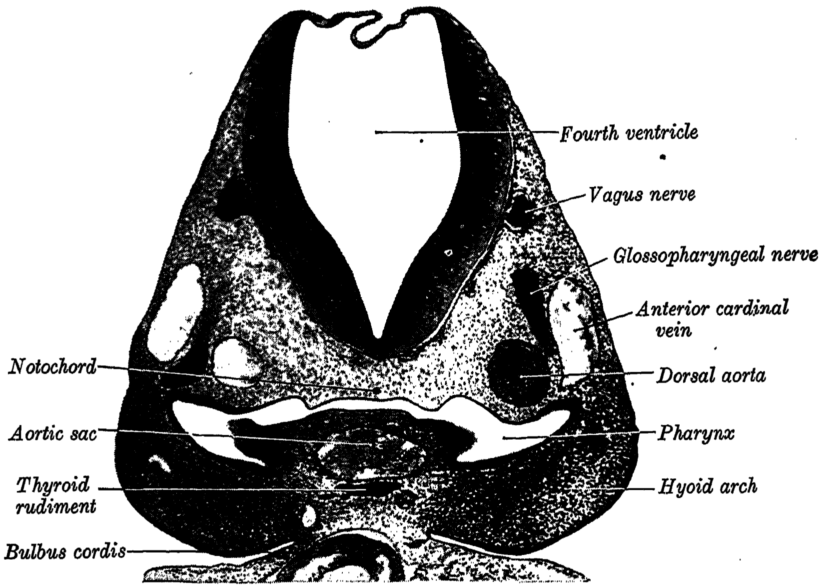
The early appearance of the arches and their intimate relationship to the mouth and to the heart and pericardium, not only in man but in the embryos of all the vertebrata, are explained by their functional significance in the lower vertebrates. They provide for water-breathing animals a convenient and efficient respiratory apparatus. From the arterial, headward end of the heart there emerge two ventral aortæ which pass headwards on the ventral aspect of the pharynx and send branches dorsally, one entering the substance of each arch. In the substance of the arches these vessels break down into a thin-walled capillary plexus from which corresponding vessels emerge and run dorsally to join the dorsal aortæ—two large vessels situated on the dorsal aspect of the pharynx. The branchial clefts in these animals break down and a series of gill slits develop which communicate between the exterior and the inside of the pharynx. Periodically the oxygen-bearing water is taken into the pharynx through the mouth and expelled through the gill slits. In its passage it bathes the entodermal surfaces of the branchial arches, which are specially adapted to expose to it a large area filled with capillaries. The blood gives up its carbon dioxide and absorbs fresh oxygen in its place, and this oxygenated blood is carried into the dorsal aortæ to be distributed all over the body. The periodic intake of water for this purpose is the equivalent of inspiration in an air-breathing vertebrate, and the process provides a respiratory mechanism in which water and not air is the oxygen carrier.

The *first* or *mandibular arch* grows ventrally and medially in the floor of the pharynx until it meets the corresponding arch of the opposite side in the median plane. It comes to lie, therefore, between the primitive mouth and the pericardium (fig. 118). The *second* or *hyoid arch* grows ventrally on its caudal side, and separated from it on the outside by the first cleft. It, too, ultimately reaches the median plane and fuses with its fellow. The

succeeding *third* and *fourth arches* never attain any great degree of prominence, and are for the most part sunk in a depression produced by the caudal overlapping of the hyoid arch. The *fifth* and *sixth arches* cannot be recognised on the outside of the neck and their presence can only be demonstrated by the arrangement of the mesenchyme and the projections in the pharyngeal wall.

It should be observed that each arch consists of an ectodermal covering, a mesodermal core, and an entodermal covering (fig. 119). The mesodermal core gives rise to a *skeletal element*, which subsequently chondrifies in whole or in part and extends dorsally until it comes into contact with the membranous capsule of the hind-brain. Most of the remainder of the mesodermal core later gives rise to striated *muscle*, which may migrate and lose all attachment to the

Fig. 119.—Coronal section through the head of a mole embryo, 4·5 mm. long. The section passes through the hind-brain, the pharynx, the hyoid and a part of the third visceral arch.



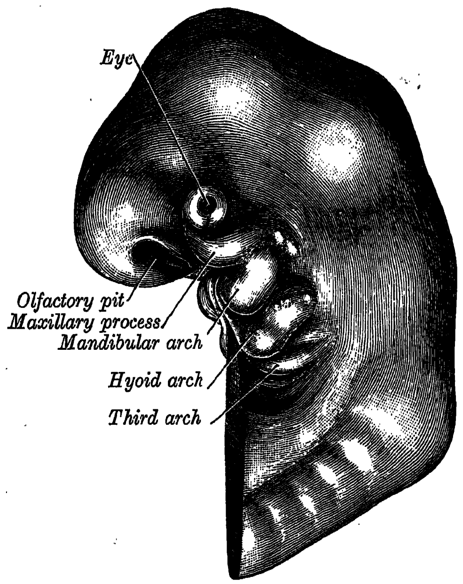
primitive skeletal element of the arch. The history of these muscle masses can, however, easily be traced by reference to their nerve-supply. The dorsal end of each arch, as has already been pointed out, lies close to the ventrilateral aspect of the hind-brain (fig. 119) and the motor *nerves* which arise from this part of the brain pass directly into the arches. The innervation of the muscle masses once established will persist, no matter how far the muscle may migrate from the site of its development. Thus, the mandibular division of the trigeminal nerve supplies the mandibular arch ; the facial nerve, the hyoid arch ; the glossopharyngeal, the third arch ; the vagus and accessory, the remaining arches. It is probable that the recurrent laryngeal nerve is distributed to the sixth arch and the superior laryngeal to the fourth, but the individual nerve of the fifth arch—which is always difficult to identify and leaves few traces of its existence—is uncertain.

The development of the branchial apparatus plays an important part in the formation of the face and neck, the mouth, the pharynx and the larynx, but before a detailed survey is made of the history of the arches it is convenient at this stage to describe the steps which lead to the formation of the face and the demarcation of the nasal cavity.

Development of the face, nose and palate.—While the mandibular arch is invading the floor of the pharynx, the mesenchyme which intervenes between the floor of the fore-brain and the epithelial roof of the mouth becomes thicker

and deeper and, together with its covering ectoderm, constitutes the *frontonasal process*. During the fifth week a thickened patch of ectoderm appears on the ventrilateral surface of the frontonasal process on each side. These specialised patches, which are widely separated from each other, are termed the *olfactory placodes*, and they soon become depressed to form the *olfactory pits*. The frontonasal process can now be subdivided into a *median nasal process*, which occupies the wide field intervening between the pits, and two *lateral nasal processes*, which lie on either side of it.

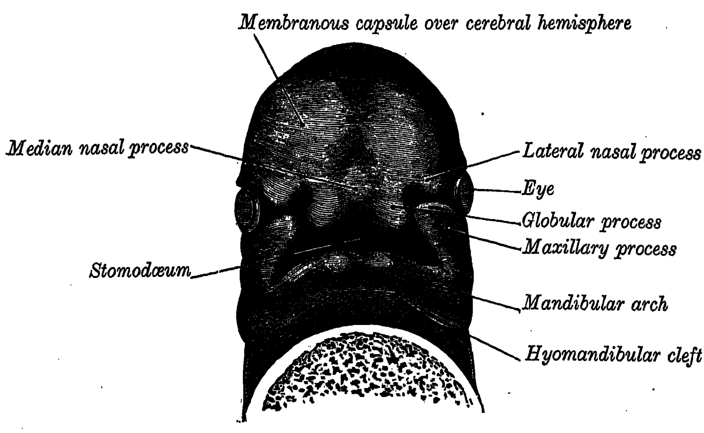
Fig. 120.—The head-end of a human embryo, about the fifth week. Lateral aspect. (From a model by Peter.)



While these changes are in progress a somewhat triangular process grows ventrally from the cephalic side of the dorsal end of the mandibular arch. It is termed the *maxillary process* and, like the frontonasal process, it consists of a core of mesenchyme covered with ectoderm. The maxillary process grows ventrally to fuse with the lateral nasal process, from which it is separated at first by a groove, termed the *naso-optic furrow*. While it is enlarging, the median nasal process gives origin to two rounded swellings, termed the *globular processes*, which project beyond the lateral nasal processes and grow dorsally and laterally below the olfactory pits.

The opposed margins of the lateral nasal and maxillary processes fuse with each other to establish continuity between the side of the nose and the adjoining

Fig. 121.—The head of a human embryo 8 mm. long. Ventral aspect. (From a model by His.)



part of the cheek (fig. 125). The ectoderm along the line of fusion does not disappear, but gives rise to a solid, cellular rod, which sinks beneath the surface. Its caudal, free end secondarily establishes a connexion with the caudal part of the lateral wall of the nasal cavity. Later, this rod becomes canaliculised to form the *nasolacrimal duct*. The blunted apex of the triangular maxillary process projects beyond the lateral nasal process and carries that process on its cephalic surface to meet and fuse with the globular process below

the olfactory pit (figs. 122 and 123). In this way a new upper boundary is formed for the oral fissure by the globular and maxillary processes. It is really the upper lip, although it has not yet been freed from the deeper tissues which form the maxillary alveolus (figs. 126 and 128). At the same time the olfactory pit is converted into a shallow nasal cavity, and now possesses a floor formed by the lateral nasal and maxillary processes. At this stage the nares are completely defined, but they are still widely separated from each other by an area which later becomes relatively narrower, owing to the fusion of the mesenchymal cores of the globular processes. The mesenchyme of the maxillary processes invades the median area and makes a substantial contribution to the formation of the *philtrum* of the upper lip (fig. 125). This invasion of the median area explains the innervation of the philtrum by the maxillary nerve.

FIG. 122.—The head-end of a human embryo in the sixth week. Ventral aspect. (From a model by K. Peter.)

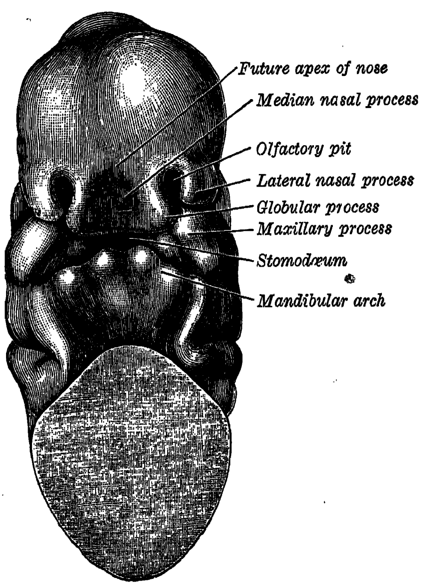


FIG. 123.—The same embryo as is shown in fig. 122, with the front wall of the pharynx removed.

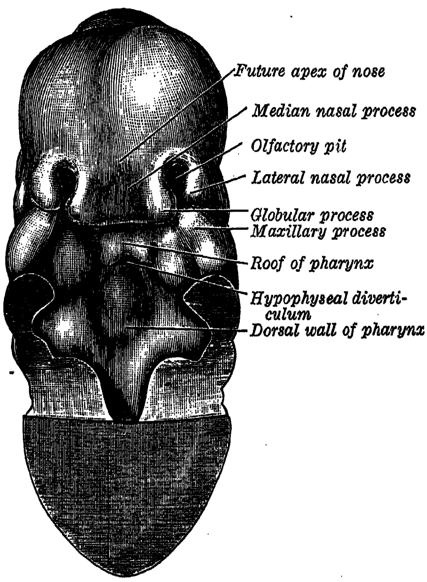

The nasal cavity deepens, and for a time it is only separated from the cavity of the mouth on each side by the *bucconasal membrane*, which consists of the epithelial lining of the pit and the epithelial lining of the roof of the mouth (fig. 126). This membrane ruptures about the fifth week and *primitive posterior nasal apertures* open on the fore part of the roof of the mouth. The area between these openings and the line along which the teeth subsequently develop, constitutes the *primitive palate* (fig. 126), since it intervenes between the cavities of the mouth and nose.

As the head grows in size the mesenchyme which intervenes between the floor of the fore-brain and the mouth increases greatly in amount and the nasal fossæ deepen (i.e. extend towards the fore-brain). At the same time they extend backwards from the primitive posterior nasal apertures as two narrow but deep grooves in the roof of the mouth, separated by a broad partition which increases in depth as the fossæ deepen. This partition is the *nasal septum*, and its broad caudal surface lies free in the roof of the mouth and is at first in contact with the dorsum of the developing tongue (fig. 127). The nasal cavity is thus subdivided into right and left parts, which communicate freely with the cavity of the mouth except ventrally, where the floor is formed by the primitive palate.

In the sixth week the inner surface of the maxillary process gives rise to a *palatine process*, which projects caudally from it and lies in contact with the side of the tongue (fig. 127). The two palatine processes are separated at first by the whole breadth of the tongue, and at this stage the cephalic margin of the oral

fissure extends ventrally beyond the caudal margin. Further growth of the mandibular region in a ventral direction carries the tongue with it *caudal* to the ventral ends of the palatine process, which thereafter grow towards each other and coalesce in the interval between the tongue and the free margin of the nasal septum (fig. 129). As the palatine processes fuse with each other, they fuse also with the caudal border of the nasal septum in its ventral three-fourths, leaving

FIG. 124.—The face of a human embryo of about eight weeks, in which the nose and mouth are formed. (From a model by His.)

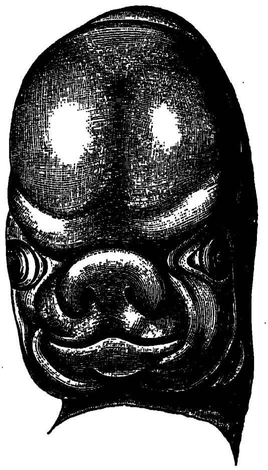

FIG. 125.—A diagram showing the parts of the adult face which are related to the frontonasal and maxillary processes and the mandibular arch.

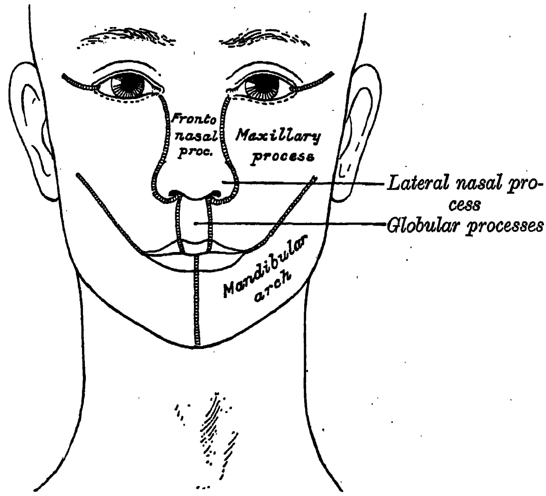
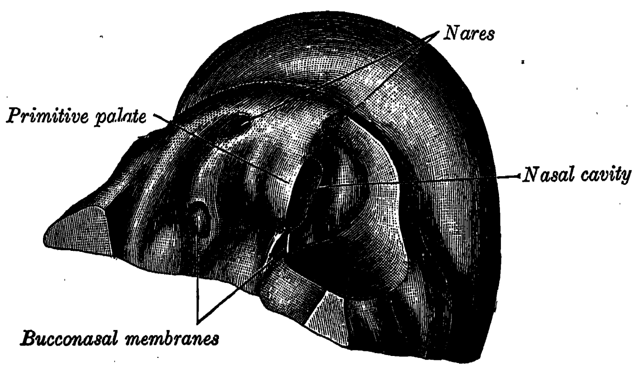


its dorsal fourth free to form the posterior margin of the septum in the adult. In this way the *definitive posterior nasal apertures* are established, opening above the palate into the nasal pharynx. Later, the palatine processes are continued backwards on the side wall of the pharynx and meet and fuse with each other to form the soft palate. At their ventral ends the palatine processes encroach on the primitive palate, which retains its position and constitutes the premaxillary portion in the adult.

FIG. 126.—The primitive palate of a human embryo in the seventh week. (From a model by K. Peter.)

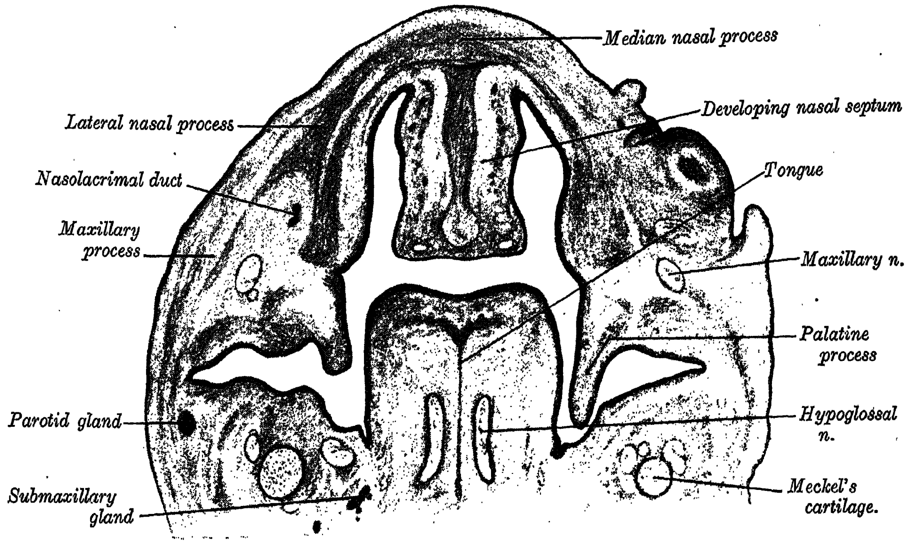


On the left side the lateral wall of the nasal cavity has been removed.

On each side of the nasal septum, at its caudal and ventral part, the ectoderm is invaginated to form a diverticulum which extends dorsally and headwards into the nasal septum. These diverticula form the *vomeronasal organs*, which open below, close to the junctions of the premaxillæ and maxillæ, but they are always rudimentary in man.

Congenital malformations involving arrest of development during the formation of the face and palate are not uncommon. In the simplest form, the maxillary process on one side fails to fuse completely with the globular process and a fissure is present between the philtrum and the lateral part of the upper lip. The condition is known as *hare-lip*. A similar type of malformation, but of comparatively rare occurrence, results from the failure of the maxillary process to fuse with the frontonasal process. In this case the nasolacrimal duct

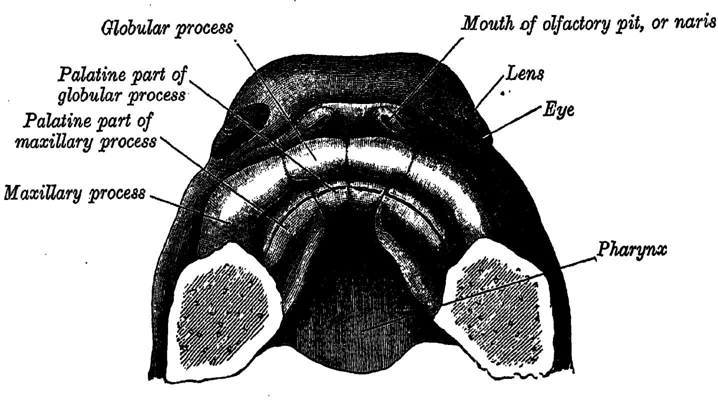
FIG. 127.—Oblique coronal section through the head of a human embryo 23 mm. long. The nasal fossæ communicate freely with the cavity of the mouth.



forms an open furrow along the side of the nose, and the condition is usually associated with the presence of hare-lip on the same side.

The palatine processes may fail to fuse with each other and with the nasal septum, giving rise to the condition of *cleft palate*. In its grossest form no fusion occurs in the roof of the mouth. The edges of the palatine process are separated by a wide median fissure in which the free lower border of the nasal septum can be seen. Anteriorly the premaxillary

FIG. 128.—The roof of the mouth of a human embryo about two and a half months old, showing the mode of formation of the palate. (From a model by His.)

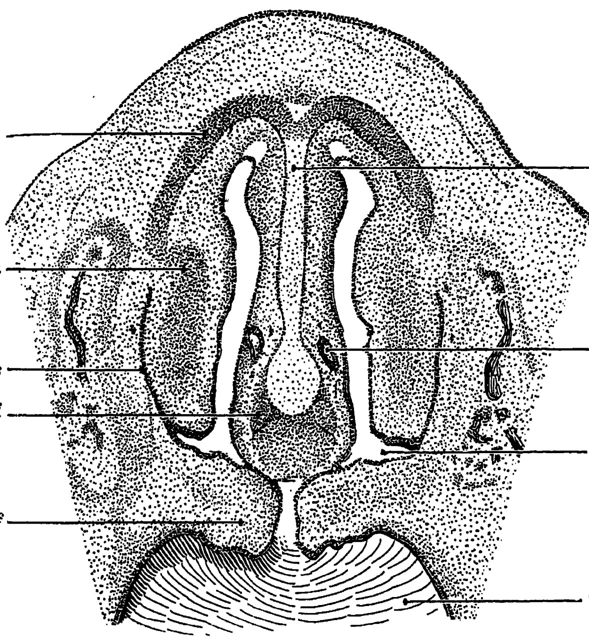


portion of the palate is separated from the palatine processes by a fissure on each side, and these fissures are continuous in front with the clefts in a double hare-lip. In such cases the median nasal process remains separate, but it is, of course, continuous above and behind with the nasal septum. The floor of the nasal fossa is deficient throughout its whole extent and the posterior nasal apertures have never been defined. All varieties of milder degrees of cleft palate have been recorded. In the commonest type the condition is unilateral, i.e. one palatine process has fused with the primitive palate and with the nasal septum, but the other

has failed to do so and the extent of the cleft is variable. The mildest degree results in a bifid uvula only, or in a cleft which affects the soft palate only.

Such arrests of development are indicative of nutritional disturbances in the embryo during the second month of development, and the grosser varieties are usually associated with malformations affecting other parts of the body.

FIG. 129.—A coronal section through the nasal cavity of a human embryo 28 mm. long. (Kollmann.)



The subsequent history of the visceral arches.—The visceral arches contribute extensively to the formation of the face, the neck, the mouth, the pharynx and the larynx ; the visceral clefts, with the exception of the first, which forms the external auditory meatus, disappear entirely ; the pharyngeal pouches give origin to the tympanic cavity and the pharyngo-tympanic (auditory) tube, the tonsillar pits, the thymus and the parathyroids.

Ectodermal derivatives.—The ectoderm over the mandibular arch is responsible for the formation of that part of the skin of the face which covers the mandible (fig. 125) and, in addition, it takes part in the formation of the auricle (p. 132). The ectoderm on the cephalic aspect of the arch thickens along a curved line which is later converted into the labiodental sulcus. The epithelial proliferation invades the underlying mesenchyme and subsequently breaks down, so as to separate the lower lip from the developing gum. Before it does so, however, it gives rise on its inner surface to an epithelial lamina (fig. 1136) from which the enamel of the teeth is derived at a later stage (p. 1279).

The first cleft becomes obliterated in its ventral portion, but its dorsal end, surrounded by tubercles which arise from the mandibular and hyoid arches to form the auricle, deepens and forms the epithelial lining of the external auditory meatus.

At the end of the fifth week the third and fourth arches lie at the bottom of a small depression, which is termed the *precervical sinus*. On the cephalic side the sinus is bounded by the hyoid arch ; dorsally, by a ridge produced by downgrowths from the occipital myotomes and by premuscle tissue which subsequently forms the sternomastoid ; and caudally, by a smaller ridge termed the epipericardial ridge (Frazer) which separates the sinus from the pericardium and curves headwards, medial to the ventral ends of the arches to reach the mandibular arch. The muscle cells which migrate from the occipital myotomes to reach the tongue follow the epipericardial ridge and carry the hypoglossal nerve with them. The fourth arch becomes buried by the growth of the dorsal border

of the sinus, which, together with the epipericardial ridge and the reduced second and third arches, eventually constitutes the whole of the side of the neck.

At the dorsal ends of the first, second and third clefts, thickened patches of ectoderm, termed *epibranchial placodes*, are intimately related, and may possibly make contributions, to the ganglia of the seventh, ninth and tenth cranial nerves. As growth proceeds they retain their relationship to the ganglia and therefore become more and more deeply placed, although for a time they remain connected to the surface by epithelial strands.

The above outline of the development of the neck follows the work of Frazer,* but it should be mentioned that it differs in several respects from the description current in most textbooks. According to the latter, the hyoid arch meets its fellow in the median plane and, caudally, grows over and buries the whole of the precervical sinus, fusing eventually with the ectoderm over the headward aspect of the pericardium.

The buried epithelium of the precervical sinus may give rise to a *branchial cyst*, or, if its connexion with the surface is retained, to a *branchial fistula*. In the latter case the opening of the fistula is placed low down in the neck, close to the anterior border of the sternomastoid muscle.

Mesodermal derivatives.—Each arch is traversed by an artery, which connects the ventral to the dorsal aorta and is termed an *aortic arch*. Phylogenetically each visceral arch possesses two nerves, one running along its cephalic and the other along its caudal border. In the human embryo this double innervation can only be determined in the first arch. Each arch contains a *skeletal element*, typically a bar of cartilage connected to the chondrocranium at its dorsal end and meeting its fellow of the opposite side at its ventral end. The cartilage develops *in situ* from the mesoderm of the arch, which also gives origin to a mass of *muscle*.

The first and second *aortic arches* of each side disappear, but the third aortic arch persists as the lower, or proximal, portion of the internal carotid artery and the distal part of the common carotid (fig. 130). The fourth aortic arch of the right side forms the proximal part of the right subclavian artery, but on the left side it becomes the part of the arch of the aorta which lies between the origins of the left common carotid artery and the left subclavian. The fifth aortic arch disappears entirely, but the sixth on each side gives off a branch to the developing lung-bud. When the truncus arteriosus becomes divided into the pulmonary trunk and the ascending aorta the sixth arches remain in connexion with the former. On the right side the dorsal portion of the sixth aortic arch disappears, but on the left side it forms the *ductus arteriosus*, which functions during intra-uterine life and becomes converted into the fibrous *ligamentum arteriosum* after birth.

The *nerves* of the arches are derived from the hind-brain and at once enter the dorsal ends of their arches. Typically, they are mixed nerves; their motor branches supply the muscle of the corresponding arch and their sensory branches are distributed to the skin and mucous membrane derived from it. In fishes the nerves and their ganglia lie at the dorsal ends of the clefts, and each sends a pretrematic branch into the arch on the cephalic side of its cleft and a post-trematic branch into the arch on its caudal side. In mammals, although both may be distinguished in the first arch, only one nerve can be identified with certainty in the second, third, fourth and sixth arches, while the nerve of the fifth arch is unknown and may have disappeared.

The mandibular division of the trigeminal nerve is the post-trematic nerve of the first arch, and the chorda tympani is its pretrematic nerve.† The facial supplies the second arch, the glossopharyngeal the third, the superior laryngeal nerve the fourth, and the recurrent laryngeal nerve the sixth. In lower animals the nerve to the fifth arch is a branch of the vagus.

The difference in the behaviour of the recurrent laryngeal nerves on the two sides of the body in the adult can be understood on reference to the history of the aortic arches. The nerve enters the arch caudal to the sixth aortic arch. It retains this position on the left side of the body, and in the adult is found on

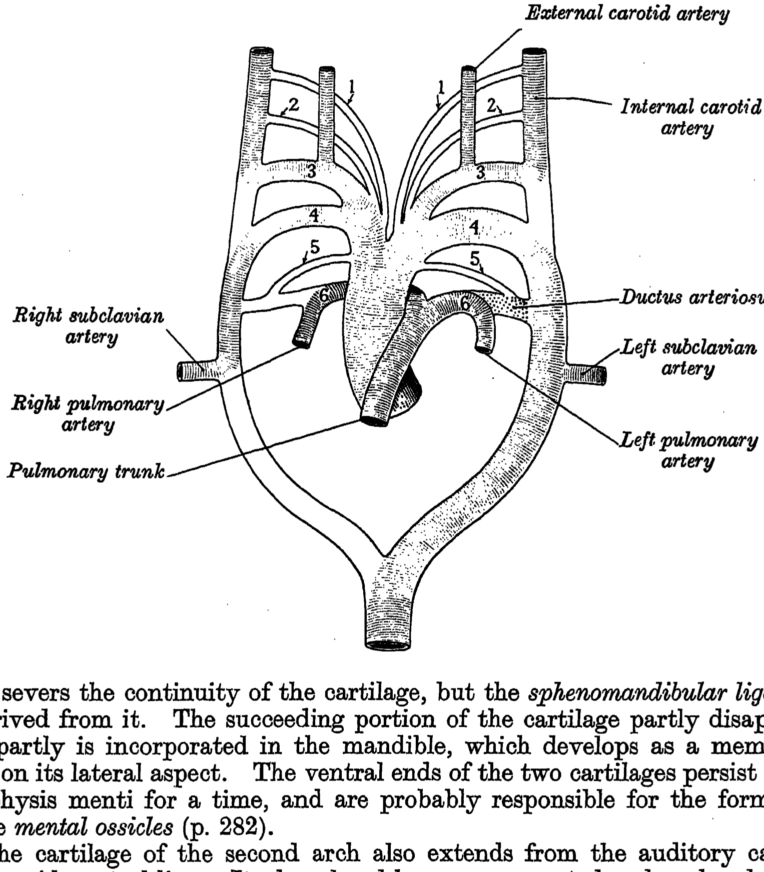
* J. Ernest Frazer, *Journal of Anatomy*, Oct. 1926.

† Professor Frazer does not regard the chorda tympani as a pretrematic nerve, for reasons explained in his *Manual of Embryology*, p. 242.

the left side of (i.e. caudal to) the ligamentum arteriosum. On the right side, however, owing to the disappearance of the dorsal part of the sixth aortic arch and of the whole of the fifth aortic arch, the nerve is found on the caudal aspect of the subclavian artery, i.e. the fourth aortic arch.

The *skeletal element* of the first arch is termed *Meckel's cartilage*. It extends from the basal aspect of the developing auditory capsule into the mandibular arch, and, ventrally, it turns upwards in contact with its fellow of the opposite side (fig. 116). The dorsal end of the cartilage becomes separated and forms the *incus* and the *malleus*, including its anterior process. The completion of the

FIG. 130.—A scheme of the aortic arches and their transformations. (After Congdon.)



skull severs the continuity of the cartilage, but the *sphenomandibular ligament* is derived from it. The succeeding portion of the cartilage partly disappears and partly is incorporated in the mandible, which develops as a membrane bone on its lateral aspect. The ventral ends of the two cartilages persist in the symphysis menti for a time, and are probably responsible for the formation of the *mental ossicles* (p. 282).

The cartilage of the second arch also extends from the auditory capsule to the mid-ventral line. Its dorsal end becomes separated and enclosed in the tympanic cavity, forming the *stapes*. Thereafter the cartilage is represented in the adult by the *styloid process*, the *stylohyoid ligament*, the *lesser cornu* and the *upper part of the body of the hyoid bone* (fig 131).

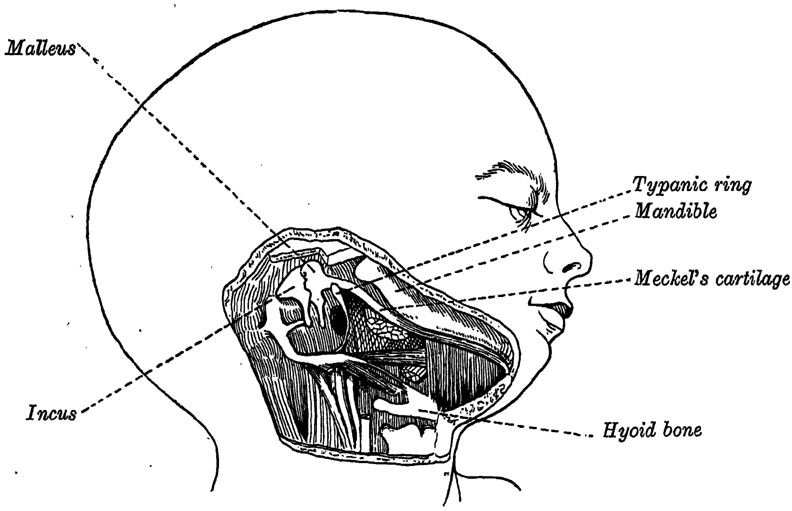
The cartilage of the third arch loses its connexion with the cerebral capsule, but its ventral portion persists as the *greater cornu of the hyoid bone* and the *lower part of its body*. According to Frazer, the body of the hyoid bone chondrifies in the base of the hypobranchial eminence and belongs to the third arch only, its connexion with the skeletal element of the second arch being acquired secondarily.

The cartilages of the fourth, fifth and sixth arches all lose their connexion with the cerebral capsule, but their ventral portions persist and take part in the formation of the cartilages of the larynx. The *thyroid cartilage* is formed from the fourth and, probably, the fifth; the *epiglottis* develops in the fourth arch, but it is very doubtful whether the skeletal element of this arch contributes to its formation. The *arytenoids* are derived from the skeletal elements of the sixth arches. The origin of the *cricoid* is uncertain. Most authorities

regard it as a modified tracheal ring which has become included in the larynx, but Fawcett * believes that it is derived from the skeletal element of the fifth arch and Frazer refers it to the sixth arch.

The *muscle mass* of the mandibular arch forms the *tensor tympani*, the *tensor palati* and the *muscles of mastication*, including the mylo-hyoid and the anterior belly of the digastric (all supplied by the mandibular nerve). The tensor tympani retains its attachment to the skeletal element of the arch, but the muscles of mastication transfer their attachment to the mandible. The muscles of the hyoid arch for the most part migrate widely from their original position, but they retain their nerve-supply from the facial nerve. The *stapedius*, the *stylo-hyoid* and the *posterior belly of the digastric muscle* retain their attachment to the skeletal element of the arch, but the *muscles of facial*

Fig. 131.—The head and neck of a human embryo, eighteen weeks old, with Meckel's cartilage and the hyoid bar exposed. (After Kölliker.)



expression, the *platysma*, the *auricular muscles* and the *occipito-frontalis* (*epicranius*) lose all connexion with it. Their migration is facilitated by the obliteration of the first cleft and pouch in their ventral parts.

The muscle masses of the remaining arches form the *muscles of the pharynx, soft palate* and *larynx*. The *stylo-pharyngeus* can be attributed definitely to the third, the *cricothyroid* to the fourth and the remaining laryngeal muscles to the sixth arch, but the precise origin of the constrictor muscles and the muscles of the soft palate is uncertain.

Entodermal derivatives.—The description of the entodermal derivatives of the visceral arches and pharyngeal pouches is equivalent to the description of the development of the mouth, pharynx and larynx, and will therefore be considered later (p. 162).

THE LOCOMOTOR APPARATUS

The limbs.—In the fifth week the limbs appear as small elevations or buds from a slight lateral ridge at either side of the trunk (figs. 256, 257). Prolongations from several primitive segments extend into each bud, and carry with them the anterior primary rami of the corresponding spinal nerves ; the nerves supplying the limbs indicate the number of primitive segments which contribute to their formation—the upper limb being derived from seven, viz. fourth cervical to second thoracic inclusive, and the lower limb from ten, viz. twelfth thoracic

* Professor E. Fawcett. *Proceedings of the Anatomical Society of Great Britain and Ireland*, 1916.

to fourth sacral inclusive. The axial part of the mesenchyme of the limb-bud condenses and is converted into its cartilaginous skeleton, and by the ossification of this the bones of the limbs are formed. The musculature of the limbs is developed *in situ* from the mesoderm which surrounds the developing skeletal elements, and such muscles as the latissimus dorsi, which possess an extensive attachment to the axial skeleton in the adult, gain that attachment secondarily during intra-uterine life, as the result of active migration. The limbs are at first directed tailwards nearly parallel to the long axis of the trunk (fig. 133); by the end of the sixth week their long axes are at right angles to that of the trunk, and the three chief divisions of each limb are marked off by furrows—arm, forearm, and hand in the upper limb; thigh, leg, and foot in the lower (fig. 134). The future *flexor* surface of the limb is directed ventrally; the *extensor* surface, dorsally; one border (the *pre-axial*) looks towards the cephalic end of the embryo, and the other (the *post-axial*) towards the caudal end. The lateral epicondyle of the humerus, the radius, and the thumb lie along the preaxial border of the upper limb; the medial epicondyle of the femur, the tibia, and the big toe along the corresponding border of the lower limb. The limbs next become adducted and flexed on the trunk and, during this process, they undergo a rotation or torsion through an angle of 90° around their long axes, the upper limb being rotated in a lateral and the lower limb in a medial direction. As a consequence of this rotation the pre-axial (radial) border of the fore-limb is directed laterally, and the pre-axial (tibial) border of the hind-limb medially; thus the flexor surface of the fore-limb is turned forwards, and that of the hind-limb backwards. The pre-axial part is derived from the cephalic primitive segments, the post-axial from the caudal primitive segments of the limb-bud; and this explains, to a large extent, the cutaneous innervation of the adult limb, the nerves of the higher segments being distributed along the pre-axial (radial or tibial), and those of the lower segments along the post-axial (ulnar or fibular) border of the limb.

FIG. 132.—Diagram indicating the segments concerned with the formation of the upper limb-bud.

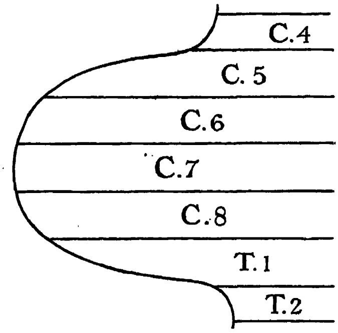


FIG. 133.—A human embryo about 9 mm. long. (Drawn from a stereoscopic photograph.)

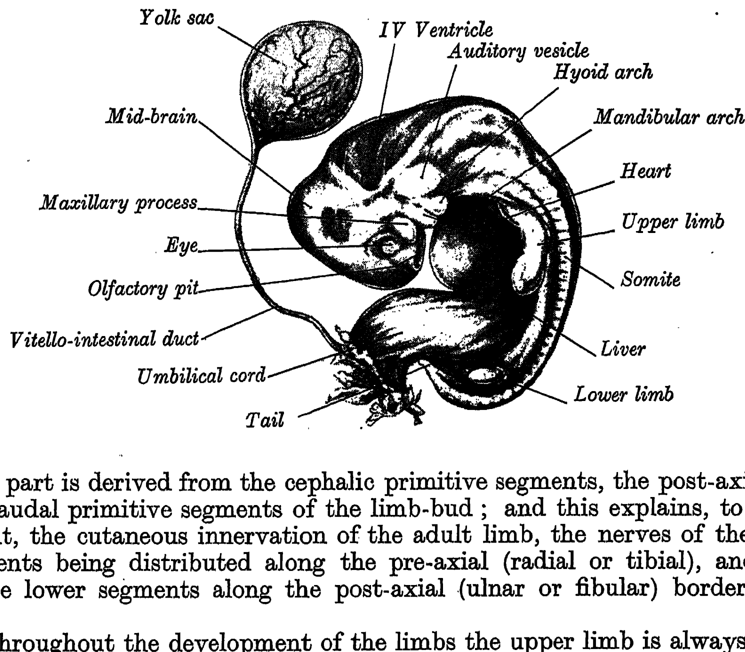


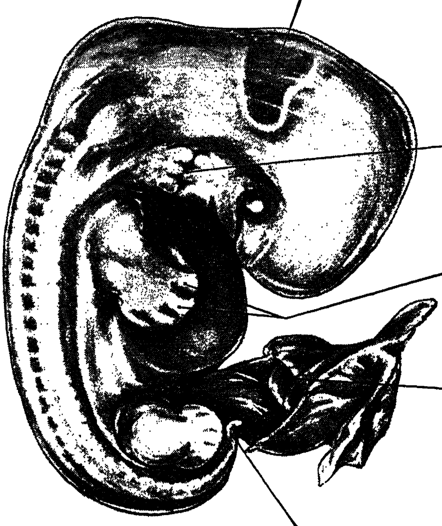
Throughout the development of the limbs the upper limb is always a little in advance of the lower limb. The foot and hand resemble each other closely at first, each being represented by a plate-like enlargement at the extremity of the bud. The mesenchymal core of the peripheral part of the plate becomes

condensed to outline the digits, and the thinner, intervening areas break down from the circumference towards the centre. This process may be carried out incompletely or it may be prematurely arrested, and in such cases varying degrees of *webbing of the fingers* or *toes* are present at birth.

The ossification of the limb-bones is described along with the description of the individual bones.

The **joints**.—The mesenchyme from which the different parts of the skeleton are formed shows no differentiation at first into masses corresponding with the individual bones; thus, continuous cores of mesenchyme form the axes of the limb-buds and a continuous column of mesenchyme the future vertebral column. The first indications of the differentiation of the bones and joints are circumscribed condensations of the mesenchyme; these condensed parts become chondrified and finally ossified to form the bones of the skeleton. The inter-

FIG. 134.—A human embryo about 15 mm. long. (Drawn from a stereoscopic photograph.)



vening non-condensed portions consist at first of undifferentiated mesenchyme, which may be converted into fibrous tissue as in the case of the skull bones, a fibrous joint being the result; or it may become partly fibrocartilaginous, in which case a cartilaginous joint is formed; or it may become looser in texture, a cavity ultimately appearing in its midst, while the cells lining the sides of this cavity form a synovial stratum, and thus a synovial joint is developed; in some synovial joints portions of the mesenchyme persist and form articular discs.

The tissue surrounding the original mesenchymal core forms fibrous sheaths for the developing bones (perichondrium and periosteum) which are continued between the ends of the bones over the synovial strata as the capsular ligaments of the joints. These capsules are not of uniform thickness, and specially strengthened bands—the precursors of ligament—can be recognised in them. This, however, is not the only method of formation of ligaments. In some cases by modification of, or derivation from, the tendons surrounding the joint, additional ligamentous bands are provided to strengthen the articulations.

The **muscles**.—With the exception of certain muscles of the head and neck which are developed from the mesodermal cores of the visceral arches (p. 100), and the muscles of the limbs, which develop *in situ* from the mesoderm of the limb-buds (p. 101), all the *voluntary muscles* of the body are derived from the myotomes (p. 65). Typically, each myotome divides into a dorsal and a ventral portion. The former takes up its position on the dorsilateral aspect

of the vertebral column and is innervated by the posterior primary ramus of the corresponding spinal nerve ; the cells of the latter migrate ventrally into the body wall or somatopleure and are innervated by the corresponding anterior primary ramus. In fishes these two primary subdivisions of the myotomes are separated from each other by the transverse processes of the vertebræ and a fibrous septum which extends from them to the lateral line. The pre-muscle masses, derived from the myotomes, may split longitudinally or tangentially, and the portions so derived may remain separate, e.g. the intercostal muscles, or they may fuse with the corresponding portions of adjoining myotomes, e.g. the external and internal oblique muscles and the transversus. In mammals the derivatives of the ventral portions of the myotomes may subsequently migrate so as to cover derivatives of the dorsal portions, but, as their nerve supply is determined at a very early stage, they carry their nerves with them as they migrate. As a result such muscles as the serratus posterior, superior and inferior, which are attached to the vertebral spines and cover the sacrospinalis, are supplied by anterior primary rami because they have been derived from the ventral portions of certain myotomes and have secondarily acquired their adult position and vertebral attachment. Numerous examples could be cited, but those already given will suffice to suggest others.

The muscles of the orbit and the muscles of the tongue require special mention. The hypoglossal nerve, as will be pointed out later (p. 1031), is a compound nerve and is serially homologous with the anterior nerve roots of the spinal nerves. Its inclusion within the skull is secondary. The myotomes of the corresponding somites, probably four in number, migrate from their original site into the tongue, carrying their nerve supply with them.

No mesodermic somites have yet been observed in the head region of the human embryo, but, on the evidence of comparative anatomy, it seems probable that a large number of somites, seven or more, originally developed in this situation. Of the corresponding myotomes, however, portions of only three persist, and they form the muscles supplied by the oculomotor, trochlear and abducent nerves.

In man and the higher vertebrates many of the derivatives of the myotomes degenerate and some disappear entirely. Others are converted into fibrous tissue, which may take the form of aponeuroses (e.g. the aponeuroses of the abdominal muscles) or ligaments (e.g. the sacrotuberous ligament).

The involuntary muscles are derived from the mesoderm of the splanchnopleure and develop *in situ*.

THE SKIN AND ITS APPENDAGES

The epidermis, hairs, nails, sebaceous and sudoriferous glands are developed from the ectoderm, the corium or true skin from the mesoderm. The ectoderm at first consists of a single stratum of cells, but in the sixth week two strata can be recognised, a superficial, named the *epitrichium*, consisting of flat cells, the nuclei of which stain readily, and a deep, named the *stratum germinativum*, consisting at first of cubical cells, but later of columnar. By multiplication and differentiation of the cells of the stratum germinativum the different layers of the epidermis are developed. Towards the end of the third month the mesoderm condenses to form the corium, and at about the same time the subcutaneous areolar tissue is differentiated ; in the fourth month the dermal papillæ begin to make their appearance. A considerable desquamation of the epidermis takes place, and this desquamated epidermis, mixed with sebaceous secretion, constitutes the *vernix caseosa*, with which the skin is smeared during the last three months of fœtal life.

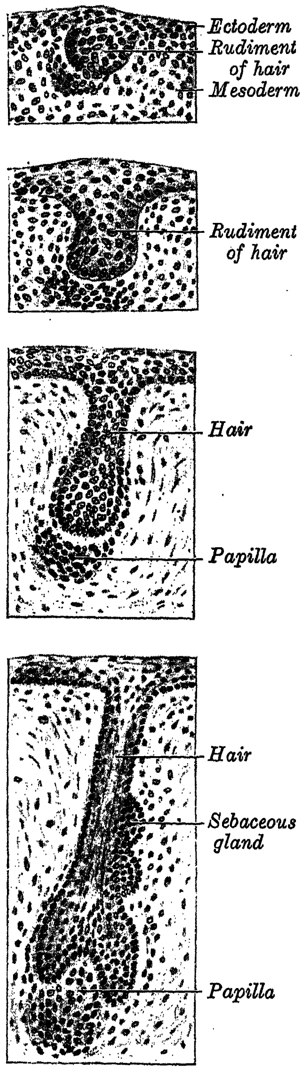
The *hairs* (fig. 135) originate as thickenings of the epidermis which grow obliquely downwards as solid buds into the corium, each bud consisting of an outer stratum of columnar cells and a core of polygonal cells. The deep end of each bud expands to form the hair-bulb, which is moulded over a papilla of condensed mesoderm. The cells of the hair-bulb proliferate and form a cone of cells, from which the scapus or shaft of the hair and its inner sheath are developed ; the hairs gradually lengthen by growth at the hair-bulb, and ultimately project on the surface.

The *sebaceous glands* originate as lateral outgrowths from the sides of the hair-buds, and, pushing their way into the mesenchyme, divide into three or four oval or flask-shaped alveoli, the lining cells of which are derived from the stratum germinativum.

The rudiments of the *sudoriferous* or *sweat glands* make their appearance on the palms

of the hands and soles of the feet in the fourth month, and closely resemble the rudiments of the hairs, each beginning as a solid downgrowth of the ectoderm. The ectodermal downgrowth lengthens, and its deeper part coils on itself and forms the body of the gland. A lumen is developed in the downgrowth about the seventh month of intra-uterine life, and opens on the surface by a duct which is lined with two layers of cells. In the secreting part of the gland the outer layer of cells is modified to form a stratum of smooth muscle-fibres which lies between the epithelium of the gland and the basement-membrane. Many sudoriferous glands arise as ectodermal downgrowths from the superficial portions of the hair-follicles and later acquire independent openings on the surface of the skin.

FIG. 135.—Successive stages in the development of a hair.



The rudiments of the *nails* can be seen in embryos of about 4·5 cm. in length, and appear as *primary nail-fields* of ectoderm on the dorsal surfaces of the distal phalanges of the digits. At the proximal end and sides of each nail-field the epidermis is invaginated to form the nail-folds, while the distal end, which will ultimately form the free end of the nail, is bounded by a shallow groove. The nail is developed from the posterior nail-fold and consists of modified stratum lucidum. The stratum corneum covers the nail and forms the *eponychium*; this disappears from the surface of the nail, with the exception of a narrow fold which overlaps the proximal part of the lunule.

The *mammary gland* may be looked upon as a collection of greatly modified sudoriferous glands; the epithelial lining of its ducts and alveoli is derived from the ectoderm, its supporting connective tissue from the mesenchyme. On each side of the ventral surface of young embryos a thickened band of ectoderm, termed the *milk-ridge*, extends obliquely from the axilla to the inguinal region, and in some of the lower mammals mammæ are developed at intervals along this ridge; in man, no definite ridge is found, and only one mamma, as a rule, is developed on each side of the median plane, but supernumerary mammæ or nipples are sometimes found above or below the fully developed gland.

The rudiment of the mammary gland appears as a thickening and subsequent ingrowth of the ectoderm; from this ingrowth fifteen or twenty solid cords branch off, each cord representing a future lactiferous tubule and lobe of the gland. The deep ends of the cords subdivide in the mesenchyme and form the alveoli of the gland. The region where the ectodermal thickening occurred is subsequently raised to form the nipple, and about the time of birth the tubules and alveoli become canalised. At the age of puberty, and in a greater degree towards the end of pregnancy, a marked enlargement of the gland, and a development of additional lobules and alveoli, take place.

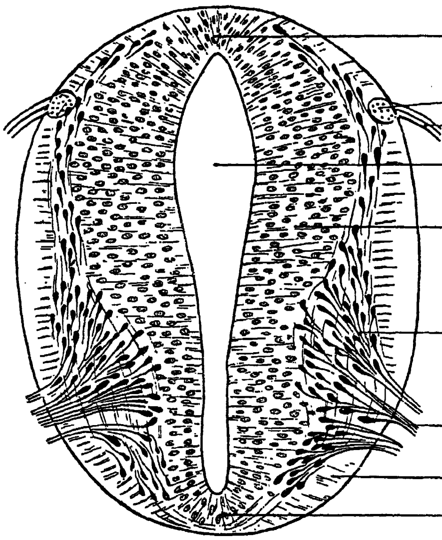
THE DEVELOPMENT OF THE NERVOUS SYSTEM AND SENSE-ORGANS

The appearance of the medullary plate and its further differentiation into a median neural groove limited on each side by neural folds which fuse with each other during the fourth week to form a neural tube, have already been

described (p. 60). The cephalic end of the neural tube develops into the brain and its ventricles, and the remainder of the tube forms the spinal cord and its central canal.

The **spinal cord.**—At the time when the neural tube is closing the cells in the neural folds are proliferating so rapidly that their cell boundaries are lost, and they form a syncytium in which the nuclei are closely packed together. On the outside and on the inside of the tube the syncytium condenses to form an *outer* and an *inner limiting membrane.* As growth proceeds it becomes possible to distinguish an inner or *ependymal layer*, an intermediate or *mantle layer*, and an outer or *marginal layer* (fig. 136). The cells of the inner layer give

FIG. 136.—A transverse section through the spinal cord of a human embryo four weeks old. (His.)



rise to cells which migrate into the mantle layer, and also to the ependymal cells which subsequently line the central canal. The cells of the intermediate or mantle layer are of two varieties, termed *spongioblasts* and *neuroblasts*. The former give origin to neuroglia and the latter to nerve cells. Increase in the number of cells in the mantle layer is brought about partly by the subdivision of its constituent cells and partly by the migration into it of cells derived from the ependymal layer. The outer or marginal layer consists of a non-nucleated protoplasmic syncytium and forms a framework for the various tracts by which it is subsequently invaded. The roof- and floor-plates of the neural tube remain thin, and their cells only contribute to the formation of ependyma.

The nerve-cells are large and, at first, round or oval in shape. Soon they become pear-shaped, and the narrow end of the cell becomes drawn out to form the axis cylinder process or axon. These cells are therefore primarily unipolar, but further differentiation leads to the development of dendritic processes, and they become typical multipolar nerve-cells. In the developing spinal cord the nerve-cells occur in small clusters, and two or more of them may be connected to one another by their apical processes. It is uncertain whether such groups represent nerve-cells undergoing rapid division, or whether the fusion of the developing axons is secondary. The former seems the more probable explanation.

The spongioblasts are connected to one another by strands of the syncytium in which numerous branching fibrils develop, and as the neuroglia cells mature the syncytium becomes condensed around them so that they assume their characteristic spider-like appearance with multiple processes proceeding from each cell.

At first the neural tube is oval in outline and its lumen is narrow and slit-

like (fig. 136). The lateral walls rapidly become thicker, but the *roof-plate* and the *floor-plate* remain thin and do not share in this cellular proliferation. As its lateral walls thicken the lumen widens in its dorsal part and presents a somewhat lozenge-shaped appearance on cross-section (fig. 138, A). The widest part of the canal subdivides each lateral wall into a ventral or *basal lamina* and a dorsal or *alar lamina*. This separation is fundamental and indicates a functional difference, for the cells in the basal lamina become the motor cells of the anterior and lateral grey columns, while the cells of the alar lamina form neurones on the afferent, sensory, pathways. The widening of the canal is due to the development of a longitudinal *sulcus limitans* on the inner wall on each side. At its caudal end the canal exhibits a fusiform dilatation which is known as the *terminal ventricle*.

The cells of the ependymal layer are closely packed at this stage and tend to arrange themselves in radial columns. The cells of the mantle layer are more loosely arranged, and they increase in number at first in the region of the basal lamina. This enlargement outlines the *anterior column* of the grey matter and it causes a forward projection on each side of the median plane, the floor-plate remaining at the bottom of the shallow groove so produced. As growth proceeds, these enlargements, further increased by the development of the anterior white columns, encroach on the groove until it becomes converted into the slit-like anterior median fissure of the adult spinal cord (fig. 138, A and B). The axons of the nerve-cells in the anterior grey column traverse the marginal zone and emerge on the anterolateral aspect of the spinal cord as the *anterior nerve roots*.

In the thoracic and upper lumbar regions the cells of the mantle layer in the dorsal part of the basal lamina outline a *lateral column*. The axons of its cells join the emerging anterior nerve roots and pass through white rami communicantes to the ganglia of the sympathetic trunk to be distributed to the viscera and blood-vessels. At the same time a lateral column is laid down in the mid-sacral region also, and gives origin to the parasympathetic fibres which form the pelvic splanchnic nerves (p. 1138).

As the anterior and lateral grey columns assume their final form the cells in the ventral part of the ependymal layer gradually cease to proliferate, and the layer becomes reduced in thickness until it ultimately forms the single-layered ependyma. The *posterior column* is somewhat later in its development, and, as a result, the ependymal layer is for a time much thicker in the alar lamina than it is in the basal lamina.

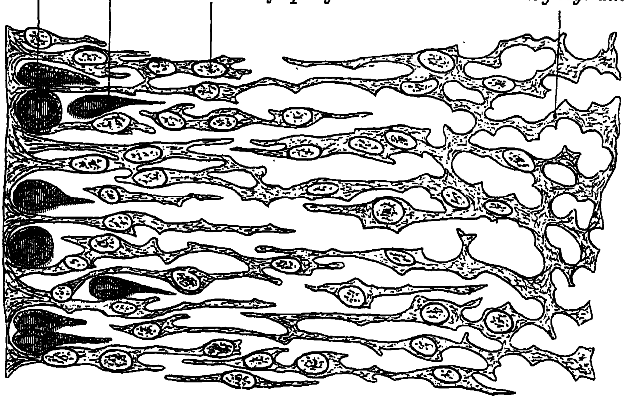
While the columns of grey matter are being defined, the dorsal portion of the central canal becomes narrow and slit-like, and its walls come into apposition and fuse with each other (fig. 138). In this way the central canal becomes considerably reduced in size and somewhat triangular in outline.

About the end of the fourth week nerve-fibres appear in the marginal layer. The first to develop are the short intersegmental fibres from the neuroblasts in the mantle zone, and the fibres of the posterior roots of the spinal nerves which pass into the spinal cord from the cells of the spinal ganglia. By the sixth week the fibres of the posterior roots of the spinal nerves form a well-defined *oval bundle* in the peripheral part of the alar lamina ; this bundle increases in size, and spreading towards the median plane forms the rudiment of the posterior white column. As the posterior white columns increase in thickness, their opposed medial surfaces come into contact with each other, and the *posterior median septum*, which subsequently separates them, is neuroglial in origin. The long intersegmental fibres begin to appear about the third month, and the cerebrospinal fibres about the fifth month. All nerve-fibres are at first destitute of medullary sheaths, and different groups of fibres receive their sheaths at different times, e.g. the anterior and posterior nerve-roots are medullated about the fifth month, the cerebrospinal fibres after the ninth month. The source of the myelin is uncertain. It has been regarded as a modification of the outermost part of the axis cylinders and, in the case of the peripheral nerves, its formation has been attributed to the cells of the nucleated neurolemma sheaths. Recently, it has been suggested that the myelin has an extraneural origin and is derived from the blood-stream, being deposited round the axons in some manner unknown.

The cervical and lumbar enlargements appear simultaneously with the development of the limb-buds.

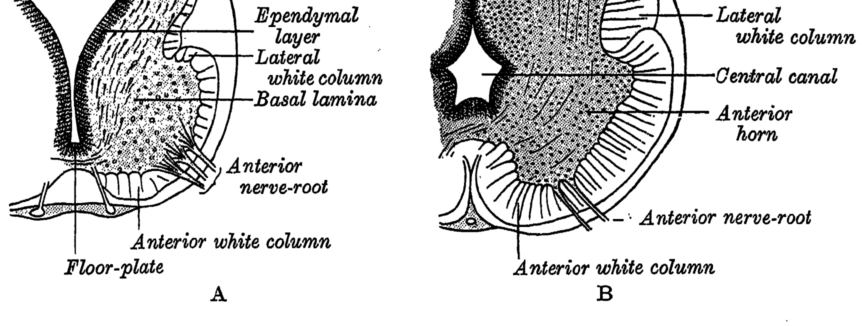
In early fœtal life the spinal cord occupies the entire length of the vertebral canal, and the spinal nerves pass outwards at right angles. After the embryo

Fig 137.—A transverse section through the spinal cord of a human embryo at the beginning of the fourth week. (After His.) The left edge of the figure corresponds to the lining of the central canal.



has attained a length of 30 mm. the vertebral column begins to grow more rapidly than the spinal cord, which gradually assumes a higher position within the vertebral canal. The principal part of this upward migration occurs during the first half of intra-uterine life. By the twenty-fifth week of intra-uterine life the terminal ventricle of the spinal cord (p. 893) has ascended from

Fig. 138.—Transverse sections through the spinal cord of a human embryo. A, about six weeks old. B, about three months old. (His.)



the level of the second coccygeal vertebra to that of the third lumbar vertebra, or a distance of nine segments, and there remain but two segments before the adult position is reached (Streeter *). As the migration upwards commences, the caudal end of the terminal ventricle, which has become adherent to the overlying ectoderm, remains *in situ*, and the walls of the ventricle and its

* George L. Streeter, *American Journal of Anatomy*, vol. 25, 1919.

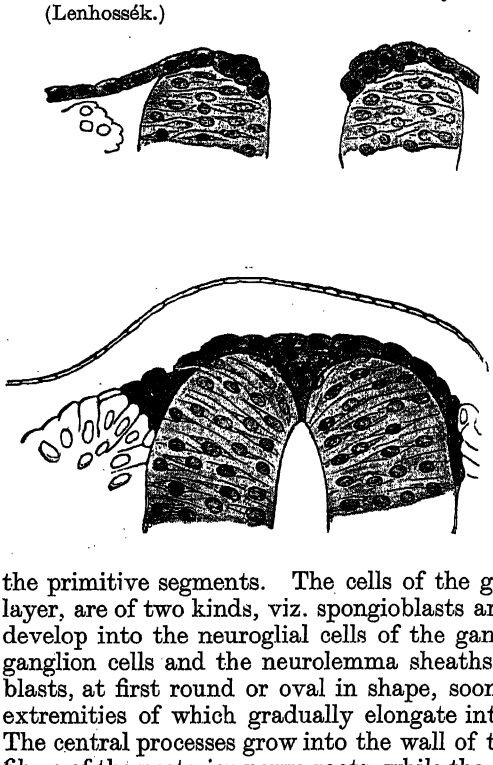
covering pia mater become drawn out to form a delicate filament, termed the *filum terminale*. The separated portion of the terminal ventricle persists for a time but it disappears as a rule before birth. It does, however, occasionally give rise to congenital cysts in the neighbourhood of the coccyx.

The spinal nerves.—Each spinal nerve is attached to the spinal cord by an anterior root and a posterior root.

The fibres of the anterior roots are formed by the axons of the neuroblasts which lie in the ventral and lateral parts of the mantle layer ; these axons pass out through the overlying marginal layer into the myotomes of the primitive segments, and are ultimately aggregated to form the anterior nerve-roots (fig. 138).

The fibres of the posterior roots are developed from the cells of the spinal ganglia. Before the neural groove is closed to form the neural tube a ridge of ectodermal cells termed the *ganglion-ridge* or *neural crest* (fig. 139) appears along the prominent margin of each neural fold. When the folds meet in the median plane the two ganglion-ridges fuse and form a wedge-shaped area along the line of closure of the tube. Opposite the primitive segments the cells of this area proliferate rapidly to form a series of oval-shaped masses, which migrate for a short distance in a lateral and ventral direction. From the ventral part of each mass a small portion is detached to form sympathochromaffin cells (p. 124), while the remainder is converted into a spinal ganglion. The spinal ganglia are arranged symmetrically at the sides of the neural tube and, except in the region of the tail, are equal in number to the primitive segments. The cells of the ganglia, like the cells of the mantle layer, are of two kinds, viz. spongioblasts and neuroblasts. The spongioblasts develop into the neuroglial cells of the ganglia, the nucleated capsules of the ganglion cells and the neurolemma sheaths of the spinal nerves. The neuroblasts, at first round or oval in shape, soon assume the form of spindles the extremities of which gradually elongate into central and peripheral processes. The central processes grow into the wall of the neural tube, and constitute the fibres of the posterior nerve-roots, while the peripheral processes grow forwards to mingle with the fibres of the anterior root in the spinal nerve. As development proceeds the original bipolar form of the cells in the spinal ganglia changes ; the two processes become approximated until they ultimately arise from a single stem in a T-shaped manner. The bipolar form is retained in the retina and in the ganglia of the auditory nerve. Some observers hold that the T-form is derived from the branching of a single process which grows out from the cell.

FIG. 139.—Two stages in the development of the neural crest in the human embryo. (Lenhossék.)

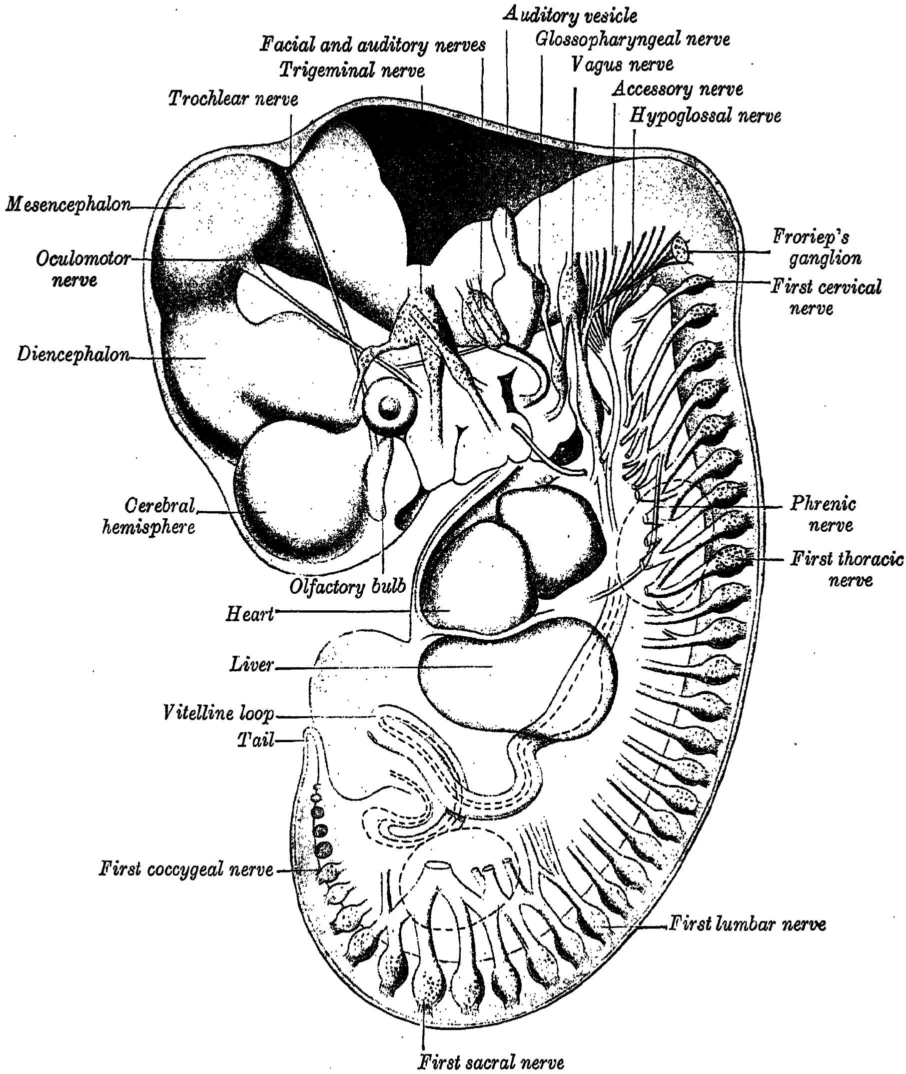


The precise manner in which a motor nerve-cell establishes contact with its effector is still uncertain. On the whole, the balance of the evidence, both embryological and experimental, supports the view that the axon grows out from the body of the cell and finds its way to the effector, and that the processes of the sensory nerve-cells develop in the same way. On the other hand, many embryologists maintain that, from the earliest stages of development, the ectodermal motor cells are in direct connexion with the mesodermal muscle cells by means of protoplasmic bridges and that this connexion, though it may undergo considerable lengthening, is never lost. Harrison * has carried out a long series

* R. G. Harrison, *American Journal of Anatomy*, 1906.

of experiments, chiefly on amphibian larvæ, which all tend to support the view that the axons grow out actively from the nerve-cells. The same observer and others have succeeded in culturing nerve-cells *in vitro*, and they have found that in the complete absence of other tissues the cells give rise to long processes which, so far as can be ascertained, are identical with axis cylinder processes. The opponents of this view depend mainly on histological observations. Graham Kerr * has traced back the development of the motor nerve-trunk

FIG. 140.—A human embryo 10·2 mm. long, showing the peripheral nerves. (After a reconstruction by His.) (From Quain's Elements of Anatomy, vol. i., Embryology.)



The abducent nerve is not labelled, but is seen passing forwards to the eye deep to the mandibular and maxillary nerves.

in *Lepidosiren paradoxa* to a period in which it is represented by a bridge of soft granular protoplasm connecting the spinal cord and myotome at a stage when these structures are in close apposition. As the myotome is pushed outwards it remains connected with the spinal cord by the ever-lengthening strand of nerve, which soon loses its granular protoplasmic character and assumes a fibrillated appearance. Cameron and Milligan † hold that in early embryonic life the cell-elements of the sense-epithelium of the auditory vesicle are connected with those of the hind-brain by a continuous tract of nucleated protoplasm

* J. Graham Kerr, *Transactions of the Royal Society of Edinburgh*, vol. xli. part i. 1903-4.

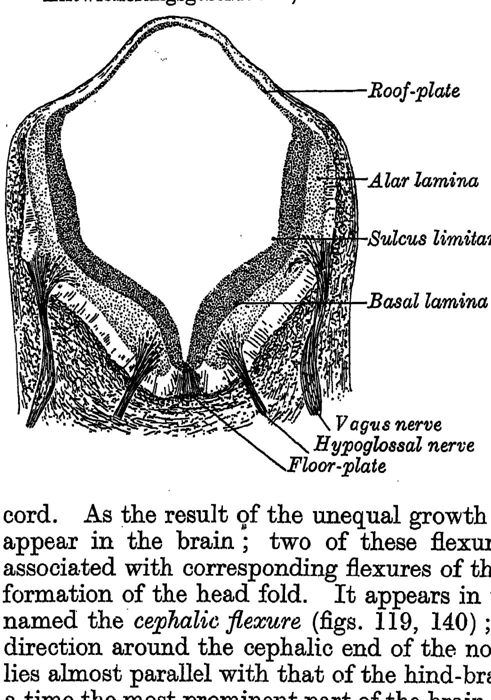
† "The development of the auditory nerve in vertebrates," *Journal of Anatomy and Physiology*, vol. xliv.

(syncytium) which is never severed. This syncytium, at first undifferentiated, becomes fibrillated longitudinally to form a continuous tract of nerve-fibres (the future auditory nerve) uniting the sense-epithelium of the auditory organ with the hind-brain.

Frances M. Ballantyne * believes that the posterior roots of the spinal nerves are similarly developed, the rudiments of the spinal ganglia being from the first connected to the spinal cord by protoplasmic bridges which are never severed, but become fibrillated and lengthen out as the embryo grows.

The cells which form the neurolemma sheaths of the peripheral nerves have been ascribed to a variety of sources. Harrison † excised the neural crest in young amphibian larvæ and discovered that the motor fibres derived from the corresponding portion of the neural tube developed as naked axons. Later, however, these fibres acquired a neurolemma sheath, the constituent cells migrating from the wall of the neural tube. He came to the conclusion that the sheaths are ectodermal in origin, formed partly from the cells of the neural crest and partly from the cells of the neural tube.

Fig. 141.—A transverse section through the medulla oblongata of a human embryo, 10·2 mm. long. × 32. (From Kollmann's Entwickelungsgeschichte.)



The brain.—Prior to the closure of the neural tube the neural folds become expanded considerably in the head region to outline the brain (fig. 79). Subsequent to its closure these expansions form the three primary cerebral vesicles (fig. 144). These are marked off from each other by constrictions, and are named the *rhombencephalon* or *hind-brain*, the *mesencephalon* or *mid-brain*, and the *prosencephalon* or *fore-brain*—the first being continuous with the spinal cord. As the result of the unequal growth of its different parts three flexures appear in the brain; two of these flexures are concave ventrally and are associated with corresponding flexures of the head. The first is caused by the formation of the head fold. It appears in the region of the mid-brain, and is named the *cephalic flexure* (figs. 119, 140); the fore-brain bends in a ventral direction around the cephalic end of the notochord and fore-gut until its floor lies almost parallel with that of the hind-brain (fig. 140). The mid-brain is for a time the most prominent part of the brain, since its dorsal surface corresponds with the convexity of the flexure. The second bend appears at the junction of the hind-brain and spinal cord, and is termed the *cervical flexure* (fig. 140). It increases from the fifth week to the end of the seventh, when the hind-brain forms nearly a right angle with the spinal cord; after the seventh week erection of the head takes place and the cervical flexure diminishes and disappears. The third bend is named the *pontine flexure* (fig. 144), because it is found in the region of the future pons. It differs from the other two in that (*a*) its convexity is forwards, and (*b*) it does not affect the head.

The lateral walls of the hind-brain and mid-brain, like those of the spinal cord, are divided into dorsal or alar and ventral or basal laminæ (fig. 142) by the upward continuation of the limiting sulci of the spinal cord.

The rhombencephalon or hind-brain.—By the time the cephalic flexure appears, the hind-brain exceeds in length the combined lengths of the other two brain vesicles. At its cephalic end it exhibits a constriction termed the *isthmus rhombencephali* (fig. 144, Isthmus), which is best seen when the brain is viewed from the dorsal aspect. Ventrally it is separated from the dorsal wall of the primitive pharynx only by the notochord, the two dorsal aortæ, and a small

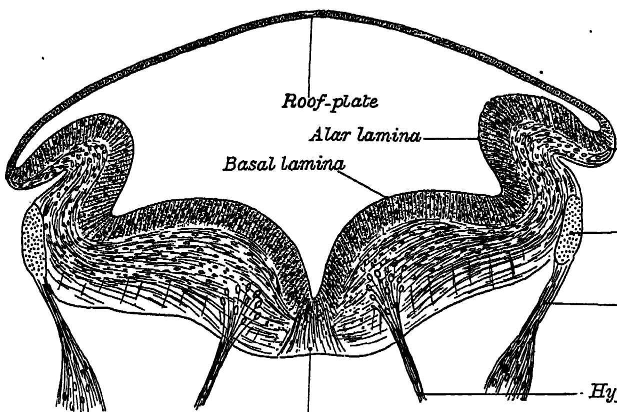
* "The continuity of the vertebrate nervous system," *Transactions of the Royal Society of Edinburgh*, vol. liii. p. 663, 1925.

† R. G. Harrison, *Journal of Comparative Neurology*, 1924.

amount of mesenchyme, and on each side it is closely related to the dorsal ends of the visceral arches (fig. 119).

The formation of the pontine flexure throws a strain on the thin, epithelial roof-plate, which becomes stretched and widened, the maximum increase in width corresponding to the region of maximum convexity, so that the outline of the roof-plate becomes rhomboidal in form. At the same time, the lateral walls fall outwards away from each other (fig. 142) and the cavity of the hind-brain, which subsequently forms the fourth ventricle, becomes flattened and somewhat triangular on cross-section. The pontine flexure becomes more and more acute until, at the end of the second month, the alar and basal laminæ of its cephalic (metencephalon) and caudal (myelencephalon) slopes are opposed

Fig. 142.—A transverse section through the medulla oblongata of a human embryo. (After His.)



to each other and, at the same time, the lateral angles of the cavity become drawn out to form the lateral recesses of the fourth ventricle.

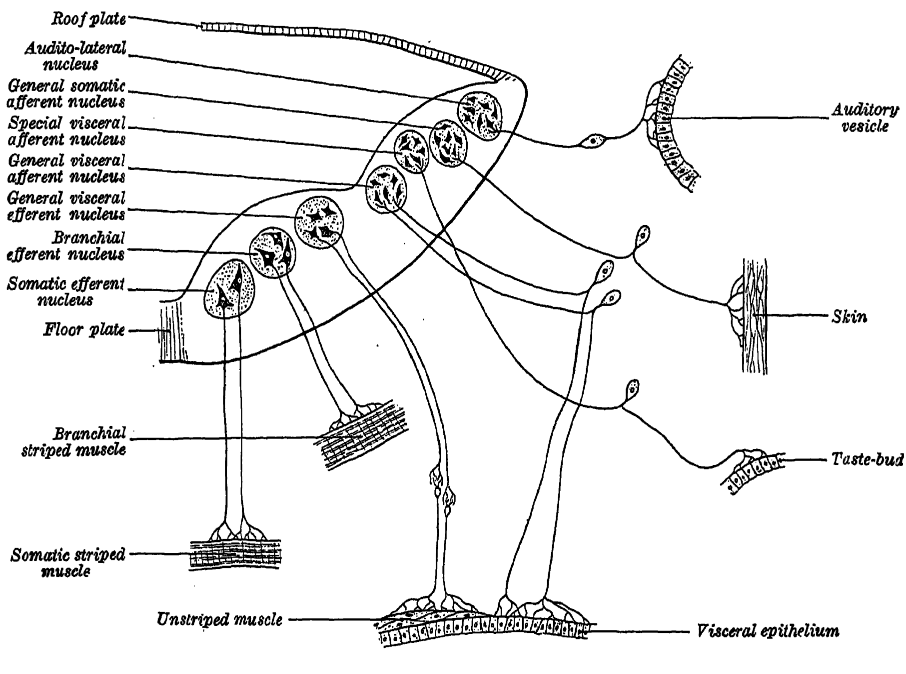
About the end of the fourth week, when the pontine flexure is beginning to be discernible, a series of six transverse grooves appears in the basal lamina of the hind-brain. These are termed the *rhombic grooves* and they bear a very definite relationship to the motor nuclei of certain of the cranial nerves. The first two overlie the nucleus of the trigeminal nerve; the third overlies the nucleus of the facial nerve, the fourth that of the abducent nerve, the fifth that of the glossopharyngeal and the sixth that of the vagus nerve. These grooves, though transient, are constant in character but their significance is uncertain. They are probably associated with the appearance of the visceral arches, but the association of the fourth groove with the nucleus of the abducent nerve cannot be harmonised with this arrangement.

The differentiation of the lateral walls of the hind-brain into basal and alar laminæ has a similar significance to the corresponding differentiation in the lateral wall of the spinal cord, and ependymal, mantle and marginal layers are formed in the same way. The cells of the basal lamina are motor in function and they form three elongated, but interrupted, columns. The most ventral column is in line with the anterior grey column of the spinal cord and is destined for the supply of muscles which are myotomic in origin. It is represented in the caudal part of the hind-brain, where it forms the nucleus of the hypoglossal nerve, and it reappears at a higher level as the nucleus of the abducent nerve, both of which are termed *somatic efferent nuclei.* The intermediate column, which is only represented in the upper part of the spinal cord, is destined for the supply of the musculature derived from the branchial arches. It is interrupted also, but the lower part, which gives fibres to the eleventh, tenth and ninth cranial nerves, forms the elongated nucleus ambiguus. At higher levels this column gives origin to the motor nuclei of the facial and trigeminal nerves. These three nuclei are termed *branchial* (or *special visceral*)

efferent nuclei. The most dorsal column is represented in the spinal cord by the lateral grey column and, like it, is destined for the innervation of viscera. It is interrupted also, its large lower part forming the dorsal nucleus of the vagus and its higher part the upper and lower salivatory nuclei. These are termed *splanchnic*, or *general visceral, efferent nuclei.*

Similar interrupted columns are formed in connexion with the alar lamina and give-rise to *general visceral afferent, special visceral afferent, general somatic afferent* and *special somatic afferent* columns (fig. 143). These columns, like those of the basal lamina, are interrupted and broken up into nuclei, but, although they tend to, and may, retain their primitive position, in many instances they migrate from their site of origin—presumably in accordance with the principle of neurobiotaxis (p. 911).

FIG. 143.—Diagram of a transverse section through the developing hind-brain to show the relative positions of the nuclei of the different varieties of nerve components.



The caudal slope of the hind-brain constitutes the *myelencephalon,* which develops into the medulla oblongata. The nuclei of the ninth, tenth, eleventh and twelfth cranial nerves develop in the situations already indicated, and afferent fibres from the ganglia of the ninth and tenth nerves form an oval bundle in the marginal zone in the region of the alar lamina (fig. 142). The dorsal edge of the alar lamina throughout the rhombencephalon gives attachment to the thin expanded roof-plate and is termed the *rhombic lip.* As the walls of the rhombencephalon fall outwards, the rhombic lip forms a lateral edge (fig. 143) which becomes folded over the adjoining area (fig. 142). According to the generally accepted view it later becomes adherent to this area, and the cells of the rhombic lip migrate actively into the marginal zone of the basal lamina. In this way the oval bundle of the tractus solitarius becomes buried beneath the surface. The cells which migrate from the rhombic lip are believed to give origin to the olivary and arcuate nuclei and the scattered grey matter of the formatio reticularis. While this migration is in progress the thin floor-plate is invaded by fibres which cross the median plane, and it becomes thickened to form the median raphe.

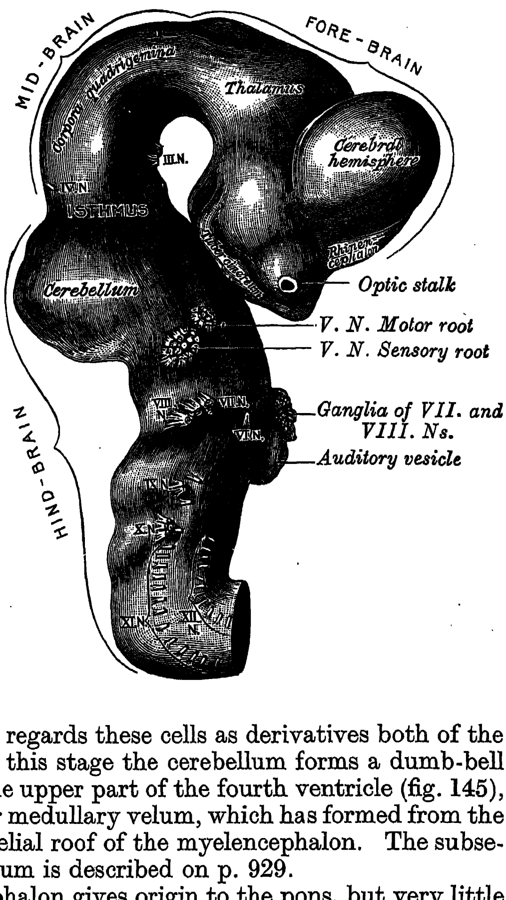
The lower part of the myelencephalon takes no part in the formation of the fourth ventricle, and, in its development, it closely resembles the spinal cord. The large nuclei, gracilis and cuneatus, are derived from the alar lamina, and

their efferent arcuate fibres play a large part in the formation of the median raphe.

About the fourth month the descending cerebrospinal fibres invade the ventral part of the medulla oblongata to form the pyramid and ascending fibres from the spinal cord, together with olivocerebellar and arcuate fibres, form the inferior cerebellar peduncle (restiform body).

The upper or headward slope of the hind-brain is termed the *metencephalon* and from it both the cerebellum and the pons are developed. Prior to the formation of the pontine flexure the alar laminæ of the metencephalon are parallel with one another. Subsequent to its formation the roof-plate of the hind-brain becomes rhomboidal and the alar laminæ of the metencephalon lie obliquely, being close to one another at the headward end of the fourth ventricle, but widely separated in the region of its lateral angles. The accentuation of the pontine flexure approximates the upper angle of the ventricle to the lower, and the alar laminæ of the metencephalon now lie almost horizontally and in line with each other.

Fig. 144.—The brain of a human embryo about 10·2 mm. long. Right lateral surface. (From a model by His.)



While these changes are occurring the cells in the rhombic lip and dorsal part of the alar lamina of the metencephalon proliferate to form the rudiment of the cerebellum. Two rounded swellings are formed which, at first, project partly into the ventricle (fig. 146), and they form the rudimentary cerebellar hemispheres. The uppermost part of the roof of the metencephalon originally separates the two swellings, but it becomes invaded by cells which form the rudiment of the vermis. Frazer * regards these cells as derivatives both of the basal and of the alar laminæ. At this stage the cerebellum forms a dumb-bell shaped swelling stretched across the upper part of the fourth ventricle (fig. 145), continuous above with the superior medullary velum, which has formed from the isthmus, and below with the epithelial roof of the myelencephalon. The subsequent development of the cerebellum is described on p. 929.

The remainder of the metencephalon gives origin to the pons, but very little is known of the individual stages in the transformation. Ependymal, mantle and marginal zones are formed in the usual way, and the nuclei of the fifth, sixth and seventh nerves develop in the mantle layer. It is probable that the grey matter of the formatio reticularis is derived from the basal lamina and that of the nuclei pontis from the alar lamina by the active migration of cells from the rhombic lip. About the fourth month the pons is invaded by cerebropontine and cerebrospinal fibres, becomes proportionately thicker, and takes on its adult appearance.

The region of the *isthmus rhombencephali* undergoes a series of changes which are very difficult to interpret. As a result, the greater part of the region apparently becomes taken up into the caudal end of the mid-brain, only the roof-plate, in which the superior (anterior) medullary velum is formed, and the dorsal parts of the alar laminæ, which become invaded by the fibres of the

* J. Ernest Frazer, *Manual of Embryology*, 1931.

superior cerebellar peduncles, remaining as recognisable derivatives in the adult. Frazer * believes that during the earlier changes the cells of the basal lamina extend dorsally until they meet in the roof-plate, and intervene between the alar lamina and the interior of the tube. In this way he provides an explanation for the dorsal position of the superficial origin of the fourth nerves, which, although apparently emerging from the dorsal aspect of the isthmus, are in reality emerging from its morphological floor.† It should be noted, too, that originally the decussation of the two fourth nerves is placed on the hind-brain side of the isthmus, but as the growth changes occur it is displaced in a headward direction until it reaches its adult position. The same author considers that these changes are also responsible (1) for the movement in the same direction of the nucleus of the fourth nerve, whereby it comes to lie in the mid-brain, and (2) for the position of the mesencephalic nucleus of the fifth nerve, which is also a derivative of the isthmus rhombencephali. (See footnote on p. 945.)

Fig. 145.—The cerebellum of a fœtus in the fifth month. (From Kollmann's Entwickelungsgeschichte.)

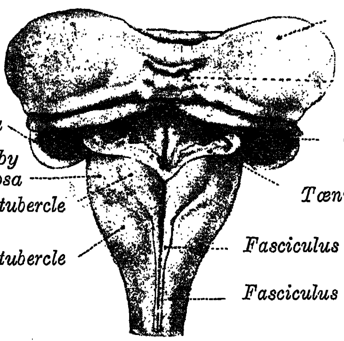


Fig. 146.—The hind-brain of a human embryo about three months old. Viewed from behind and partly from the right side. (From a model by His.)

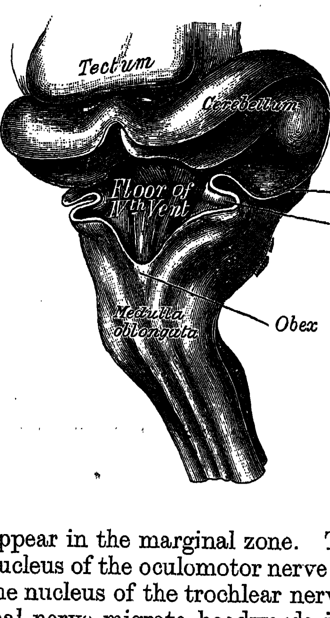


The **mesencephalon** or **mid-brain** (figs. 140, 144, 146, and 147 to 151) exists for a time as a thin-walled tube enclosing a cavity of some size, and is separated by slight constrictions from the isthmus and from the fore-brain. Its cavity becomes relatively reduced in diameter, and in the adult brain it forms the aqueduct of the mid-brain. The basal laminæ of the mid-brain increase in thickness to form the cerebral peduncles, which are at first of small size, but enlarge rapidly after the fourth month, when their fibre-tracts begin to appear in the marginal zone. The cells of the basal lamina give origin to the nucleus of the oculomotor nerve and to the grey matter of the tegmentum, while the nucleus of the trochlear nerve and the mesencephalic nucleus of the trigeminal nerve migrate headwards into the mid-brain owing to the developmental changes which occur in the isthmus rhombencephali. The cells of the dorsal

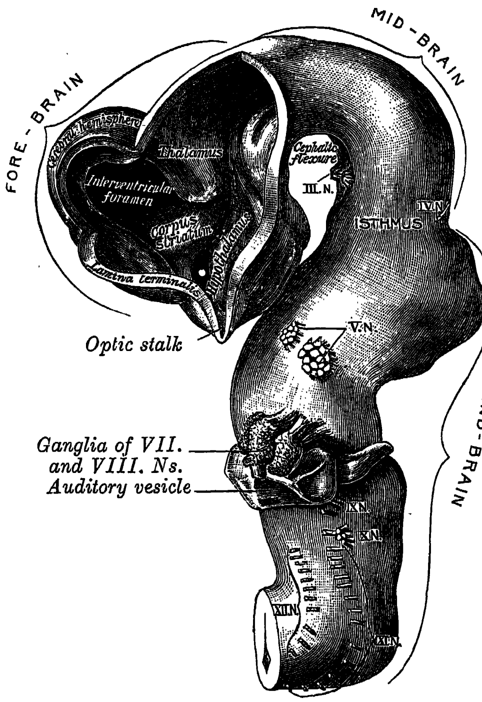
* J. Ernest Frazer, *Journal of Anatomy*, Oct. 1928, and *loc. cit.*

† Those who hold that the sulcus limitans is continued into the mid-brain, and has the same morphological value there as it has in the hind-brain and spinal cord, find it difficult to accept this explanation for the mode of behaviour of the trochlear nerves.

part of the alar laminæ proliferate and invade the roof-plate, which therefore becomes thickened and is later divided into corpora bigemina by a median groove. At its caudal end this groove becomes a median ridge, which persists in the adult as the frenulum veli. The corpora bigemina are later subdivided into corpora quadrigemina by a transverse furrow. The origin of the red nucleus, which is clearly defined at the end of the third month, is uncertain, but it is, on the analogy of the olivary nuclei of the medulla oblongata, formed probably by cells of the alar lamina which migrate in a ventrimedial direction.

The **prosencephalon** or **fore-brain.**—A transverse section through the early fore-brain shows the same parts as are displayed in similar sections of the spinal cord and medulla oblongata, viz. a pair of thick lateral walls connected by thin floor- and roof-plates. Moreover, each lateral wall is divided into a dorsal area and a ventral area separated internally by a furrow termed the *hypothalamic sulcus.* This sulcus ends anteriorly at the medial end of the optic stalk, and in the adult brain is retained as a slight groove extending backwards from the interventricular foramen to the aqueduct of the mid-brain.

FIG. 147.—The brain of a human embryo, about 10·2 mm. long. (From a model by His.)



At a very early period—in some animals before the closure of the cephalic part of the neural tube—two lateral diverticula termed the *optic vesicles* appear, one on each side of the fore-brain; for a time they communicate with the cavity of the fore-brain by relatively wide openings. The distal parts of the optic vesicles expand, while the proximal parts are reduced to tubular stalks termed the *optic stalks*; their further development is given on pp. 125 to 130. The fore-brain then grows forwards, and gives origin to two diverticula which rapidly expand to form two large pouches, one on each side. These diverticula subsequently form the cerebral hemispheres, and their contained cavities are the rudiments of the lateral ventricles; they communicate with the median part of the fore-brain cavity by relatively wide openings which ultimately form the interventricular foramen. The anterior part of the roof-plate of the fore-brain consists of a thin sheet termed the *lamina terminalis* (figs. 147, 150), which stretches from the interventricular foramen to the recess at the base of the optic stalk. The anterior part of the fore-brain, including the rudiments of the cerebral hemispheres, is named the *telencephalon,* and the posterior portion the *diencephalon*; both contribute to the formation of the third ventricle.

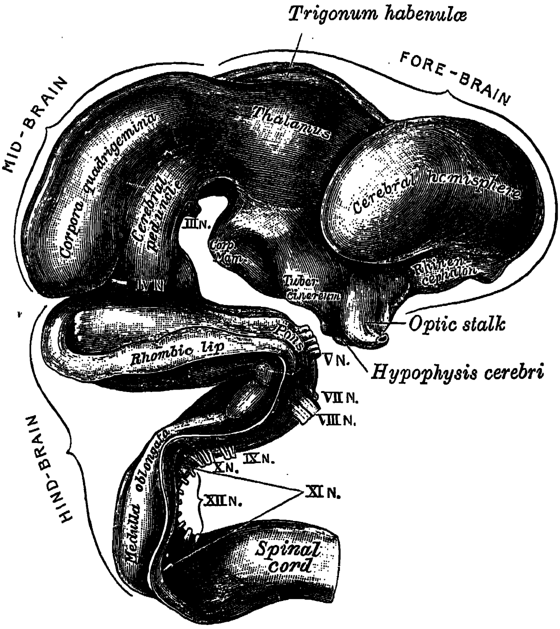
The *diencephalon.*—The thalamus and the metathalamus are developed from the dorsal area of the diencephalon. The *thalamus* (figs. 147 to 153) arises as a thickening which involves the anterior part of the dorsal area. Caudal to the thalamus, the lateral and medial geniculate bodies, which constitute the *metathalamus*, are recognisable at first as surface depressions. As the thalami enlarge they gradually narrow the wide interval between them into a slit-like cavity which forms the greater part of the third ventricle. After a time these medial surfaces come into contact and become adherent to each other over a variable area, the connexion constituting the *connexus interthalamicus* (*inter-*

mediate mass). The backward growth of the thalamus excludes the geniculate bodies from the lateral wall of the third ventricle.

At first the lateral aspect of the developing thalamus is separated from the medial aspect of the cerebral hemisphere by an extraneural cleft, but as growth proceeds the cleft becomes obliterated (p. 119) and the thalamus comes into intimate relationship with the corpus striatum. Later, with the development of the itinerant (projection) fibres of the neopallium, the thalamus becomes related to the internal capsule, which intervenes between it and the lateral part of the corpus striatum (lentiform nucleus).

Below (ventral) to the hypothalamic sulcus the lateral wall of the diencephalon forms a large part of the hypothalamus, including the lateral and posterior hypothalamic nuclei.

Fig. 148.—The brain of a human embryo, 13·6 mm. long. Right lateral aspect; the roof of the hind-brain has been removed. (From a model by His.)



The *epithalamus*, which includes the pineal body, the posterior commissure and the trigonum habenulæ, develops in association with the caudal part of the roof-plate and the adjoining portions of the lateral walls of the diencephalon. The pineal body arises as a hollow outgrowth from the roof-plate, immediately in front of the mesencephalon. Its distal portion becomes solid, but its proximal portion, or stalk, remains hollow, containing the recessus pinealis of the third ventricle. In many reptiles the pineal outgrowth is double. The anterior outgrowth (parapineal organ) develops into the pineal eye (p. 962) while the posterior outgrowth is glandular in character. It is the posterior outgrowth which is homologous with the pineal body in man. The anterior outgrowth also develops in the human embryo, but it very soon disappears entirely.

The posterior commissure is formed by fibres which invade the lower wall of the pineal recess from both sides.

The nucleus habenulæ, which is the most important constituent of the trigonum habenulæ, is formed from the lateral wall of the diencephalon and is at first in close relationship with the geniculate bodies, from which it becomes separated by the backward growth of the thalamus.

The roof-plate of the diencephalon, in front of the pineal body, remains thin and epithelial in character, and is subsequently invaginated by the choroid plexuses of the third ventricle. Prior to the development of the corpus callosum and the fornix it lies at the bottom of the longitudinal fissure, which separates the two cerebral hemispheres from each other.

The floor of the diencephalon takes part in the formation of the *hypothalamus*, including the corpora mamillaria, the tuber cinereum and the infundibulum of the hypophysis cerebri.

The corpora mamillaria arise as a single thickening which becomes divided by a median furrow during the third month. Anterior to the corpora mamillaria the tuber cinereum develops as a cellular proliferation which extends forwards as far as the infundibulum.

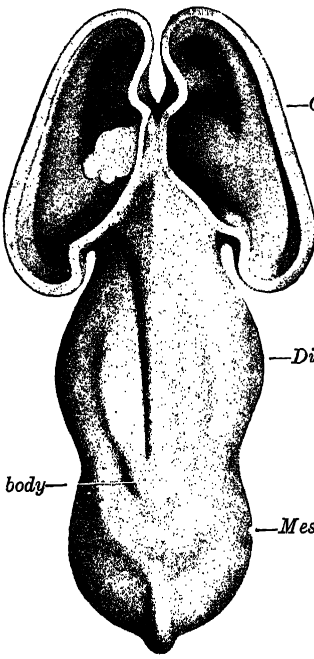
In front of the tuber cinereum the floor of the diencephalon gives origin to

a wide-mouthed diverticulum, which grows downwards and comes into relationship with the posterior aspect of Rathke's pouch (p. 166). These two ectodermal diverticula, the one derived from the floor of the neural tube and the other from the roof of the stomodœum, together form the *hypophysis cerebri* (fig. 209, p. 166). The upper end of the neural outgrowth persists as the infundibular recess of the third ventricle.

The optic vesicles, which are described with the development of the eye (p. 125), are derived from the lateral wall of the prosencephalon before the telencephalon can be identified. They are usually regarded as derivatives of the diencephalon, and the optic chiasma indicates the boundary between the di- and the telencephalon.

The *telencephalon* consists of a median portion and two lateral diverticula. The median portion forms the anterior part of the cavity of the third ventricle, and is closed below and in front by the *lamina terminalis*. The lateral diverticula consist of outward pouchings of the lateral walls of the prosencephalon, which may correspond to the alar laminæ, although this is uncertain; the cavities represent the future lateral ventricles, and their walls the nervous matter of the cerebral hemispheres. The roof-plate of the median part of the telencephalon remains thin, and is continuous behind with the roof-plate of the diencephalon. In the floor-plate and the lateral walls of the prosencephalon ventral to the primitive interventricular foramen the anterior part of the *hypothalamus* is developed; this includes the optic chiasma and the optic recess. The optic chiasma is formed by the meeting and partial decussation of the optic nerves which subsequently grow backwards as the optic tracts and end in the diencephalon and mid-brain.

FIG. 149.—Dorsal view of the prosencephalon of a human embryo 13·6 mm. long (after His). Observe that the cerebral hemispheres are just beginning to overlap the diencephalon.



The cerebral hemispheres arise as diverticula of the lateral walls of the telencephalon, with which they remain in continuity around the upper, anterior and lower margins of the large, interventricular foramen. At the posterior margin of the foramen the wall of the hemisphere is continuous with the anterior part of the lateral wall of the diencephalon (fig. 147); as growth proceeds the hemisphere enlarges forwards, upwards and backwards and acquires an oval outline, with medial and superolateral walls and a floor. As a result the medial surfaces are separated from each other by a cleft which subsequently becomes the longitudinal fissure. At this stage the floor of the cleft is formed by the epithelial roof-plate of the telencephalon, which is directly continuous posteriorly with the epithelial roof-plate of the diencephalon (fig. 151).

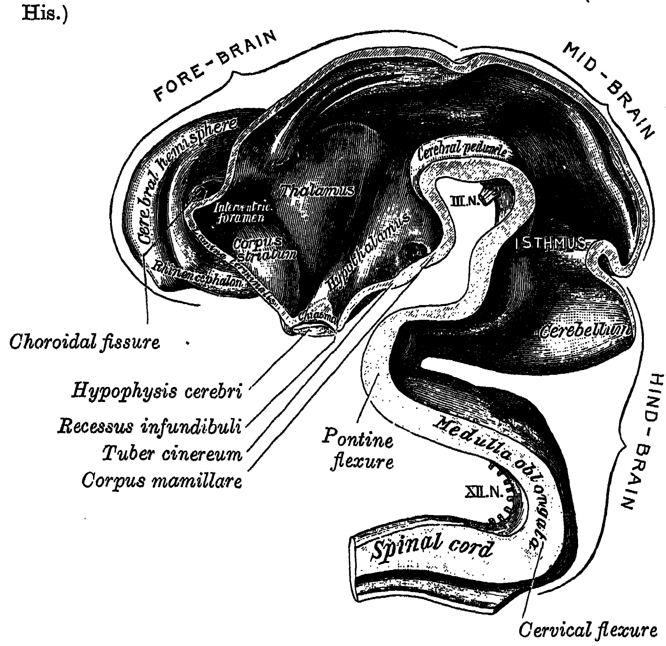
The anterior pole of the oval hemisphere becomes the frontal pole, but, as the hemisphere enlarges, its original posterior pole is apparently carried downwards and forwards to form the temporal pole and a new posterior pole becomes defined, which will persist as the occipital pole of the adult brain. The enormous expansion of the cerebral hemispheres is characteristic of the mammalia and especially of man, and in their subsequent growth they hide, successively, the diencephalon, the mesencephalon and the cerebellum.

About the fourth week a longitudinal groove appears in the anteromedial

part of the floor of the ventricle. This groove deepens and forms a hollow diverticulum connected to the hemisphere by a short stalk. The diverticulum becomes connected on its ventral or inferior surface to a ganglionic mass, the cells of which receive the afferent axons of the sensory cells of the olfactory plate. As the head increases in size the diverticulum grows forwards and, subsequently losing its cavity, becomes converted into the solid olfactory bulb. The forward growth of the bulb is accompanied by the elongation of its stalk, which forms the olfactory tract, and the portion of the floor of the hemisphere to which the tract is attached constitutes the *piriform area.*

The pia mater which covers the epithelial roof of the third ventricle at this stage consists of loosely arranged mesenchyme. In the meshes of this tissue numerous blood-vessels develop, and on each side of the median plane these

Fig. 150.—The brain of a human embryo 13·6 mm. long. Medial surface of right half. The roof of the hind-brain has been removed. (From a model by His.)

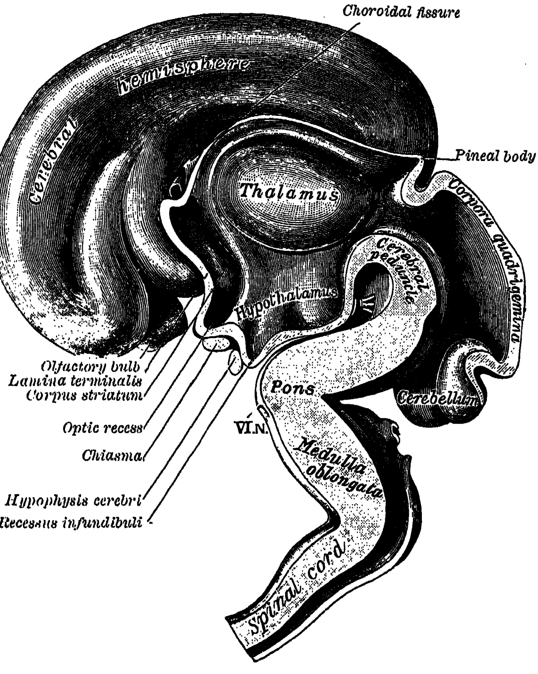


vessels subsequently invaginate the roof of the ventricle to form its *choroid plexuses.* The lower part of the medial wall of the hemisphere, which immediately adjoins the epithelial roof of the interventricular foramen and the anterior extremity of the diencephalon, remains epithelial in character while elsewhere the walls of the hemisphere are thickening to form the pallium. This thin part of the medial wall of the hemisphere is invaginated by vascular tissue, continuous in front with the choroid plexus of the third ventricle and constituting the choroid plexus of the lateral ventricle. This invagination occurs along a line which passes upwards and backwards, parallel with the anterior and upper boundaries of the interventricular foramen, and the curved indentation of the ventricular wall is termed the *choroidal fissure.*

At first growth proceeds more actively in the floor and the adjoining part of the lateral wall of the developing hemisphere, and an elevation is formed which encroaches on the cavity of the lateral ventricle. This elevation is the rudimentary *corpus striatum,* and it extends forwards to the floor of the interventricular foramen where it is separated from the developing anterior end of the thalamus only by a groove. Posteriorly the corpus striatum is, from the beginning, in close relationship to the temporal pole of the hemisphere and, when the occipital pole grows backwards and the general enlargement of the hemisphere carries the temporal pole downwards and forwards, it is continued from the floor of the body of the ventricle into the roof of the inferior horn.

As the hemisphere enlarges the posterior part of its medial surface overlaps and hides the lateral surface of the diencephalon (thalamic part), being separated from it by a narrow cleft occupied by vascular connective tissue. At this stage (end of second month) a transverse section made behind the interventricular foramen passes successively through: (1) the developing thalamus, (2) the narrow cleft just mentioned, (3) the thin medial wall of the hemisphere, and (4) the cavity of the lateral ventricle with the corpus striatum in its floor and lateral wall (fig. 152, A). As the thalamus increases in extent it acquires a superior, in addition to its medial and lateral surfaces, and the lateral part of its superior surface fuses with the thin medial wall of the hemisphere, so that, in the adult, this part of the thalamus is covered with the ependyma of the lateral ventricle immediately below the choroidal fissure (fig. 152, B). As a

FIG. 151.—The brain of a human embryo, about three months old. Medial surface of right half. (From a model by His.)



result the corpus striatum is approximated to the thalamus and separated from it only by a deep groove, which becomes obliterated by increased growth along the line of contact. The lateral aspect of the thalamus is now in continuity with the medial aspect of the corpus striatum, so that a secondary union between the diencephalon and the telencephalon is effected over a wide area, providing a satisfactory and convenient route for the subsequent passage of itinerant (projection) fibres to and from the pallium.

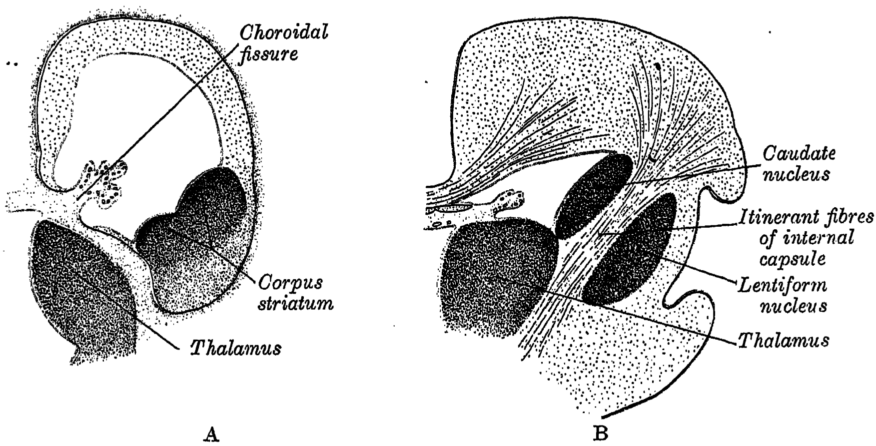
The pallial area which borders the interventricular foramen and lies outside the choroidal fissure constitutes the *archipallium*, and is associated with the reception, interpretation and association of olfactory impressions. It is the first part of the pallium to undergo differentiation, and at first it forms a continuous, almost circular strip on the medial and inferior aspects of the hemisphere, i.e. along the medial fringe of the pallium. Below and in front, where the stalk of the olfactory tract is attached, it constitutes the *piriform area*. The area outside the curve of the choroidal fissure constitutes the *hippocampal formation* (fig. 153).

In this region the cells of the pallium proliferate, and the wall of the hemisphere thickens and produces an elevation which projects into the medial side of the ventricle. This elevation is the *hippocampus*. It appears first on the medial wall of the hemisphere above the area in front of the lamina terminalis

(preterminal area) and gradually extends backwards into the region of the temporal pole where it adjoins the piriform area. The marginal zone in the region of the hippocampus becomes invaded by nerve cells which form the *dentate gyrus*. This structure is practically co-extensive with the hippocampus, and, like it, extends from the preterminal area backwards above the choroidal fissure and follows its curve downwards and forwards towards the temporal pole, where it runs into the piriform area. A shallow surface depression, which has been termed the *hippocampal sulcus*, grooves the medial surface of the hemisphere in the region of the hippocampal formation, but it is not responsible for the elevation which the hippocampus forms in the interior of the ventricle.

The efferent fibres from the cells of the hippocampus collect along its medial edge and run forwards immediately above the choroidal fissure. Anteriorly

FIG. 152.—Diagrams illustrating transverse sections across the developing thalamus and cerebral hemisphere.



In *A* the lateral aspect of the thalamus is separated from the medial aspect of the hemisphere by an interval containing vascular mesenchyme.

In *B* this interval has disappeared; the expanded upper surface of the thalamus is covered by the ependyma of the lateral ventricle; and the approximation of the thalamus and the corpus striatum has provided a pathway for the itinerant (projection) fibres of the internal capsule.

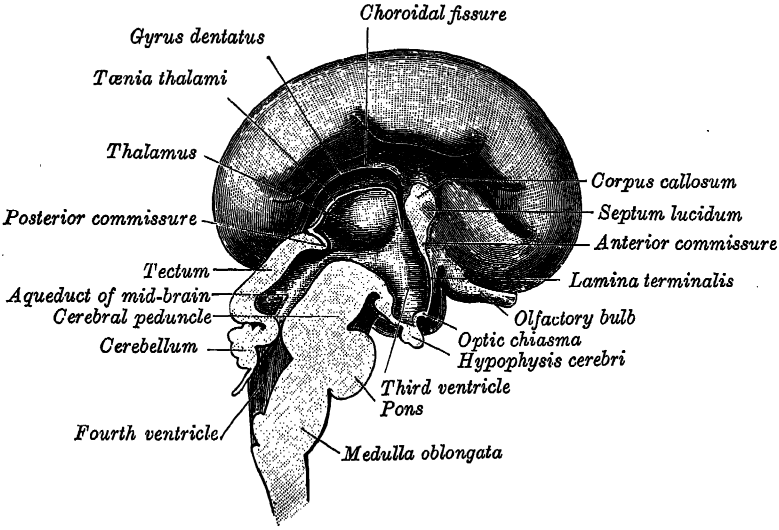
they turn downwards and enter the lateral part of the lamina terminalis in order to gain the hypothalamus, where they terminate in the corpus mamillare. These efferent, hippocampal fibres form the *fimbria* and the *fornix*.

The development of the commissures effects a very profound alteration on the medial wall of the hemisphere. At the time of their appearance the two hemispheres are connected to each other by the median part of the telencephalon. The roof-plate of this area remains epithelial and non-nervous, while its floor becomes invaded by the fibres of the optic nerves. These two routes are not available for the passage of commissural fibres passing from hemisphere to hemisphere across the median plane, and these fibres are therefore compelled to pass through the anterior wall of the interventricular foramen, i.e. the *lamina terminalis*. The first commissures to develop are those associated with the rhinencephalon. Fibres of the olfactory tracts cross in the ventral or lower part of the lamina terminalis and constitute the anterior part of the *anterior commissure*. In addition the two hippocampi become connected to each other by transverse fibres which cross from fornix to fornix in the upper part of the lamina terminalis and give origin to the *hippocampal commissure*.

The neopallial commissures develop later and follow the pathways already established by the commissures of the rhinencephalon. Fibres coming from the tentorial surface of the hemisphere join the anterior commissure and constitute its larger, posterior part. All the other commissural fibres of the neopallium associate themselves closely with the hippocampal commissure and lie on its dorsal surface. These fibres increase enormously in number, and the bundle rapidly outgrows its neighbours to form the corpus callosum (fig. 153).

The first fibres of the corpus callosum lie within the limits of the lamina terminalis, but as the commissure increases in size it extends forwards and upwards and then backwards far beyond those limits. Since the fibres which enter the commissure from the temporal, parietal and occipital regions outnumber those coming from the frontal region, the principal enlargement occurs in a backward direction. As the corpus callosum grows backwards it extends above the choroidal fissure, carrying the hippocampal commissure on its under surface. In this way a new floor is formed for the longitudinal fissure, and additional structures come to lie above the epithelial roof of the third ventricle. In its backward growth the corpus callosum invades the area hitherto occupied

FIG. 153.—The brain of a human embryo, four months old. Medial surface of left half. (Marchand.)



by the upper part of the hippocampal formation, and the corresponding parts of the dentate gyrus (fig. 153) and hippocampus are reduced to mere vestiges, viz. the indusium griseum and the longitudinal striæ.

The lower parts of both the dentate gyrus and the hippocampus persist, for owing to the forward growth of the temporal lobe the brain stem presents an impassable barrier to further growth of the corpus callosum.

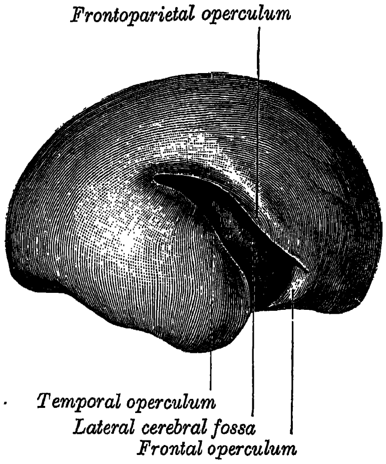
The growth of the neopallium and its enormous expansion is associated with the appearance of the itinerant (projection) fibres during the latter part of the third month. These fibres follow the pathway provided by the apposition of the lateral aspect of the thalamus with the medial aspect of the corpus striatum, and, as they do so, they divide the latter, almost completely, into a lateral part (the lentiform nucleus), and a medial part (the caudate nucleus), these two nuclei remaining unseparated only in their antero-inferior portions.

At the end of the third month the lateral aspect of the cerebral hemisphere shows a slight depression above and in front of the temporal pole. This hollow corresponds to the site of the corpus striatum in the floor and lateral wall of the ventricle, and its presence is due to the more rapid growth of the adjoining pallial areas. This lateral cerebral fossa gradually becomes overlapped and submerged so that the fossa is converted into the lateral cerebral sulcus and its floor becomes the insula (fig. 154). The process, however, is not completed in its most anterior part until after birth.

The growth changes in the temporal lobe which help to submerge the insula produce important changes in the rhinencephalon. The olfactory tract is continuous, on the one hand, with the medial olfactory gyrus, which turns upwards in front of the lamina terminalis, and, on the other hand, with the lateral olfactory gyrus, which is directly continuous with the piriform area. The forward growth of the temporal pole and the general expansion of the neopallium cause the lateral olfactory gyrus to bend laterally, the summit

of the convexity lying at the antero-inferior corner of the developing insula (fig. 155). During the fourth and fifth months the piriform area becomes submerged by the adjoining neopallium, and in the adult only a part of it remains visible on the inferior aspect of the cerebrum.

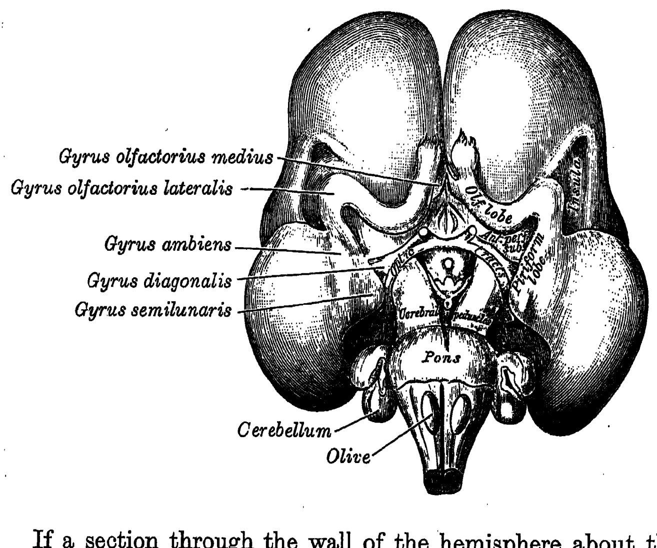
FIG. 154.—The right cerebral hemisphere of a human embryo, about five months old. Lateral surface.



Apart from the shallow hippocampal sulcus and the lateral cerebral fossa the surfaces of the hemisphere remain smooth and uninterrupted until the beginning of the fourth month (fig. 154). The parieto-occipital sulcus appears about that time on the medial aspect of the hemisphere, and its appearance is due to the traction exerted by the splenial fibres of the corpus callosum. At about the same period the postcalcarine sulcus appears as a shallow groove extending forwards from the region of the occipital pole. It is a true infolding of the cortex and forms in the long axis of the striate area, producing at the same time an elevation named the calcar avis on the medial wall of the posterior horn of the ventricle.

During the fifth month the sulcus cinguli appears on the medial aspect of the hemisphere, but it is not until the sixth month that sulci appear on the inferior and superolateral aspects. The central, precentral and postcentral sulci appear each in two parts, upper and lower, which usually coalesce shortly afterwards, although they may remain ununited. The superior and inferior frontal, the intraparietal, occipital, temporal and collateral sulci make their appearance during the same period, and by the end of the seventh month all the important sulci can be recognised.

FIG. 155.—The brain of an embryo at the beginning of the fourth month. Inferior surface. (Kollmann.)



If a section through the wall of the hemisphere about the sixth week be examined microscopically it is seen to consist of a thin marginal layer, an intermediate mantle layer and an inner, thick ependymal layer. It therefore resembles the spinal cord at the same stage. Thereafter, however, neuroblasts from the ependymal and mantle layers migrate into the deep part of the marginal layer and form the cells of the cerebral cortex in that situation. The differentiation of the cortex is described on p. 988.

At birth the volume of the brain is approximately 25 per cent. of its volume in adult life. The greater part of the increase occurs during the first year of life, at the end of which the volume of the brain has increased to 75 per cent. of its adult volume. The growth can be accounted for partly by increase in the size of the nerve-cells in the cerebral blood-vessels, but it is the acquisition of their medullated sheaths by the nerve fibres which is principally responsible for it. The great sensory pathways, visual, auditory and somatic, become medullated first, and later the pyramidal fibres. During the second year and subsequent years growth proceeds much more slowly, and the brain attains its adult size by the seventeenth or eighteenth year. The continued growth is connected with the continued medullation of nerve fibres.

A summary of the parts derived from the cerebral vesicles is given in the following table :—

Rhombencephalon or hind-brain	1. Myelencephalon	Medulla oblongata. Lower part of fourth ventricle.
	2. Metencephalon	Pons. Cerebellum. Intermediate part of fourth ventricle.
	3. Isthmus rhombencephali	Superior medullary velum. Superior cerebellar peduncles. Upper part of fourth ventricle.
Mesencephalon or mid-brain		Cerebral peduncles. Tectum (lamina quadrigemina). Aqueduct.
Prosencephalon or fore-brain	1. Diencephalon	Thalamus. Metathalamus. Epithalamus. Posterior part of hypothalamus. Posterior part of third ventricle.
	2. Telencephalon	Anterior part of third ventricle. Anterior part of hypothalamus. Cerebral hemispheres. Lateral ventricles. Interventricular foramen.

The cranial (cerebral) nerves.—With the exception of the olfactory and optic nerves, which will be considered separately, the cranial nerves are developed in a similar manner to the spinal nerves.

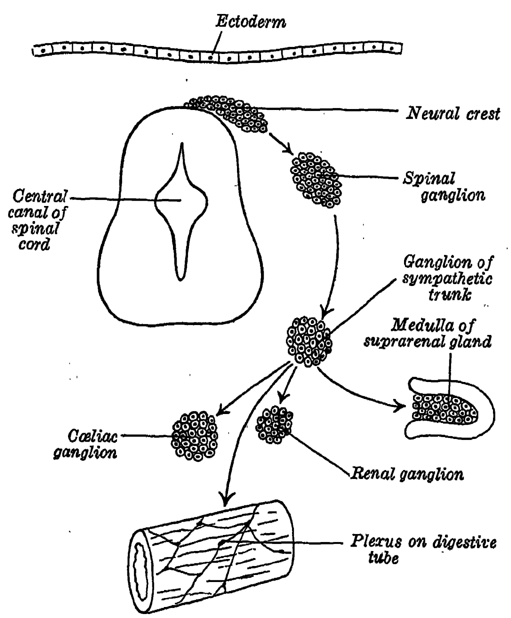
The fibres of the motor cranial nerves are the axons of cells in the basal lamina of the mid- and hind-brains, and pass outwards to their distribution, but whereas the motor fibres of the spinal nerves form one series, those of the cranial nerves form two, according as they are derived from the medial or lateral parts of the basal lamina. The first series comprises the oculomotor, trochlear, abducent and hypoglossal nerves ; the second comprises the accessory nerve, and the motor parts of the trigeminal, facial, glossopharyngeal and vagus nerves, all of which supply the striped muscles derived from the visceral arches.

As the lips of the neural groove fuse with each other in the region of the hind-brain, a *ganglion-crest* is formed which is homologous with the neural crest of the spinal cord. The ganglia of the vagus, glossopharyngeal, auditory (in part), facial and trigeminal nerves are derived from the ganglion-crest, but they migrate ventrally and soon come to lie on the ventrilateral aspect of the hind-brain. It is probable that the crest is not the sole source of origin of the cells in some of these ganglia. Thickened patches of ectoderm (epibranchial placodes) which are developed at the dorsal ends of the branchial clefts probably contribute cells to the facial, glossopharyngeal and vagal ganglia, and the cells of the auditory vesicle are believed to make a substantial contribution to the formation of the ganglia on the auditory nerve. The central processes of the cells of these ganglia form the sensory roots of these nerves and

enter the alar lamina of the hind-brain, while their peripheral processes enter the nerves themselves. The incoming fibres from the facial, glossopharyngeal and vagus nerves collect to form an oval bundle, termed the tractus solitarius (p. 112), on the lateral aspect of the myencephalon. This bundle is the homologue of the oval bundle of the spinal cord.

The **autonomic system.**—The ganglion cells of the *sympathetic system* are derived from the neural crest through the medium of the primitive spinal ganglia. Certain of the cells in the ventral parts of these ganglia migrate towards the sides of the aorta, where they subsequently form the ganglia of the sympathetic trunks. Others migrate still further and eventually form the subsidiary sympathetic ganglia (fig. 156). In the rabbit the original migration is limited to the thoracic and upper lumbar regions. Thereafter the chain grows headwards and tailwards until the whole trunk is laid down. The view has been advanced that the sympathetic ganglion cells are, at least in part, derived from cells which migrate from the basal lamina along the anterior nerve roots. The results of destruction of the neural crest in chick embryos and of excision of the neural crest and portions of the neural tube in frog embryos have been somewhat contradictory in the hands of different investigators. On the whole the balance of the evidence favours the earlier view.

FIG. 156.—Diagram showing the chief derivatives of the neural crest.



The ganglion cells of the cranial part of the *parasympathetic system* are probably derived from the ganglion crest through the medium of the primitive ganglia of the fifth, seventh, ninth and tenth cranial nerves. The ciliary ganglion is formed by cells which migrate from the trigeminal (semilunar) ganglion along the ophthalmic nerve, but it almost certainly is reinforced by cells migrating from the nucleus of the oculomotor nerve. The sphenopalatine ganglion receives contributions from the ganglia of the fifth and seventh nerves; the otic from those of the fifth and ninth; and the submandibular (submaxillary) from those of the fifth and seventh cranial nerves.

The **meninges.**—The dura mater, which is always intimately related to skeletal structures, is mesodermal in origin. The arachnoid mater and the pia mater, however, are more closely related to the brain and the spinal cord, and, although it is customary to regard them as mesodermal in origin, recent experimental work * is strongly suggestive of their derivation from the neural crest ectoderm. Portions of the neural tube transplanted without the adjoining portion of the neural crest develop a covering of dura mater, but no fluid spaces, such as the subarachnoid space, are formed and no choroid plexus develops. If, however, the adjoining part of the neural crest is included in the graft, the transplant develops coverings of arachnoid mater and pia mater and subarachnoid and subdural spaces in addition to an outer covering of dura mater.

The **chromaffin organs.**—The tissue from which the sympathetic ganglia are formed is at first a syncytium of cells termed *sympathochromaffin cells*, but later two varieties of cells—small and large—are differentiated from it; the small cells (sympathoblasts) are transformed into the sympathetic nerve-cells, the large become chromaffin cells, and, separating from the others, accumulate to

* S. C. Harvey and H. S. Burr, *Arch. of Neurology and Psychiatry*, vol. xv., 1926.

form the chromaffin organs. In the trunk of the sympathetic the chromaffin bodies are situated in depressions in the ganglia; the medulla of the suprarenal glands is formed from the chromaffin cells (fig. 156). In connexion with certain, but not all, of the secondary plexuses of the sympathetic system chromaffin organs are found; the largest members of this series are the *aortic bodies*, which lie along the sides of the abdominal aorta between the superior mesenteric and common iliac arteries; to this group belong also the *carotid glomera* (carotid bodies). After birth the aortic bodies and the chromaffin bodies of the sympathetic ganglia degenerate and can no longer be isolated by gross dissection, but chromaffin tissue can be recognised with the microscope in the sites originally occupied by them.

The suprarenal glands.—Each suprarenal gland consists of a cortical portion derived from the cœlomic epithelium and a medullary portion originally composed of sympathochromaffin tissue. The cortical portion is first recognisable about the beginning of the sixth week as a series of buds from the cœlomic cells at the root of the mesentery. Later these buds are separated from the cœlomic epithelium and form a suprarenal ridge projecting into the cœlom between the mesonephros and the root of the mesentery. In the eighth week cells from the neighbouring masses of sympathochromaffin tissue migrate into this cortical portion along the line of its central vein and form the medullary portion of the gland.

The nose.—The development of the nose has already been considered (pp. 92 to 97).

The *olfactory nerves* are developed from the cells of that part of the ectoderm which lines the olfactory pits; these cells undergo proliferation and give rise to what are termed the *olfactory cells* of the nose. The central processes of these cells are usually described as growing into the overlying olfactory bulb and forming the olfactory nerves. It has, however, been shown that the olfactory cells are from the first connected with the brain by a bridge of protoplasm which is never severed, and that the olfactory nerve fibres are developed in this bridge.*

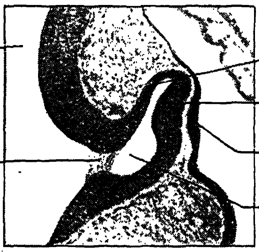
The eyes.—The rudiments of the eyes appear as a pair of hollow diverticula from the lateral aspects of the fore-brain. These diverticula are visible before the closure of the anterior neuropore; after its closure they are known as the *optic vesicles*. They project towards the sides of the head, and the distal part of each expands while the proximal part remains narrow and constitutes the *optic stalk* (figs. 157, 159). A small area of ectoderm overlying the optic vesicle becomes thickened and depressed in its centre. The depression deepens and its edges come together and fuse so as to enclose a hollow vesicle (figs. 157, 158) which soon loses its connexion with the surface ectoderm. This is the *lens-vesicle*, or rudiment of the lens. The outer wall of the optic vesicle increases in thickness and undergoes invagination so that the vesicle is converted into a cup, termed the *optic cup*, consisting of two strata of cells (fig. 158). These two strata are continuous with each other at the cup-margin, which ultimately overlaps the front of the lens and reaches as far forward as the future aperture of the pupil. The invagination is not limited to the outer wall of the vesicle, but involves also its caudal surface and extends in the form of a groove for some distance along the optic stalk, and thus, for a time, a wide gap, termed the *choroidal fissure*, exists in the caudal part of the cup (fig. 159). Through the groove and fissure mesenchyme extends into the optic stalk and cup, carrying the hyaloid artery with it; as growth proceeds, the edges of the fissure become approximated and they close during the seventh week, including the artery in the distal portion of the stalk. Sometimes the choroidal fissure persists, and when this occurs the choroid and iris in the region of the fissure remain undeveloped, giving rise to the condition known as *congenital coloboma* of the choroid or iris.

The retina is developed from the optic cup. The outer stratum of the cup persists as a single layer of cells, which assume a columnar shape, acquire pigment, and form the pigmented layer of the retina, the pigment first appearing

* Consult (*a*) an article on "The Cerebral Cortex in Lepidosiren," by Grafton Elliot Smith, *Anatomischer Anzeiger*, Band 33, p. 513, and (*b*) an article by Frances M. Ballantyne on "The Continuity of the Vertebrate Nervous System," *loc. cit.*

in the cells near the edge of the cup. The cells of the inner stratum proliferate and form a layer of considerable thickness from which the nervous elements and the sustentacular fibres of the retina, together with a portion of the vitreous body, are developed. In the portion of the cup which overlaps the lens the inner stratum is not differentiated into nervous elements, but persists as a

Fig. 157.—Section through the optic vesicle of a mole embryo, 3·5 mm. long.



layer of columnar cells which, together with the corresponding part of the pigmented layer, form the *pars ciliaris* and *pars iridica retinæ*.

The cells of the inner layer of the cup proliferate and form an outer nuclear zone and an inner marginal zone, devoid of nuclei. At 12 mm. the cells of the nuclear zone invade the marginal zone, and at 17 mm. the nervous stratum of the retina consists of inner and outer neuroblastic layers, separated by a narrow fibre layer, which disappears as differentiation proceeds. The inner neuroblastic layer gives origin to the ganglion cells, the amacrine

Fig. 158.—Section through the developing eye of a mole embryo, 6·5 mm. long.

cells and the nuclei of the sustentacular fibres ; the outer neuroblastic layer gives origin to the horizontal cells, the bipolar nuclei and the nuclei of the rods and cones, which first appear in the central part of the retina. By the eighth month all the layers of the retina can be identified.*

The optic stalk is converted into the optic nerve by the obliteration of its cavity and the growth of nerve-fibres into it. Most of these fibres are centripetal, and are the axons of the nerve-cells of the ganglionic layer of the retina, but a few are centrifugal and are derived from nerve-cells in the brain. The fibres of the optic nerve receive their medullary sheaths about the tenth week after birth. The optic chiasma is formed by the meeting and partial decussation of the fibres of the two optic nerves, and it marks the junction of the telencephalon with the diencephalon in the floor of the third ventricle. Behind the chiasma the fibres are continued backwards as the optic tracts to the lateral geniculate bodies.

* Ida C. Mann, *Journal of Anatomy*, July, 1927.

The lens is developed from the lens-vesicle, which recedes within the margin of the cup, and becomes separated from the overlying ectoderm by mesenchyme. The cells forming the posterior wall of the vesicle lengthen and are converted into the lens-fibres, which grow into and fill the cavity of the vesicle (fig. 161). The cells forming the anterior wall retain their cellular character, and form

Fig. 159.—The optic cup and the choroidal fissure of a human embryo, about five weeks old. Ventral aspect. (Kollmann.)

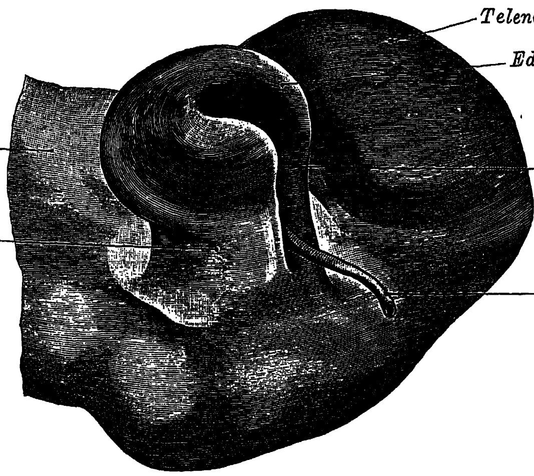


Fig. 160.—A section through the eye of a rabbit embryo, about eighteen days old. ×30. (Kölliker.)

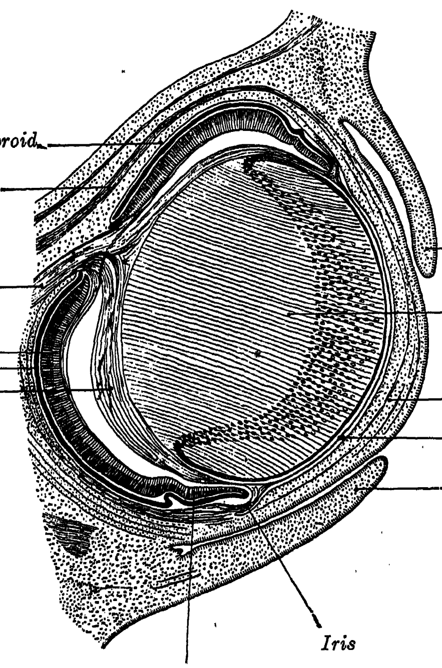
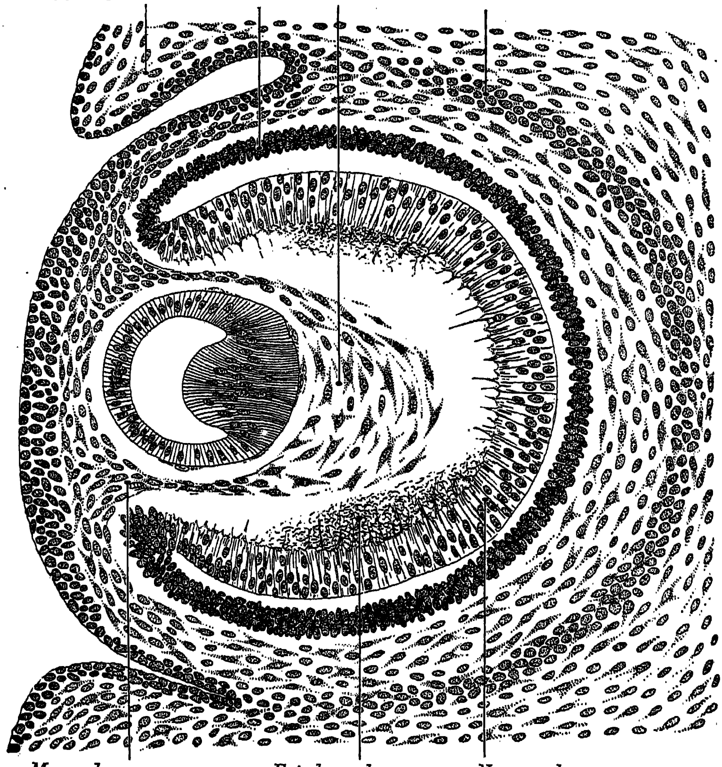


the epithelium on the anterior surface of the fully developed lens; at the equator of the lens the gradual transition of the cells into lens-fibres can be seen. By the second month the lens is invested by a vascular mesenchymal capsule termed the *capsula vasculosa lentis*, the ventral part of which, covering the lens, is named the *pupillary membrane*; the blood-vessels supplying the dorsal part of this capsule are derived from the hyaloid artery; those for the

ventral part from the anterior ciliary arteries. By the sixth month all the vessels of the capsule are atrophied except the hyaloid artery, which becomes occluded during the eighth month of intra-uterine life. Prior to this, during the fourth month, the hyaloid artery gives off retinal branches, and its proximal part persists in the adult as the central artery of the retina. The hyaloid canal, which gives passage to the artery through the vitreous, persists after the vessel has become occluded. In the newly-born child it extends more or less horizontally from the optic disc (papilla) to the posterior aspect of the lens but, when the adult eye is examined with the slit-lamp, it can be seen to follow a

FIG. 161.—A sagittal section through the eye of a human embryo, about six weeks old. (Kollmann.)



wavy, curved course, sagging downwards as it passes forwards to the lens.* With the loss of its blood-vessels the capsula vasculosa lentis disappears, but sometimes the pupillary membrane persists at birth, giving rise to the condition termed *congenital atresia of the pupil.*

The vitreous body is developed between the lens and the optic cup. The lens-rudiment and the optic vesicle are at first in contact with each other, but after the closure of the lens-vesicle and the formation of the optic cup the former is withdrawn from the retinal layer of the cup; the two, however, remain connected by a network of delicate protoplasmic processes. This network, derived partly from the cells of the lens and partly from those of the retinal layer of the cup, constitutes the primitive vitreous body (fig. 161). At first these protoplasmic processes spring from the whole of the retinal layer of the cup, but later are limited to the ciliary region, where by a process of condensation they appear to form the zonula ciliaris. The mesenchyme which enters the cup through the choroidal

* Ida C. Mann, *Journal of Anatomy,* vol. lxii.

fissure and around the equator of the lens becomes intimately united with this reticular tissue, and contributes to the formation of the vitreous body, which is therefore derived partly from the ectoderm and partly from the mesoderm.

The aqueous chamber of the eye appears as a cleft in that part of the mesenchyme which intervenes between the lens and the ectoderm. The layer of mesenchyme ventral to the cleft forms the substantia propria of the cornea, that dorsal to the cleft the mesenchymal stroma of the iris and the pupillary membrane.

The sclera and choroid are derived from the mesenchyme surrounding the optic cup, and the anterior part of the choroid is modified to form the ciliary body and ciliary processes. The fibres of the ciliaris muscle are derived from the mesoderm, but those of the sphincter and dilatator pupillæ are of ectodermal origin, being developed from the cells of the pupillary part of the optic cup.

The eyelids are formed as small cutaneous folds (fig. 161). About the middle of the third month their edges come together and unite over the cornea; they remain united until about the end of the sixth month.

The epithelium of the alveoli and ducts of the lacrimal gland arise as a series of tubular buds from the ectoderm of the superior conjunctival fornix; these buds are arranged in two groups, one forming the gland proper, and the other its palpebral process. The lacrimal sac and nasolacrimal duct result from a thickening of the ectoderm in the *naso-optic furrow* between the lateral nasal and maxillary processes (p. 93). This thickening forms a solid cord of cells which sinks into the mesenchyme; during the third month the central cells of the cord break down, and a lumen—the nasolacrimal duct—is established. The lacrimal canaliculi arise as buds from the upper part of the cord of cells and secondarily establish openings (puncta lacrimalia) on the margins of the lids; the inferior canaliculus cuts off a small part of the lower eyelid to form the caruncula lacrimalis (Ask). The epithelium of the cornea and conjunctiva is of ectodermal origin, as are also the eyelashes and the lining cells of the tarsal and other glands which open on the margins of the eyelids.

The ears.—The rudiments of the internal ears appear shortly after those of the eyes, as two patches of thickened, surface ectoderm, termed the *auditory plates*, which are situated in the region of the hind-brain. Each auditory plate is invaginated and converted into an *auditory pit* (fig. 162). The mouth of the pit is then closed, and a vesicle, termed the *auditory* (*otic*) *vesicle* or *otocyst,* is formed (fig. 163); from it the epithelial lining of the membranous labyrinth is derived. The vesicle assumes a flask-shape, and the neck of the flask is obliterated (fig. 164). From the vesicle certain diverticula are given off which form the various parts of the membranous labyrinth. The first to appear springs from the middle part and forms the ductus and saccus endolymphaticus. A second, from the ventral end, elongates, and forms the coiled tube of the cochlear duct, the proximal or vestibular extremity of which is subsequently constricted to form the ductus reuniens. Before the rudiment of the cochlea can be identified, three diverticula appear as disc-like evaginations from the dorsal part of the vesicle; the central parts of the walls of the discs coalesce and disappear, while the peripheral portions of the discs persist to form the semicircular ducts; the superior duct is the first, and the lateral the last, to be completed (fig. 165). The central part of the vesicle represents the membranous vestibule, and is subdivided by a constriction into a smaller, ventral part termed the saccule, and a larger, dorsal part termed the utricle (fig. 166). This subdivision is effected by a fold which extends deeply into the proximal part of the ductus endolymphaticus, with the result that the utricle and saccule ultimately communicate with each other by means of a Y-shaped canal. The saccule opens into the cochlear duct, through the canalis reuniens; the semicircular ducts communicate with the utricle.

The mesenchyme surrounding the various parts of the epithelial labyrinth is converted into a cartilaginous ear-capsule, and this is finally ossified to form the bony labyrinth of the internal ear. For a time the cartilaginous ear capsule is incomplete, and the cochlear, vestibular, and facial ganglia are situated in the gap between its canalicular and cochlear parts. These ganglia are soon covered by an outgrowth of cartilage and at the same time the facial nerve is bridged by a growth of cartilage from the cochlear to the canalicular parts of the capsule. In the embryonic connective tissue between the cartilaginous capsule

and the epithelial wall of the labyrinth the perilymphatic spaces are developed. Streeter * states that the rudiment of the *periotic cistern* or vestibular perilymphatic space, can be seen in an embryo of from 30 to 40 mm. in length, in the reticulum between the saccule

Fig. 162.—A section through the hind-brain and auditory pits of a human embryo, about twenty-four days old. (Kollmann.)

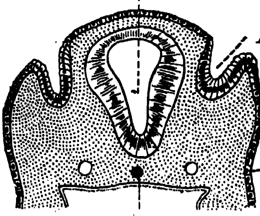


Fig. 163.—A section through the hind-brain and auditory vesicles of an embryo more advanced than that of fig. 162. (After His.)

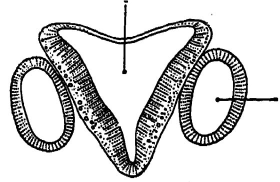

and the fenestra vestibuli. The scala tympani is next developed, and begins opposite the fenestra cochleæ; the scala vestibuli is the last to appear. The two scalæ gradually extend along each side of the ductus cochlearis, and when they reach the tip of the ductus an opening which represents the helicotrema is developed between them. The modiolus and the osseous spiral lamina of the cochlea are not preformed in cartilage but are ossified directly from connective tissue.

Fig. 164.—The left auditory vesicle of a human embryo, about 6 mm. long. Lateral aspect. (W. His, jun.)

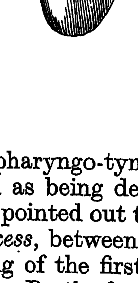

Fig. 165.—The left auditory vesicle of a human embryo, about 15 mm. long. Lateral aspect. (W. His, jun.)

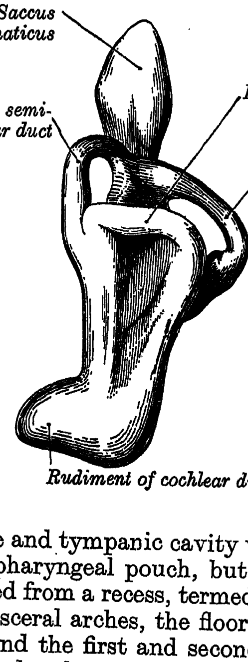


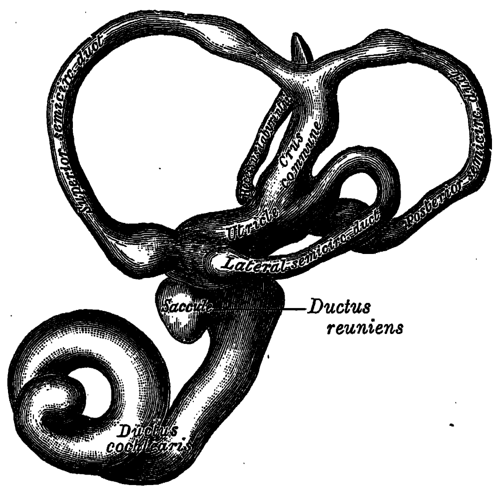
The pharyngo-tympanic (auditory) tube and tympanic cavity were formerly regarded as being derived from the first pharyngeal pouch, but Frazer † has recently pointed out they they are developed from a recess, termed the *tubotympanic recess*, between the first and third visceral arches, the floor of the recess consisting of the first and second arches and the first and second pharyngeal pouches. By the forward growth of the third arch the inner part of the recess is narrowed to form the tubal region, and the inner part of the second arch is excluded from this portion of the floor. The outer part of the recess is subsequently developed into the tympanic cavity, and the floor of this part forms the lateral wall of the tympanic cavity up to about the level of the chorda tympani nerve. From this it will be seen that the lateral wall of the tympanic cavity

* George L. Streeter, *American Journal of Anatomy*, vol. xxi.

† J. Ernest Frazer, *Journal of Anatomy and Physiology*, vol. xlviii.

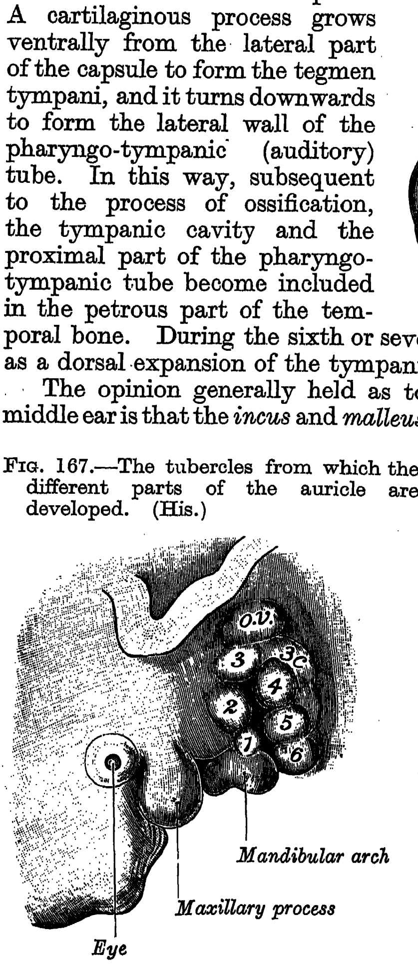
"has both first and second arch elements in it, the share taken by the first arch being limited to the part in front of the handle of the malleus. The area of the second arch includes the outer wall behind this, and turns on to the back wall to take in the tympanohyal region." The tubotympanic recess is placed at first on the infero-lateral aspect of the cartilaginous auditory capsule, but as the latter enlarges the relations become altered and the tympanic cavity comes to lie antero-lateral to the capsule. A cartilaginous process grows ventrally from the lateral part of the capsule to form the tegmen tympani, and it turns downwards to form the lateral wall of the pharyngo-tympanic (auditory) tube. In this way, subsequent to the process of ossification, the tympanic cavity and the proximal part of the pharyngo-tympanic tube become included in the petrous part of the temporal bone. During the sixth or seventh month the tympanic antrum appears as a dorsal expansion of the tympanic cavity.

Fig. 166.—The left membranous labyrinth of a human embryo, 30 mm. long. (From a model by W. His, jun.)



The opinion generally held as to the development of the ossicles of the middle ear is that the *incus* and *malleus* are derived from the dorsal end of the mandibular (Meckel's) cartilage (fig. 131), the incus representing the quadrate bone of birds and reptiles. The *stapes* is developed from the dorsal end of the cartilage of the second or hyoid arch, and first appears as a ring (annulus stapedis) encircling the small stapedial artery, which subsequently atrophies. At first the ossicles are imbedded in the mesenchymal roof of the tympanic cavity, and their extraneous origin is indicated in the adult by the covering which they receive from the mucous lining of the cavity.

Fig. 167.—The tubercles from which the different parts of the auricle are developed. (His.)



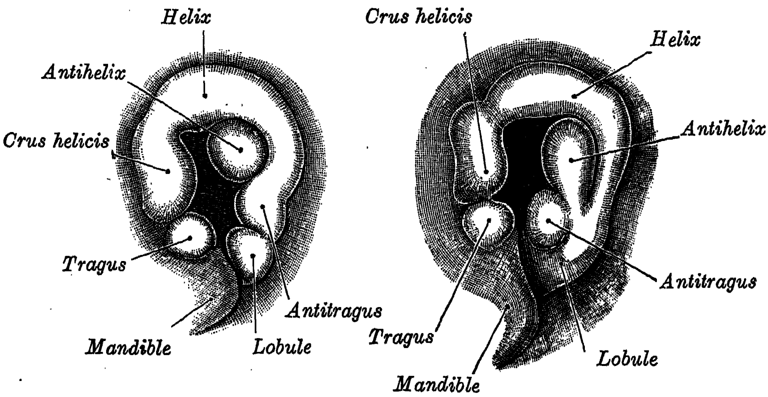
1, 2. Tubercles on mandibular arch. 3. Tubercle above groove. 3, *c*. Prolongation of 3 downwards. 4, 5, 6. Tubercles on hyoid arch. *o.v.* Auditory vesicle.

The external auditory meatus is developed from the dorsal end of the hyomandibular or first visceral cleft. The ventral part of this groove extends inwards as a funnel-shaped tube (primary meatus) from which the cartilaginous portion and a small part of the roof of the osseous portion of the meatus are developed. From the funnel-shaped tube a solid epidermal plug extends inwards along the floor of the tubotympanic recess; by the breaking down of the central cells of this plug the inner part of the meatus (secondary meatus) is produced, while the deepest cells of the ectodermal plug form the epidermal stratum of the tympanic membrane. The fibrous stratum of the tympanic membrane is formed from the mesenchyme which extends between the meatal plate and the entoderm of the floor of the tubotympanic recess.

The auricle is developed by the gradual differentiation of six tubercles (fig. 167) which appear around the margin of the hyo-mandibular cleft. Three

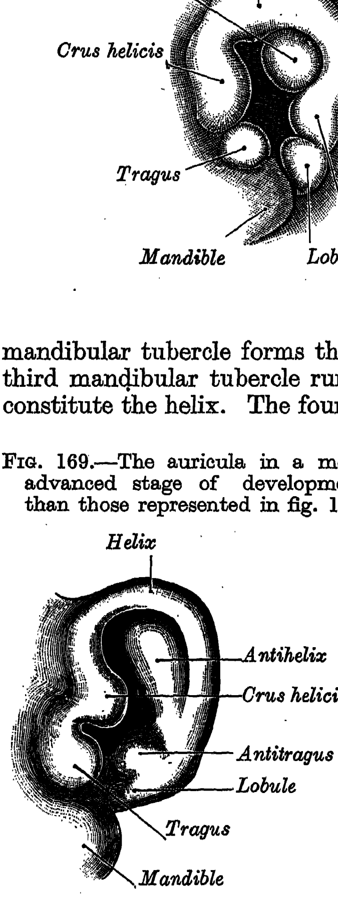
tubercles appear on the caudal edge of the mandibular arch near its dorsal end and three similar tubercles appear on the cephalic edge of the opposed part of the hyoid arch. A short ridge-like elevation, which is termed the *auricular fold,* appears dorsal and caudal to the hyoid tubercles. The first

FIG. 168.—The left auricles of human embryos, about 13·6 and 15 mm. long, respectively. (After His.)



mandibular tubercle forms the tragus, and the second the crus helicis. The third mandibular tubercle runs into the auricular fold, and the two together constitute the helix. The fourth (hyoid) tubercle forms the antihelix, the fifth the antitragus and the sixth the lobule.* Some observers maintain that the fourth and fifth tubercles fuse to form the antihelix, that the sixth becomes the antitragus, and that the lobule develops later as an independent formation. The rudiment of the auditory nerve appears in the fourth week as the *auditory ganglion,* which lies between the auditory vesicle and the wall of the hind-brain. At first it is fused with the ganglion of the facial nerve (acousticofacial ganglion) but later the two separate. The cells of the ganglion are mainly derived from those of the neural crest, but probably some come from the ectoderm of the auditory vesicle. The auditory ganglion divides into a vestibular and a cochlear part, each of which is associated with the corresponding division of the eighth nerve. The cells of these ganglia retain their bipolar shape, each sending a proximal fibre into the brain, and a peripheral fibre to the internal ear.

FIG. 169.—The auricula in a more advanced stage of development than those represented in fig. 171.



THE DEVELOPMENT OF THE VASCULAR SYSTEM

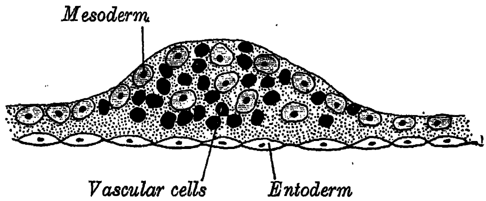
The blood-corpuscles and the blood-vessels are derived from *angioblastic tissue,* which differentiates from the mesoderm in three regions, viz.: (*a*) on the surface of the yolk-sac, (*b*) in the body-stalk, and (*c*) in the chorion.† On

* F. Wood-Jones and Wen I-Chuan believe that the whole of the auricle is developed from hyoid elements, with the exception of the tragus, which is derived from the mandibular arch.—*Journal of Anatomy,* vol. lxviii. 1934.

† J. L. Bremer, " On the Earliest Blood-vessels in Man," *Anatomical Record,* vol. viii. Feb. 1914; Donald McIntyre, " The Development of the Vascular System in the Human Embryo prior to the Establishment of the Heart," *Trans. Roy. Soc. Edin.* vol. lv. 1926; A. T. Hertig, " Angiogenesis in the Early Human Chorion," *Contributions to Embryology,* vol. xxv. 1935.

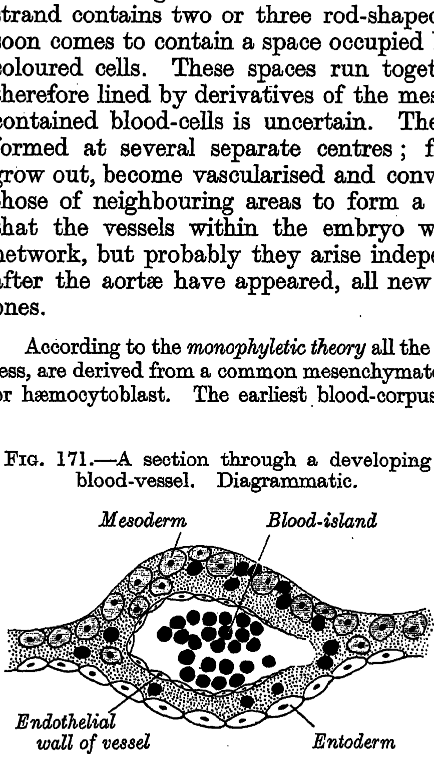
the surface of the yolk-sac and in the body-stalk small, more or less spherical, groups of cells are found early in the third week. They are termed *blood-islands*. The stages of the transformation of blood-islands into blood-containing vessels have not yet been demonstrated in detail, but it is generally believed that the peripheral cells of the islands become flattened and form the vascular endothelium, while the central cells become converted into blood-corpuscles. Later these small blood-containing spaces become continuous with one another to form a network of small vessels. In the chorionic end of the body-stalk and in the mesenchyme lining the chorion typical blood-islands are not found, but the cells of the mesenchyme, give rise to solid strands of angioblast. Each strand contains two or three rod-shaped nuclei arranged in a single row and soon comes to contain a space occupied by one or more nucleated hæmoglobin-coloured cells. These spaces run together to form blood-vessels, which are therefore lined by derivatives of the mesenchyme: the precise source of their contained blood-cells is uncertain. The earliest blood-vessels, therefore, are formed at several separate centres; from the walls of these vessels buds grow out, become vascularised and converted into new vessels, and join with those of neighbouring areas to form a close meshwork. His was of opinion that the vessels within the embryo were developed as extensions of this network, but probably they arise independently. Most observers agree that, after the aortæ have appeared, all new vessels are derived from pre-existing ones.

FIG. 170.—A section through the vascular area to show the differentiation of the primitive vascular cells. Diagrammatic.



According to the *monophyletic theory* all the corpuscles of the blood, both red and colourless, are derived from a common mesenchymatous ancestor, the primitive mesamœboid cell or hæmocytoblast. The earliest blood-corpuscles are thus all nucleated; they are also capable of subdivision and of executing amœboid movements. Some mesamœboids acquire colouring matter (hæmoglobin); their nuclei disintegrate and are extruded, and the non-nucleated red corpuscles or erythrocytes result. Other mesamœboids retain their nuclei; some remain in the blood as the leucocytes; others wander out into the tissues, particularly into the liver, the lymphoid tissues, and the marrow of the bones, where they form specialised collections from which the corpuscles of the blood are regenerated. The different varieties of leucocytes are described on p. 29.

FIG. 171.—A section through a developing blood-vessel. Diagrammatic.



On the other hand, according to the *polyphyletic theory*, which is upheld by Sabin and her school, the angioblast gives origin to red blood-corpuscles and to clasmatocytes, but all the other varieties of leucocytes are derived from a primitive basiphilic ancestor, which is also mesodermal in origin.

The development of the red blood-corpuscles is carried through in three stages. (1) *Erythroblasts* are derived from the primitive mesamœboid and endothelial cells. They are frequently termed *megaloblasts*, and they are the *ichthyoid blood cells* (of Minot), so called because of their resemblance to the typical red blood-corpuscles of fishes. These cells are large in size; they are nucleated and contain hæmoglobin in their cytoplasm. They predominate in the earlier weeks of development, but are not found in normal blood after the third month. (2) The *normoblasts*, which first appear during the second month, closely resemble the red blood-corpuscles of reptiles and were termed *sauroid blood cells* by Minot. Smaller than the erythroblasts the normoblasts have small, deeply staining, spherical nuclei, and their cytoplasm contains an increased amount of hæmoglobin. They are occasionally found in normal blood at birth. (3) The *erythrocytes*, or *blood plastids* (of Minot) are non-nucleated, spherical cells which become converted into typical red blood-

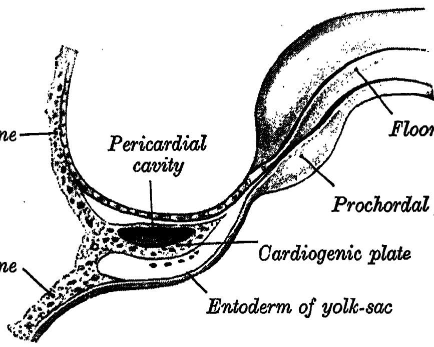
corpuscles. They represent normoblasts which have lost their nuclei, whether by extrusion or by absorption is still somewhat doubtful.

THE DEVELOPMENT OF THE HEART*

The human heart, like the hearts of all vertebrates, is formed by the fusion of two symmetrically developing tubes (p. 82), but the fusion is gradual, commencing at the bulbar, or arterial, end and extending caudally.

The pericardial cavity can be identified before the head-fold is formed or while it is in process of formation, and the heart is then represented only by groups of angioblasts which lie between the pericardium and the entoderm of the yolk-sac (fig. 172). The ventral (or yolk-sac) wall of the pericardium, *which*

Fig. 172.—Median section through the cephalic end of an early human embryo to show the position of the pericardium before the formation of the head-fold. A few scattered angioblasts are seen between the cardiogenic plate and the yolk-sac; they will ultimately form the endothelial heart tubes. (After Carl L. Davis.)



is destined to form both the epicardium and the myocardium, is thicker than the dorsal wall and is termed the *cardiogenic plate*. When the head-fold is formed, the cardiogenic plate becomes the dorsal wall of the pericardium and lies ventral to the fore-gut. While this reversal of the pericardium is taking place (figs. 173 and 174), the angioblastic tissue related to the cardiogenic plate gives rise to two paramedian endothelial tubes which subsequently fuse to form a tubular heart. Caudally each tube receives the cranial end of the corresponding vitelline vein, which lies in the floor of the pericardium in the mesoderm of the septum transversum (p. 72). Ventrally the endothelial heart tubes invaginate the cardiogenic plate into the pericardial cavity (fig. 175).

The dorsal aortæ arise *in situ* as paired endothelial vessels. They extend caudally into the body-stalk, where they establish continuity with the umbilical arteries, which precede them in time of appearance. At their cephalic ends the dorsal aortæ curve ventrally round the sides of the fore-gut to reach the pericardium to become continuous with the cephalic ends of the endothelial heart tubes, thus forming the first pair of aortic arches † (fig. 189).

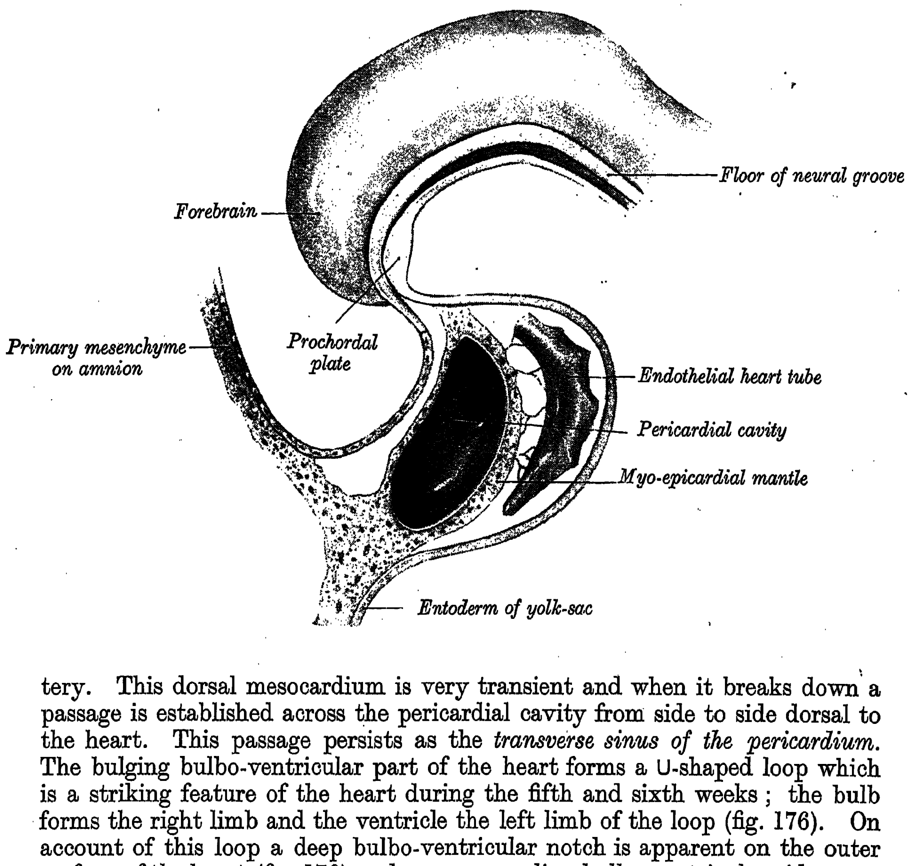
Except at its caudal end the tubular endothelial heart is separated from the cardiogenic plate—which may henceforth be termed the *myo-epicardial mantle*—by an interval occupied by a formless jelly-like substance (fig. 175). At first the pericardium is wide in proportion to its length, but as the heart tube grows the pericardium for a time lengthens proportionately. Grooves appear on the surfaces of the heart which indicate the subdivision of the tube into its primitive chambers. The most cranially situated of these grooves marks off

* See A. Girgis, *Proceedings of Zoological Society of London*, 1930 and 1933; Carl L. Davis, *Contributions to Embryology*, vol. xix. 1927; D. Waterston, *Trans. Roy. Soc. Edinburgh*, vol. lii. 1918; and J. Tandler, *Keibel and Mall's Manual of Embryology*, 1912.

† In lower vertebrates the heart and aortæ are laid down before the formation of the head-fold and the arteries communicate with the caudal end of the heart. When the head-fold forms, the ends of the heart are reversed and the cephalic ends of the dorsal aortæ are curved forwards round the sides of the fore-gut to form the first aortic arches.

the *bulbus cordis*, which is continuous with the first pair of aortic arches, from the *ventricle*. A second groove, which later becomes a localised constriction, separates the ventricle from a common *sinu-atrial chamber* and indicates the position of the *atrial canal*. At the same time the heart-tube is enlarging and the bulbo-ventricular part, which is most affected, bulges ventrally and caudally. The dorsilateral recesses of the pericardium deepen and approach one another (fig. 175) and fuse, completing the myo-epicardial covering of the heart and converting its hitherto broad dorsal attachment into a dorsal mesen-

FIG. 173.—Median section through the cephalic end of a young human embryo, showing the head-fold in process of formation and its effect on the position of the pericardium. Compare with figs. 172 and 174. (After Carl L. Davis.)



tery. This dorsal mesocardium is very transient and when it breaks down a passage is established across the pericardial cavity from side to side dorsal to the heart. This passage persists as the *transverse sinus of the pericardium.* The bulging bulbo-ventricular part of the heart forms a U-shaped loop which is a striking feature of the heart during the fifth and sixth weeks; the bulb forms the right limb and the ventricle the left limb of the loop (fig. 176). On account of this loop a deep bulbo-ventricular notch is apparent on the outer surface of the heart (fig. 176) and a corresponding bulbo-ventricular ridge projects into the interior (fig. 186).

The bulbo-ventricular loop occupies the ventral part of the pericardial cavity, while the common sinu-atrial chamber occupies its dorsal part. The atrial canal, consequent on the formation of the loop, lies to the left of the median plane, so that at this stage, it is the left part of the sinu-atrial chamber which communicates with the ventricle. During the subsequent growth changes the canal gradually moves into the median plane of the heart.

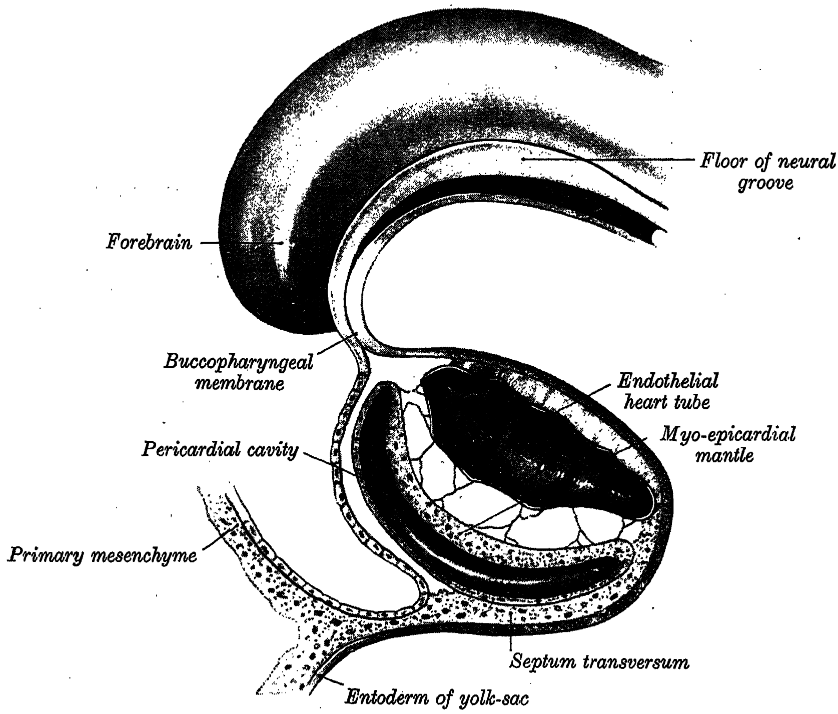
While these changes are in progress the connexion between the bulbus cordis and the first pair of aortic arches lengthens to form the *truncus arteriosus*, and the cranial end of this vessel becomes connected to the dorsal aortæ by the remaining (five) pairs of aortic arches. By this time the venous drainage of the body wall has been established. On each side an *anterior cardinal vein*, from the headward end of the embryo, unites with a *posterior cardinal vein* from the tail end, to form the *duct of Cuvier*, and this vessel opens close to the umbilical and vitelline veins into the dorsi-caudal part of the common sinu-atrial chamber.

The separation of the *sinus venosus* from the *atrium* completes the definition

of the primitive chambers of the heart. This is effected by the appearance of a crescentic fold which cuts off the dorsi-caudal part of the sinu-atrial chamber to form the sinus venosus. The fold is much deeper on the left side, so that the left horn of the sinus venosus is defined first, and opens into that part of the common sinu-atrial chamber which later becomes the right horn (fig. 178), As the crescentic fold deepens, the right horn becomes demarcated from the right half of the common atrium and its connexion with it—which is widely open in fig. 178—becomes relatively smaller. The right and left parts of the atrium enlarge and bulge forwards at the sides of the bulb (fig. 181).

The embryo has now attained a length of 3 mm. It possesses no somites and has entered on the fifth week of development. From this stage onwards it

FIG. 174.—Median section through the cephalic end of a young human embryo, after completion of the head-fold and reversal of the pericardium. Compare with figs. 172 and 173. (After Carl L. Davis.)

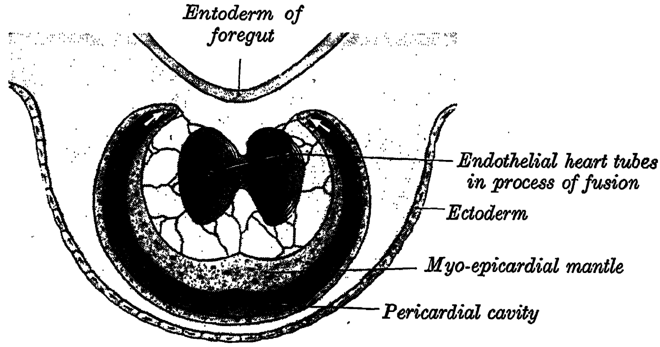


is more convenient to deal with the history of the individual chambers than with the development of the heart as a whole.

The sinus venosus.—The sinus venosus is situated in the septum transversum dorsi-caudal to the common atrium, and presents a crescentic shape (fig. 179). Its right horn increases rapidly in size at the expense of the left horn, owing to the changes brought about in the originally symmetrical arrangement of the umbilical and vitelline veins by the development of the liver (p. 154). As a result of these changes the vitello-umbilical blood-flow enters the right horn through a wide but short vessel, termed the *vena hepatis communis*, which is destined to form the cephalic end of the inferior vena cava. In addition to this vein the right horn receives the right duct of Cuvier (from the body-wall of the right side) and the left horn of the sinus, which conveys the blood from the left duct of Cuvier. Later, when transverse connexions are established between the cardinal veins of the two sides (fig. 198), the blood from the body-wall of the left side reaches the heart *viâ* the veins of the right side. The left duct of Cuvier then becomes much reduced in size and forms the oblique vein of the left atrium, while the left horn itself persists as the coronary sinus.

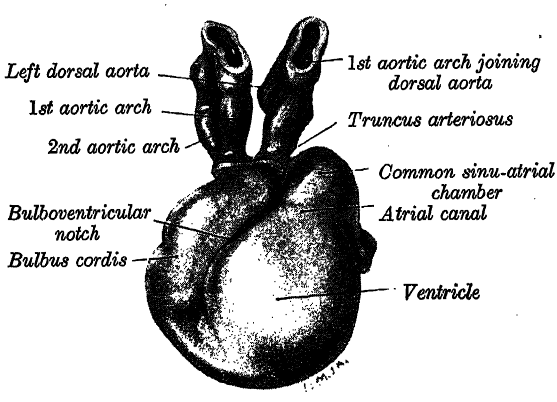
The right horn of the sinus venosus opens into the right atrium through its dorsal and caudal walls. The orifice, which is elongated and often slit-like, is guarded by two muscular folds which are termed the *right* and *left venous valves* (fig. 183). These two valves meet at the cephalic end of the orifice and become

FIG. 175.—A horizontal section through the pericardium and developing heart of the embryo shown in fig. 174. (After Carl L. Davis.) The arrows indicate the directions in which the dorsilateral recesses of the pericardium deepen so as to define the transient dorsal mesocardium.



continuous with a fold which projects into the atrium from its roof and is termed the *septum spurium* (fig. 180). At the caudal end of the orifice the two valves meet and fuse with the dorsal endocardial cushion of the atrial canal (p. 138). The cephalic part of the right venous valve disappears, but its position is indicated in the adult heart by the crista terminalis ; its caudal part forms the valve of the coronary sinus and most of the valve of the inferior vena cava. The medial (or left) end of the valve of the inferior vena cava is formed by a small

FIG. 176.—The heart of a 0·95 mm. rabbit embryo. Viewed from the ventral side. (Drawn from a model by G. Born.)



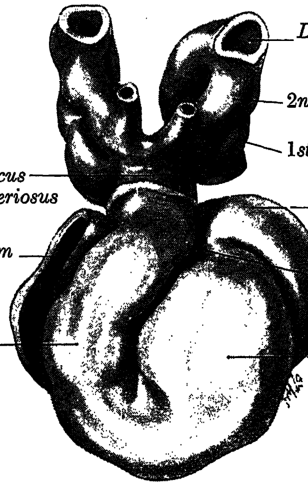
fold which projects from the dorsal wall of the sinus venosus and is termed the *sinus septum*. In the embryo the sinus septum intervenes between the orifice of the vena hepatis communis and the opening of the left horn of the sinus.

The left venous valve blends with the right side of the atrial septum and no trace of it can be seen in the adult heart.

As the venous valves undergo these changes the right horn of the sinus venosus becomes incorporated in the right atrium and forms its dorsal wall, medial to the crista terminalis. This part of the adult atrium is often termed the *sinus venarum*.

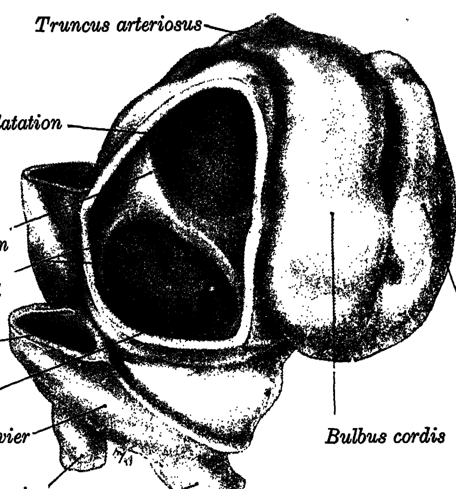
The atria.—As already stated, the common atrium is derived from the ventri-cranial part of the sinu-atrial chamber. It receives the opening of the sinus venosus in its dorsicaudal part to the right of the median plane, while

Fig. 177.—The heart of a 1·7 mm. rabbit embryo. Viewed from the ventral side. (Drawn from a model by G. Born.)



its ventral part communicates with the ventricle through the atrial canal, which lies at first to the left of the median plane. As the atrial canal moves towards the median plane, swellings appear in its ventral and dorsal walls

Fig. 178.—The heart shown in fig. 177, viewed from the right side and slightly from the ventral aspect. The right wall of the common sinu-atrial chamber has been removed to show the interior. (Drawn from a model by G. Born.)



in the space between the endothelial tube and the myo-epicardial mantle. They are termed the *atrioventricular endocardial cushions* and consist of a simple mesenchyme which stains darkly with hæmatoxylin. They encroach

Fig. 179.—The heart of a human embryo, about six weeks old. Dorsal aspect. (From a model by His.)

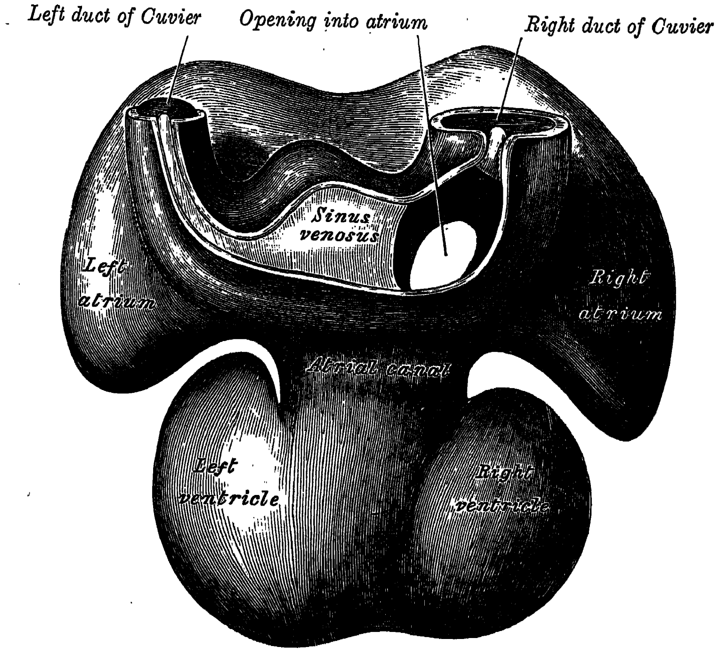


Fig. 180.—The heart of a human embryo, about thirty-eight days old. The interior of the dorsal half. (From a model by His.)

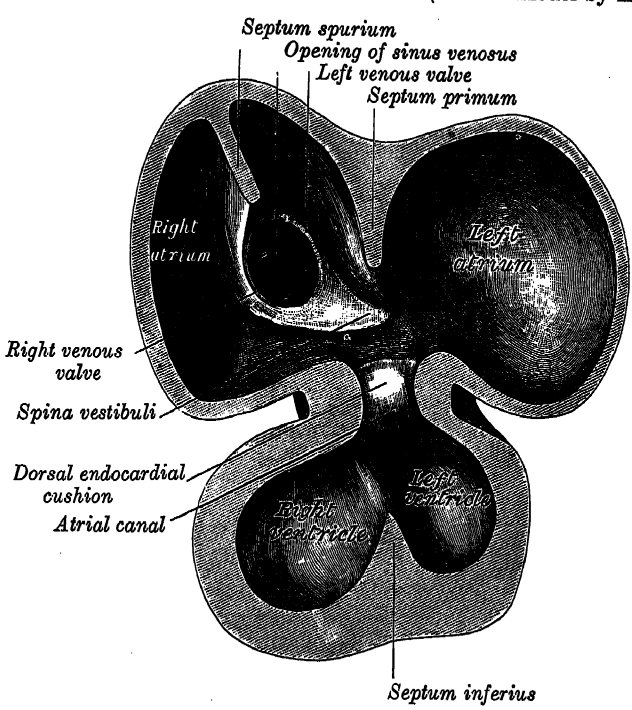
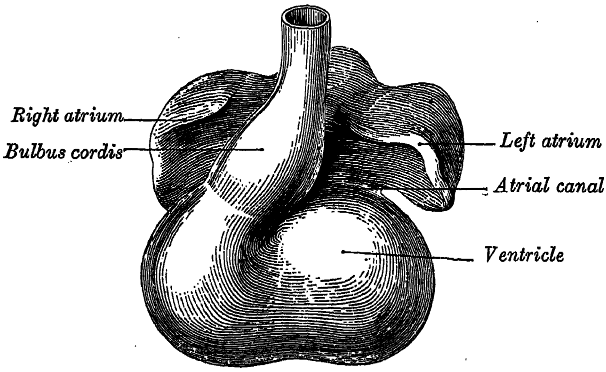


on the canal and eventually fuse with each other, leaving a relatively small orifice on each side. The fused cushions constitute the *septum intermedium*

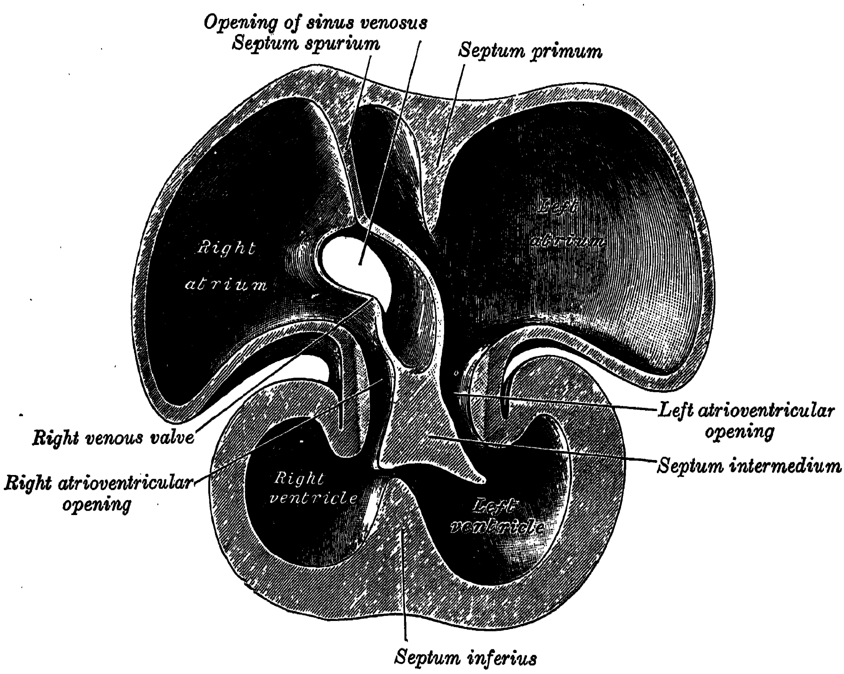
Fig. 181.—A heart showing the expansion of the atria. (From an Ecker-Ziegler model.)



(of His), and the two small orifices become the right and left atrioventricular openings.

The internal separation of the two atria is effected by the growth of two septa. The first to appear is termed the *septum primum*, and it grows from the

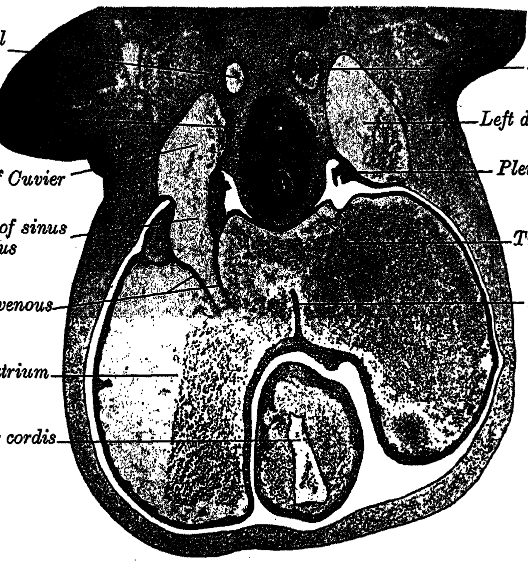
Fig. 182.—The heart of a human embryo, about six weeks old. The interior of the dorsal half. (From a model by His.)



dorsal wall as a sickle-shaped fold (fig. 184, *A*) which is separated from the left venous valve by an interval named the *intersepto-valvular space*. The ventral horn of the sickle reaches the ventral atrio-ventricular cushion, and the dorsal horn reaches the dorsal cushion. Ventral and caudal to the advancing edge of the septum the two atria communicate through the *ostium primum* (of Born) (fig. 182). Free passage of blood from the right atrium to the left is essential

throughout fœtal life, and, therefore, as the ostium primum becomes reduced in size, the dorsal part of the septum primum breaks down and a new communication, termed the *ostium secundum*, is formed between the two atria. The ostium primum becomes occluded completely by the fusion of the edge of the septum primum with the fused atrio-ventricular cushions, and it should be noted that this fusion occurs in the median plane. The ostium secundum enlarges sufficiently to ensure the free passage of blood from the right atrium to the left, and it persists throughout intra-uterine life as the *foramen ovale*. At first this opening is situated in the cephalic and dorsal portion of the septum primum

FIG. 183.—Transverse section of a human embryo, 8 mm. long. Observe how the atria bulge forwards on either side of the bulbus cordis, and compare with fig. 182. The septum primum has broken down in its dorsal portion and the two atria communicate through the foramen ovale secundum.

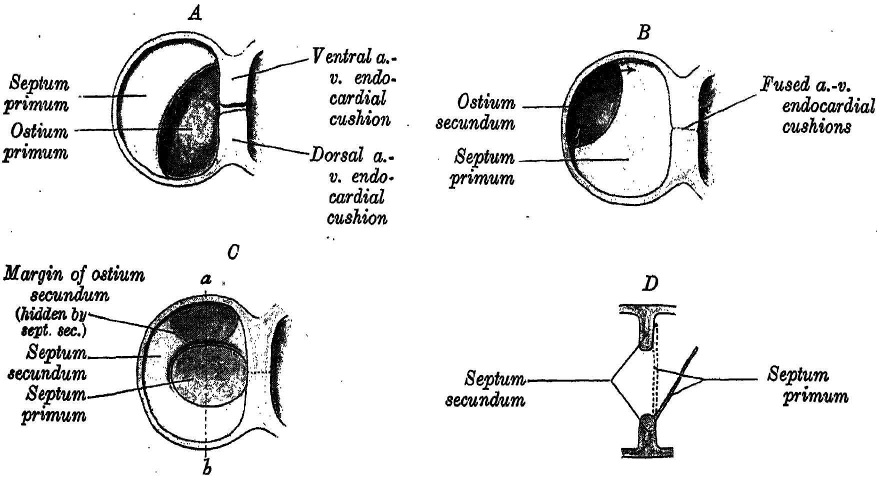


but its position becomes modified until it lies in its cephalic and ventral part (fig. 184, *C*). Towards the end of the second month the muscular wall of the atrium becomes inflected to form a crescentic septum on the right side of the septum primum. This inflection is termed the *septum secundum*, and it involves more than the whole width of the intersepto-valvular space, so that the dorsal attachments of the septum primum and the left venous valve are carried into the interior of the atrium (fig. 185) on its left and right surfaces respectively. The horns of the septum secundum fuse with the septum intermedium and the adjoining part of the septum primum. Its intervening, free, portion overlaps the foramen ovale (fig. 184, *D*) so that the septum primum can act as a flap-like valve. As the blood-pressure is greater in the right atrium than it is in the left, the blood flows from right to left, but not in an opposite direction. After birth the intra-atrial pressures are equalised, and the free edge of the septum primum is therefore kept in contact with the left side of the septum secundum and fusion occurs. Not infrequently the fusion is incomplete, but the opening left is usually small and valvular, and has no functional significance.

At an early stage in the development of the septum primum a single, common pulmonary vein can be identified opening into the caudal part of the dorsal wall of the left atrium close to the septum. This trunk is formed by the union of a right and a left pulmonary vein, and each of these is formed in turn by two small veins issuing from the developing lung-bud. Subsequently the common trunk and the two veins forming it expand and are incorporated in the left atrium to form the greater part of its cavity. This expansion reaches as far

as the orifices of the four veins, which thus open separately into the left atrium. During the second month the two atria bulge ventrally one on each side of the

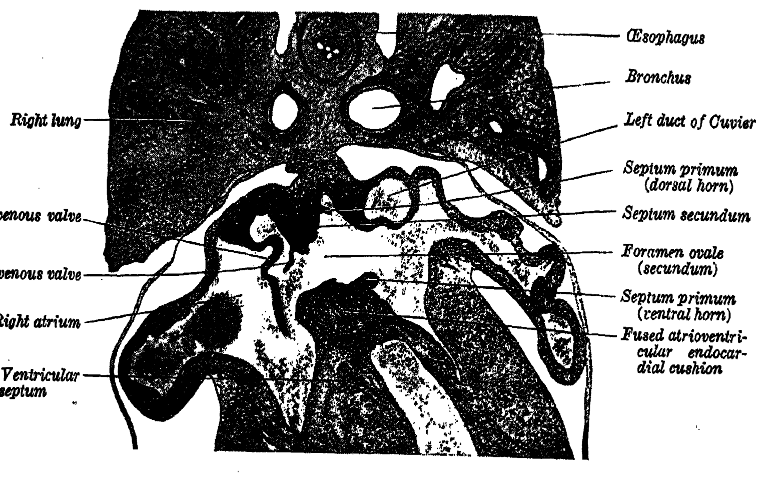
FIG. 184.—Diagrams representing three stages in the development of the atrial septum, viewed from the right side. The heart has been divided in its long axis to the right of its middle line and only the atria and the adjoining part of the ventricular cavity are depicted.



A. The septum primum has not yet obliterated the original communication between the two atrial diverticula and the atrioventricular endocardial cushions have not yet fused. *B*. The atrioventricular endocardial cushions have fused with each other and with the septum primum, which has broken down in its dorsal part. The foramen ovale secundum, thus formed, subsequently moves in the direction of the arrows. *C*. The septum secundum has formed and hides the foramen ovale secundum, the margins of which are indicated by the curved, dotted line. *D*. A section through *C* along the line *ab* to show the valve-like character of the foramen ovale secundum. When the pressure in the right atrium exceeds that in the left atrium, blood passes from the right to the left side of the heart, but when the two pressures are equal the septum primum assumes the position indicated by the dotted outline.

bulbus cordis, which lies in a groove on their ventral surface (fig. 183). These projecting parts of the atria form the auricles of the adult heart, while their dorsal parts expand to form the atria proper.

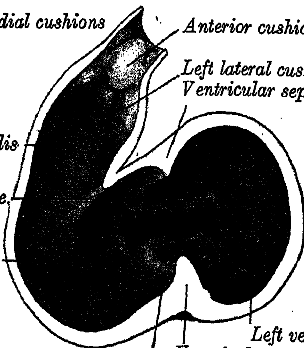
FIG. 185.—Transverse section through the thorax of a 21 mm. human embryo, showing the inflexion of the muscular atrial wall to form the septum secundum. Observe the vacuolated condition of the œsophagus which is characteristic at this stage.



The ventricles, bulbus cordis and the truncus arteriosus.—The process of separation of the two ventricles is intimately related to the separation of the

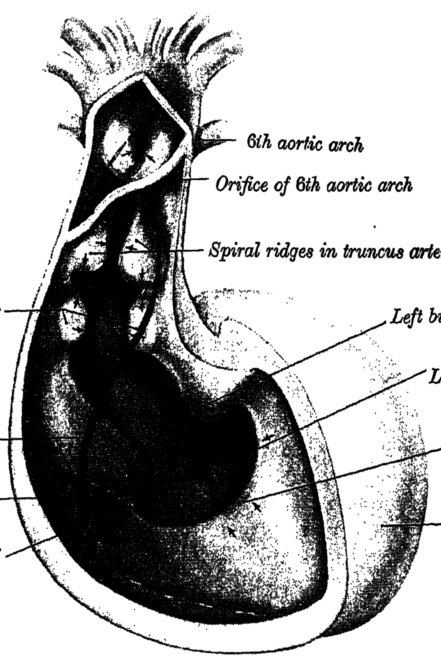
aortic and pulmonary orifices at the distal end of the bulbus and to the subdivision of the truncus arteriosus into pulmonary and aortic channels. These

FIG. 186.—A diagram showing the relations at an early stage between the atrioventricular opening and ventricles, the cavity of the bulbus cordis, and the bulboventricular ridge. The endocardial cushions at the distal end of the bulb are shown in a more differentiated state than they really exhibit at this stage. (J. Ernest Frazer.)



two processes are so closely interdependent that the history of the truncus arteriosus will be dealt with in this section, although it takes no part in the

FIG. 187.—A diagram to show the mode of formation of the septa which separate the aortic and pulmonary channels in the embryonic heart. The red arrow indicates the aortic channel, and the blue arrow, the pulmonary. The small black arrows indicate the directions of growth. (Drawn from a plasticine model made by Dr. J. Whillis.)



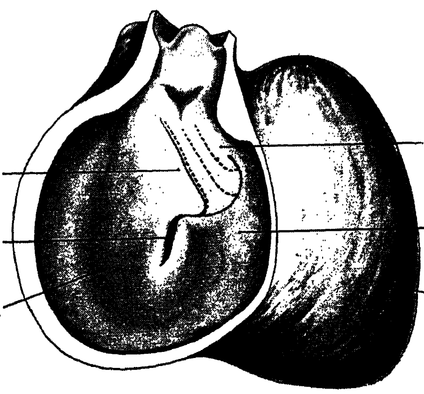
formation of the heart itself, and both will be considered before the separation of the two ventricles is described.

Four endocardial cushions—a ventral, a dorsal, a right and a left—form in the distal part of the bulbus, and the right and left cushions fuse to constitute

the *distal bulbar septum.* This septum separates a ventral, or pulmonary, orifice from a dorsal, or aortic, orifice, and later the cushions become modified to form the semilunar valves.

The separation of the pulmonary trunk from the aorta is a more complicated process. Two ridge-like thickenings project into the interior of the truncus arteriosus. Proximally, the ridges are placed on the lateral walls of the vessel, but as they are traced away from the heart, the right ridge passes obliquely on to the ventral wall and then on to the left wall, while the left ridge extends on to the dorsal wall and then on to the right wall (fig. 187). The ridges are therefore spiral and their fusion forms the *spiral aortopulmonary septum.* At its proximal end this septum meets and fuses with the distal bulbar septum, and on account of its spiral character the pulmonary trunk, which lies ventral to the aorta at its orifice, curves round to its left side as it ascends, and finally lies dorsal to it (fig. 187). At its distal end the aortopulmonary septum meets the dorsal wall of the truncus arteriosus headwards of the point where it is joined

FIG. 188.—A diagram to show the completion of the separation of the aortic and pulmonary channels. The dotted lines indicate successive positions of the left bulbar ridge as it fuses with the free edge of the ventricular septum and approaches the right bulbar ridge (J. Ernest Frazer).



by the sixth pair of aortic arches, and as a result these arches become branches of the pulmonary trunk, while the other aortic arches are left in communication with the aorta (fig. 187).

The separation of the two ventricles from each other has to be effected in such a way as to leave the right ventricle in communication both with the right atrium and with the pulmonary artery, and the left ventricle in communication both with the left atrium and the aorta. On account of the complicated character of the changes which are necessary three distinct factors contribute to the formation of the adult ventricular septum, viz. :—(*a*) the *ventricular septum* (or *septum inferius* of His), (*b*) the *proximal bulbar septum,* and (*c*) the *atrioventricular endocardial cushions* (*septum intermedium* of His).

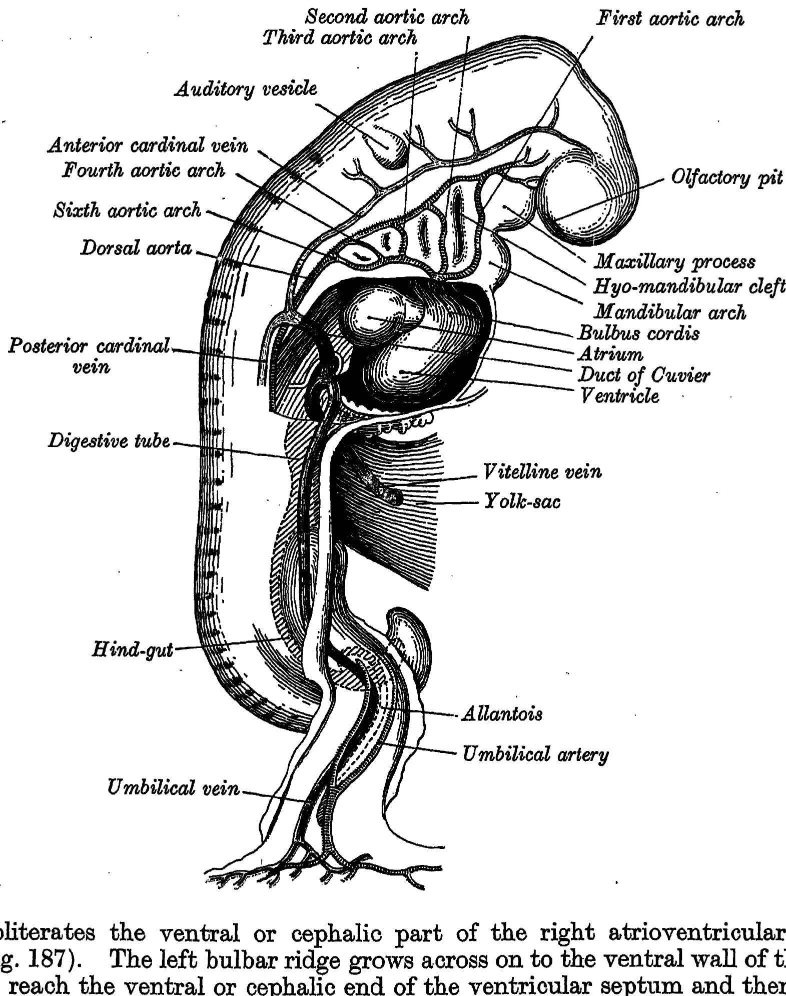
(*a*) During the fifth week the right and left ventricles are indicated as slight projections on the surface of the common ventricle. In the inside of the heart a crescentic ridge indicates the separation between them and, as the heart enlarges, this ridge deepens to form the *ventricular septum.* Dorsally it meets the dorsal endocardial cushion of the atrial canal *near its right extremity* and fuses with it. The septum has a free sickle-shaped margin, which bounds the circular interventricular foramen (fig. 187).

At first the bulbo-ventricular junction is marked by a distinct notch on the outside of the heart (fig. 186), and on the inside of the heart there is a corresponding *bulbo-ventricular ridge.* This ridge is interposed between the atrioventricular orifice and the caudal part of the bulb (fig. 186), and its absorption is essential for the development of the four-chambered heart. As a result, partly of the absorption of the bulbo-ventricular ridge and partly of the growth of the atrioventricular region, the right extremity of the atrial canal comes to

lie below the orifice of the bulb (fig. 187). This alteration in the relative positions of the structures concerned occurs while the ventricular septum is forming, and paves the way for the completion of the process of ventricular partition.

(*b*) The *proximal bulbar septum* separates the bulbus cordis into pulmonary and aortic channels, and is formed by the *right* and *left bulbar ridges*, which are in continuity with the corresponding bulbar endocardial cushions. The right bulbar ridge grows across on to the dorsal wall of the bulb and the right extremity of the fused atrioventricular endocardial cushions to reach the dorsal end of the free, sickle-shaped edge of the ventricular septum, and in doing so

FIG. 189.—A human embryo 4·2 mm. long. Right lateral aspect. (After His.)



obliterates the ventral or cephalic part of the right atrioventricular orifice (fig. 187). The left bulbar ridge grows across on to the ventral wall of the bulb to reach the ventral or cephalic end of the ventricular septum and then grows along its free margin until it meets and fuses with the right bulbar ridge.* As a result of the formation of this proximal bulbar septum the ventral part of the bulb becomes incorporated in the right ventricle and forms its infundibular part (conus arteriosus). The dorsal part of the bulb becomes absorbed almost entirely, but its position is indicated by the dorsal wall of the aortic vestibule, which, however, is formed to a large extent by the fused atrioventricular endocardial cushions. It will be clear, from the directions of growth of the two ridges, that the proximal bulbar septum is twisted, and this is necessitated by the fact that it has to connect two septa—the distal bulbar septum and the ventricular septum—which do not lie in the same plane.

(*c*) At the time of their fusion the atrioventricular endocardial cushions are

* See footnote *, p. 146.

very large relative to the size of the atrioventricular orifices. The atrial septum meets the atrial surface of the cushions at their centre, but the ventricular septum meets them near their right extremity. It follows that a portion of the fused cushions intervenes between the right atrium and the left ventricle, and it is this portion which forms the right part of the dorsal wall of the aortic vestibule (*membranous part of atrial septum*, p. 681). The membranous part of the ventricular septum, which is continuous behind with the membranous part of the atrial septum in the adult heart, is formed where the caudal end of the right bulbar ridge crosses the right extremity of the fused atrioventricular endocardial cushions to join the ventricular septum. The persistence of a communication between the two ventricles is due to arrest of development in this region.*

It should be observed that a part of the circular orifice which lies above the ventricular septum (fig. 187) becomes incorporated in the aortic vestibule and thereafter serves to connect the left ventricle with the aortic channel.

The valves of the heart.—The atrioventricular valves develop as endothelial projections directed towards the ventricles at the atrioventricular orifices. From the first they are connected with the ventricular musculature at their bases and, as growth proceeds and the flaps become enlarged, these muscular trabeculæ become freed and constitute the musculi papillares, their extremities being converted into the fibrous chordæ tendineæ. The aortic and pulmonary valves are formed from the four endocardial cushions which appear at the distal end of the bulbus cordis. The completion of the distal bulbar septum results in the division of each lateral cushion into two parts, so that the number of thickenings is increased to six, of which three are associated with the pulmonary orifice and three with the aortic. These thickenings form the rudiments of the aortic and pulmonary valves, while the pouches between the valves and the walls of the vessels gradually enlarge and form the sinuses of the aorta. At first, therefore, one cusp of the pulmonary valve lies anteriorly and the other two posterolaterally, whereas one cusp of the aortic valve lies posteriorly and the other two anterolaterally. Before birth the heart becomes rotated to the left so that the pulmonary artery assumes its permanent position to the left of, and anterior to, the aorta. This rotation also affects the relative positions of the cusps of the pulmonary and aortic valves, so that they come to occupy the positions in which they are found in the adult heart.

Applied Anatomy.—The various cardiac septa may be arrested in their development or, more rarely, the septa may form in an abnormal manner, conditions which give rise to the various forms of congenital cardiac anomalies. (*a*) The septum secundum of the atria may fail to fuse with the septum primum, rendering possible a communication between the two atria. Unless, owing to a deficiency of the septum primum, the floor of the fossa ovalis is completely or partially absent this communication is of no functional importance, because of its valvular character and the equality of the intra-atrial pressures. When free communication exists between the two atria the condition is still compatible with life and is compensated for by a marked increase in the number of the red blood-corpuscles. (*b*) The ventral part of the bulbus cordis may fail to enlarge to form a normal infundibulum (conus arteriosus). In these cases the pulmonary artery is very considerably stenosed and blood reaches the lungs through the medium of a persistent ductus arteriosus. At the same time the dorsal part of the bulb expands, instead of becoming absorbed, and the aorta communicates with both ventricles. The membranous part of the ventricular septum is deficient. (*c*) Transposition of the aorta and pulmonary artery is occasionally met with, and is usually associated with a more or less marked deficiency in the ventricular septum, although this structure may be complete. As the transposition may affect the topographical relationships of the two vessels to each other, or may involve their ventricular connexions, several distinct types of this anomaly can be differentiated.†

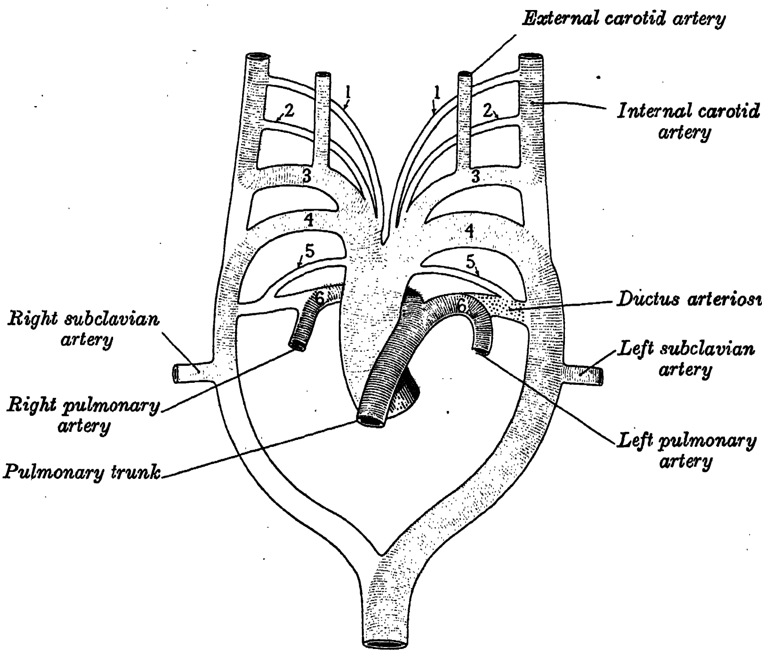
* Recent work by P. N. B. Odgers (to be published shortly in the *Journal of Anatomy*) has shown that a large part of the circular interventricular foramen is actually occluded by a proliferation from the atrioventricular endocardial cushions which fuses with the lower end of the proximal bulbar septum and with the ventricular septum. This proliferation forms the membranous part of the ventricular septum in the adult and its failure to develop results in the presence of an interventricular foramen.

† Congenital cardiac anomalies are so numerous and varied that it is impossible to give more than the merest outline. *See* Sir Arthur Keith's Hunterian Lectures, the *Lancet*, 1909, and T. Walmsley, *Quain's Anatomy*, eleventh edition, vol. iv. part iii.

The further development of the arteries.—Recent observations show that none of the main vessels of the adult arise as single trunks in the embryo. At the site of each vessel a capillary network forms, and by the enlargement of definite paths in this network the larger arteries and veins are developed. The branches of the main arteries are not always simple modifications of the vessels of the capillary network, but may arise as new outgrowths from the enlarged stem.

It has been seen (p. 134) that subsequent to the formation of the head-fold each primitive aorta consists of a ventral and a dorsal part which are continuous through the first aortic arch. The dorsal aortæ at first run caudally separately, one on each side of the notochord, but in the fourth week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single trunk—the descending aorta. Although in many animals paired

Fig. 190.—A scheme of the aortic arches and their transformations. (After Congdon.)



ventral aortæ arise from the truncus arteriosus and course headwards on the ventral surface of the pharynx, in the human embryo the ventral aortæ are fused and form a dilated vessel, termed the 'aortic sac' (Congdon).* The first aortic arches run through the mandibular arches, and caudal to them five additional pairs are developed within the corresponding visceral arches; so that, in all, six pairs of aortic arches are formed (figs. 190, 191). The fifth arches are very transitory vessels connecting the aortic sac with the dorsal ends of the sixth arches. The other arches pass between the aortic sac and the dorsal aortæ.

In fishes the aortic arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of the arteries remain as permanent structures, while others disappear or are obliterated (fig. 190).

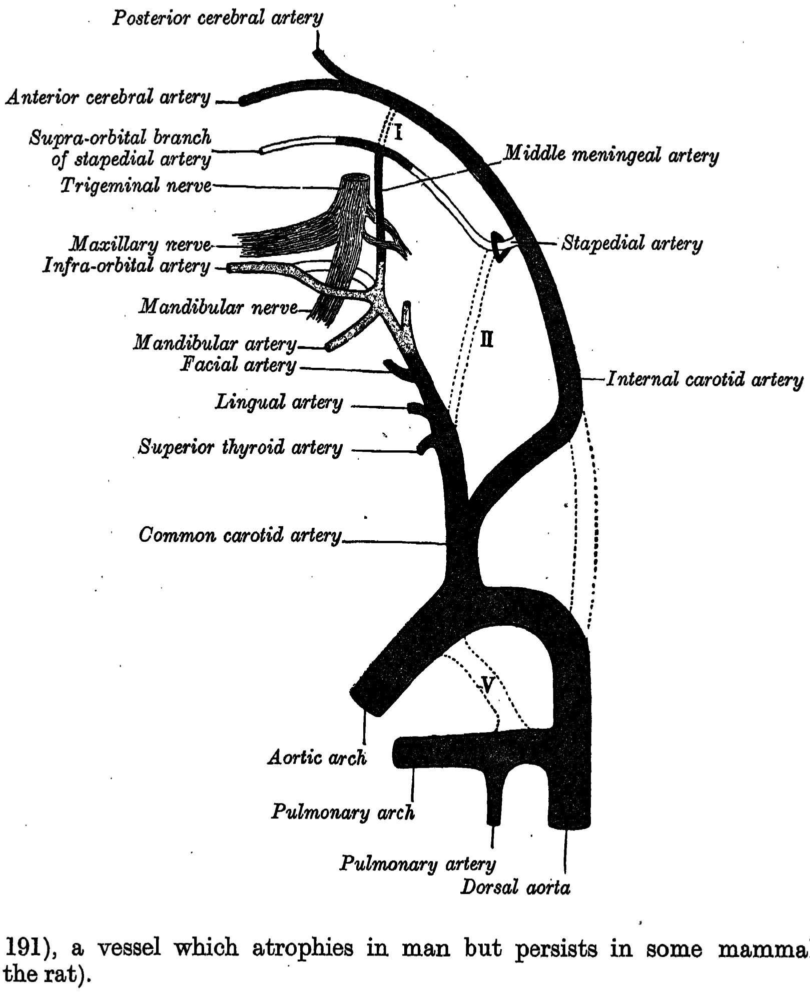
The aortic sac represents fused, paired ventral aortæ. As the embryo grows and the aorto-pulmonary septum is formed, part of the caudal end of the sac is incorporated in the trunk of the pulmonary artery. The cephalic end of the sac becomes drawn out into right and left limbs as the neck lengthens. The right limb becomes the innominate artery and the left limb forms the root

* E. D. Congdon, *Contributions to Embryology*, No. 68, 1922.

of the left common carotid artery. The remainder of the sac contributes to the formation of the arch of the aorta.

The aortic. arches.—The first and second aortic arches disappear, while the third is forming, but they are replaced by mandibular and hyoid arteries which grow into the arches from the dorsal aortæ but do not reach the aortic sac. Close to its point of origin the hyoid artery gives off the stapedial artery

FIG. 191.—A diagram showing the origins of the main branches of the carotid arteries. (Founded on Tandler by T. H. Bryce.) (From Quain's Elements of Anatomy, vol. i., Embryology.)



(fig. 191), a vessel which atrophies in man but persists in some mammals (e.g. the rat).

The stapedial artery passes through the ring of the stapes and divides into supra-orbital, infra-orbital, and mandibular branches, which follow the three divisions of the trigeminal nerve. The infra-orbital and mandibular branches arise from a common stem, the terminal part of which anastomoses with the external carotid. On the obliteration of the stapedial artery this anastomosis enlarges and forms the (internal) maxillary artery, and the branches of the stapedial artery are now branches of this vessel. The common stem of the infra-orbital and mandibular branches passes between the two roots of the auriculotemporal nerve and becomes the middle meningeal artery; the original supra-orbital branch of the stapedial artery is represented by the orbital twigs of the middle meningeal artery.

Near its ventral end the third aortic arch gives origin to a vascular sprout which passes headwards and forms the external carotid artery. After the appearance of this vessel, the ventral end of the third aortic arch persists as the distal end of the common carotid and its dorsal end as the proximal end of

the internal carotid artery. The fourth aortic arch of the right side forms the proximal part of the right subclavian, while the corresponding vessel of the left side constitutes the arch of the aorta between the origin of the left common carotid artery and the termination of the ductus arteriosus. The fifth arch disappears on both sides. The ventral part of the sixth aortic arch of the right side persists as the proximal part of the right pulmonary artery but its dorsal part disappears. The ventral part of the sixth aortic arch of the left side is absorbed into the pulmonary trunk, while its dorsal part persists as the ductus arteriosus ; this duct remains pervious during intra-uterine life, but is obliterated after birth and forms the ligamentum arteriosum of the adult. The developing lung-buds are first supplied by a capillary plexus derived from the aortic sac. Later, this plexus becomes connected to the dorsal aorta, and this vascular connexion between the latter and the aortic sac constitutes the sixth aortic arch. The continuation of the capillary plexus to the lung-bud thereafter becomes transformed into the definitive pulmonary artery.

The dorsal aortæ.—On the cephalic side of the third aortic arches the dorsal aortæ persist and form the continuations of the internal carotid arteries ; these arteries pass to the brain, and each divides into an anterior and a posterior branch, the former giving off the ophthalmic artery and the anterior and middle cerebral arteries, while the latter turns back and joins the cerebral part of the vertebral artery. Between the third and fourth arches the right dorsal aorta disappears, but from the fourth arch to the point of origin of the seventh intersegmental artery it becomes a portion of the right subclavian artery (fig. 190). Caudal to the seventh intersegmental artery the right dorsal aorta disappears as far as the point where the two dorsal aortæ fuse to form the descending thoracic aorta. The part of the left dorsal aorta between the third and fourth arches disappears, while the remainder persists to form the descending part of the arch of the aorta. A constriction, termed the *aortic isthmus*, is sometimes seen in the aorta between the origin of the left subclavian artery and the attachment of the ductus arteriosus.

Sometimes the right subclavian artery arises from the arch of the aorta distal to the origin of the left subclavian and passes upwards and to the right behind the trachea and œsophagus. This condition may be explained by the persistence of the right dorsal aorta and the obliteration of the fourth aortic arch of the right side.

In birds the fourth aortic arch of the right side forms the arch of the aorta ; in reptiles the fourth arches of both sides persist and give rise to the double aortic arch of these animals.

The heart originally lies on the ventral surface of the pharynx, immediately caudal to the stomodæum (fig. 189) ; with the elongation of the neck and the development of the lungs it recedes within the thorax, and, as a consequence, the vessels are drawn out and the original position of the fourth and sixth aortic arches is greatly modified. Thus, on the right side the fourth aortic arch recedes to the root of the neck, while on the left side it is drawn within the thorax. The recurrent laryngeal nerves originally pass to the larynx caudal to the sixth pair of aortic arches, and are therefore pulled tailwards with the descent of these structures, so that in the adult the left nerve hooks round the ligamentum arteriosum ; owing to the disappearance of the fifth aortic arch and the dorsal part of the sixth on the right side the nerve hooks round the fourth aortic arch, i.e. the commencement of the subclavian artery.

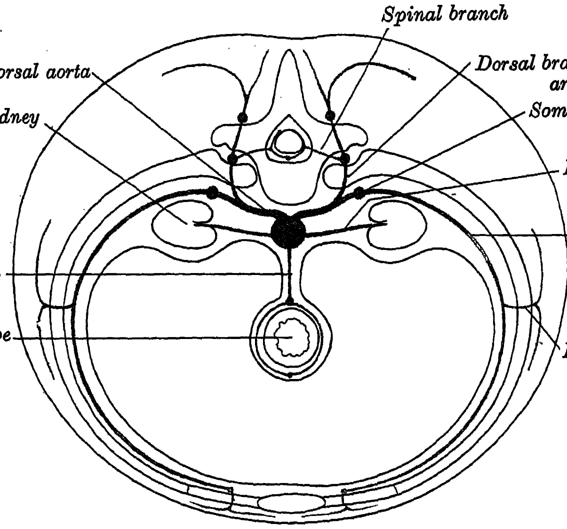
At first the aortæ are the only longitudinal vessels present, for the branches of the aortæ all run at right angles to the long axis of the embryo. Later these horizontal arteries become connected in certain situations by longitudinal anastomosing channels, and portions of these longitudinal vessels persist, forming such arteries as the internal mammary, the inferior epigastric, the gastro-epiploic, etc. Each dorsal aorta gives off segmental branches to the digestive tube (*ventral splanchnic arteries*) and to the mesonephric (Wolffian) ridge (*lateral splanchnic arteries*) and *intersegmental* branches to the body-wall (*somatic arteries*).

The *ventral splanchnic arteries* are originally paired vessels which are distributed to the wall of the yolk-sac, but after fusion of the dorsal aortæ they appear as unpaired trunks and are distributed to the primitive digestive tube.

Longitudinal anastomosing channels connect these branches along the dorsal and ventral aspects of the tube, forming dorsal and ventral splanchnic anastomoses (fig. 192). The development of these longitudinal vessels obviates the necessity for so many ventral splanchnic arteries, and these are reduced to three trunks—the cœliac, superior mesenteric and inferior mesenteric arteries. As the viscera which they supply descend into the abdomen, these vessels wander in a caudal direction; thus the origin of the cœliac artery is transferred from the level of the seventh cervical segment to the level of the twelfth thoracic, the superior mesenteric from the second thoracic to the first lumbar, and the inferior mesenteric from the twelfth thoracic to the third lumbar. The dorsal splanchnic anastomosis persists in the gastro-epiploic, pancreatico-duodenal, and the primary branches of the colic arteries, while the ventral splanchnic anastomosis forms the right and left gastric and the hepatic arteries.

The *lateral splanchnic* arteries supply, on each side, the mesonephros, the testis (or ovary) and the suprarenal gland; all these structures develop, in whole or in part, from the mesoderm of the mesonephric (Wolffian) ridge

FIG. 192.—Diagram of the segmental arteries.



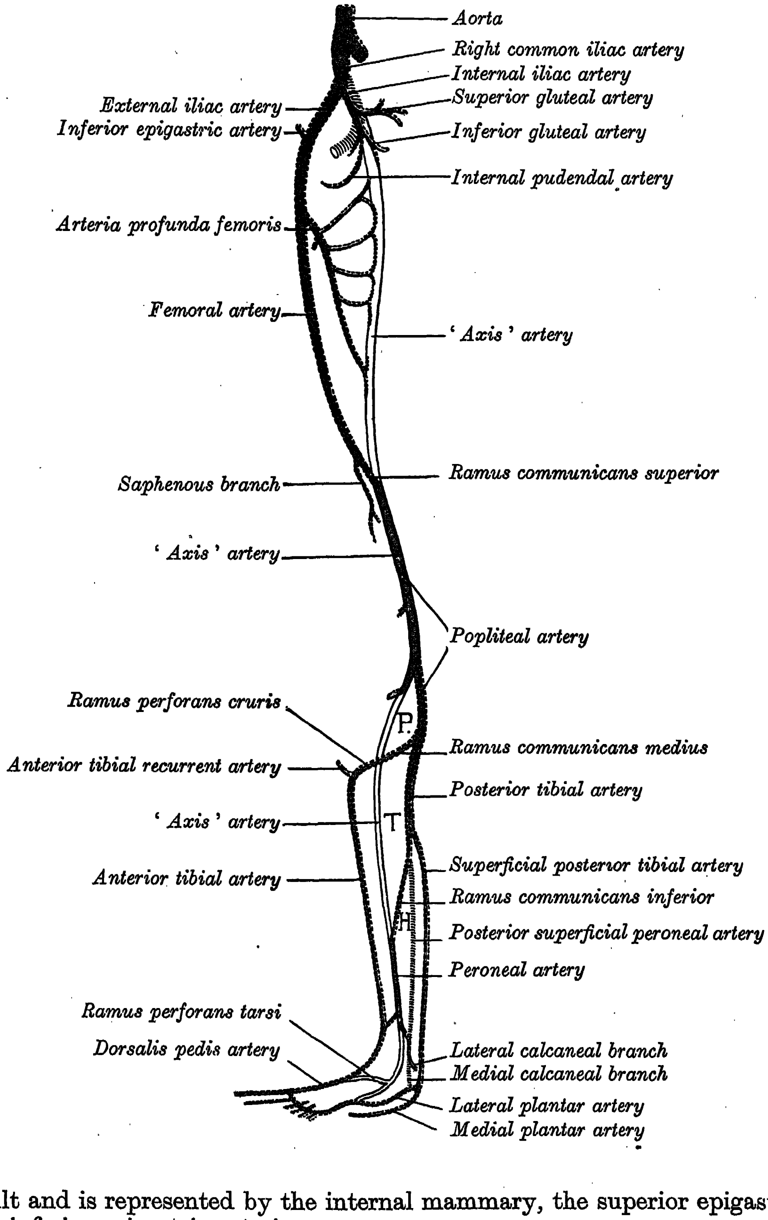
(p. 185). One testicular (or ovarian) artery and three suprarenal arteries persist on each side. The phrenic (inferior phrenic) artery arises as a branch from the first suprarenal artery, and the renal artery as a branch from the third. Additional renal arteries are frequently present and may be looked on as branches of persistent lateral splanchnic arteries.

The *somatic arteries* are intersegmental in position, and they persist, almost unchanged, in the thoracic and lumbar regions, as the posterior intercostal, subcostal and lumbar arteries. Each gives off a dorsal branch which passes backwards in the intersegmental interval and divides into medial and lateral branches to supply the muscles and superficial tissues of the back (fig. 192). In its course this dorsal branch gives off a spinal branch which enters the vertebral canal, and gives off spinal branches to the osteo-ligamentous canal and neural branches to the spinal cord. Having given off its dorsal branch the intersegmental artery runs ventrally in the body-wall, gives off a lateral branch and terminates by supplying both muscular and cutaneous branches.

Numerous longitudinal anastomoses link up the intersegmental arteries and their branches with one another. A *post-costal anastomosis* connects the dorsal branches in the interval between the neck of the rib and the vertebral transverse process. This vessel persists in the cervical region where it forms the greater part of the vertebral artery. A *post-transverse anastomosis* also connects the dorsal branches and is responsible for the greater part of the arteria profunda cervicalis. A *precostal anastomosis* connects the intersegmental

arteries beyond the origins of their dorsal branches. The ascending cervical and the superior intercostal arteries represent persistent portions of this vessel. Lastly, near the anterior median line the intersegmental arteries become linked up by a *ventral somatic anastomosis*. This vessel persists to a large extent in

FIG. 193.—A diagram to illustrate the general development of the arteries of the lower limb. The letter P indicates the position of the Popliteus; T that of the Tibialis posterior; and H that of the Flexor hallucis longus. (H. D. Senior.)



the adult and is represented by the internal mammary, the superior epigastric and the inferior epigastric arteries.

The *umbilical arteries* at first appear to be the direct continuation of the primitive dorsal aortæ and they are present in the body-stalk before any vitelline or visceral branches can be seen—an indication of the importance of the chorionic as compared with the vitelline circulation in the human embryo. After the fusion of the dorsal aortæ the umbilical arteries arise from its ventri-lateral aspect and pass medial to the primary excretory duct (Wolffian duct)

on their way to the umbilicus. Later the proximal part of the umbilical artery is joined by a vessel which leaves the aorta at its termination and passes lateral to the primary excretory duct. This new vessel, which possibly may represent the fifth lumbar intersegmental artery, constitutes the dorsal root of the umbilical artery. It gives off the axial artery of the lower limb, and, at a more proximal point, the external iliac artery. The proximal part of the umbilical artery disappears entirely, and the vessel now arises from that part of its dorsal root which lies proximal to the external iliac artery and constitutes the common iliac artery.

The arteries of the limbs.—Although a number of vessels contribute to the primitive capillary plexus of the upper limb bud, eventually only one trunk, —the subclavian—persists, and it has the position and relations of the *seventh intersegmental artery* and probably represents its lateral branch. The main trunk to the upper limb, which later forms the axillary and brachial arteries, is continued into the forearm deep to the flexor premuscle mass and terminates in a plexiform manner in the developing hand. This vessel ultimately persists as the anterior interosseous artery and the deep palmar arch. A branch from the main trunk passes dorsally between the developing radius and ulna and constitutes the posterior interosseous artery, while a second branch accompanies the median nerve into the hand, where it ends in a superficial capillary plexus. The radial and ulnar arteries are the latest arteries to appear in the forearm; at first the radial artery arises at a higher level than the ulnar and crosses in front of the median nerve, giving branches to the biceps muscle. Later, the radial artery establishes a connexion with the main trunk at or near the site of origin of the ulnar artery and the upper portion of its original stem disappears to a large extent. On reaching the hand the ulnar artery becomes linked up with the superficial palmar plexus from which the superficial palmar arch is derived, while the median artery loses its distal connexions and becomes reduced to a very small vessel. The radial artery passes to the dorsal surface of the hand but, after giving off dorsal digital branches, it perforates the first intermetacarpal space and links up with the deep palmar arch.

Senior has recently worked out the development of the arteries of the lower limb, and the following description is based on his observations.*

The primary arterial trunk (fig. 193) or ' axis ' artery of the lower limb arises from the dorsal root of the umbilical artery, and courses along the dorsal surface of the thigh, knee and leg; below the knee it lies between the tibia and the popliteus muscle, and in the leg between the crural interosseous membrane and the tibialis posterior muscle. It ends distally in a rete plantare, and gives off a perforating artery (ramus perforans tarsi) which traverses the sinus tarsi and forms a rete dorsale. The femoral artery passes along the ventral surface of the thigh, and opens up a new channel to the lower limb. It arises from a plexus of capillaries which is connected proximally with the femoral branches of the external iliac actery, and distally with the axis artery. At the proximal margin of the popliteus the axis artery gives off a *primitive posterior tibial* and a *primitive peroneal branch*, which run distally on the dorsal surface of that muscle and on the tibialis posterior to gain the sole of the foot. At the distal border of the popliteus the axis artery gives off a *perforating branch*, which passes ventrally between the tibia and the fibula and then runs downwards to the dorsum of the foot, forming the anterior tibial artery and the arteria dorsalis pedis. The primitive peroneal artery establishes one communication with the axis artery at the distal border of the popliteus and another in its course through the leg.

The femoral artery gradually increases in size, and coincidently with this increase almost the whole of the axis artery, proximal to its communication with the femoral, disappears; the root of the axis artery, however, persists as the inferior gluteal artery.

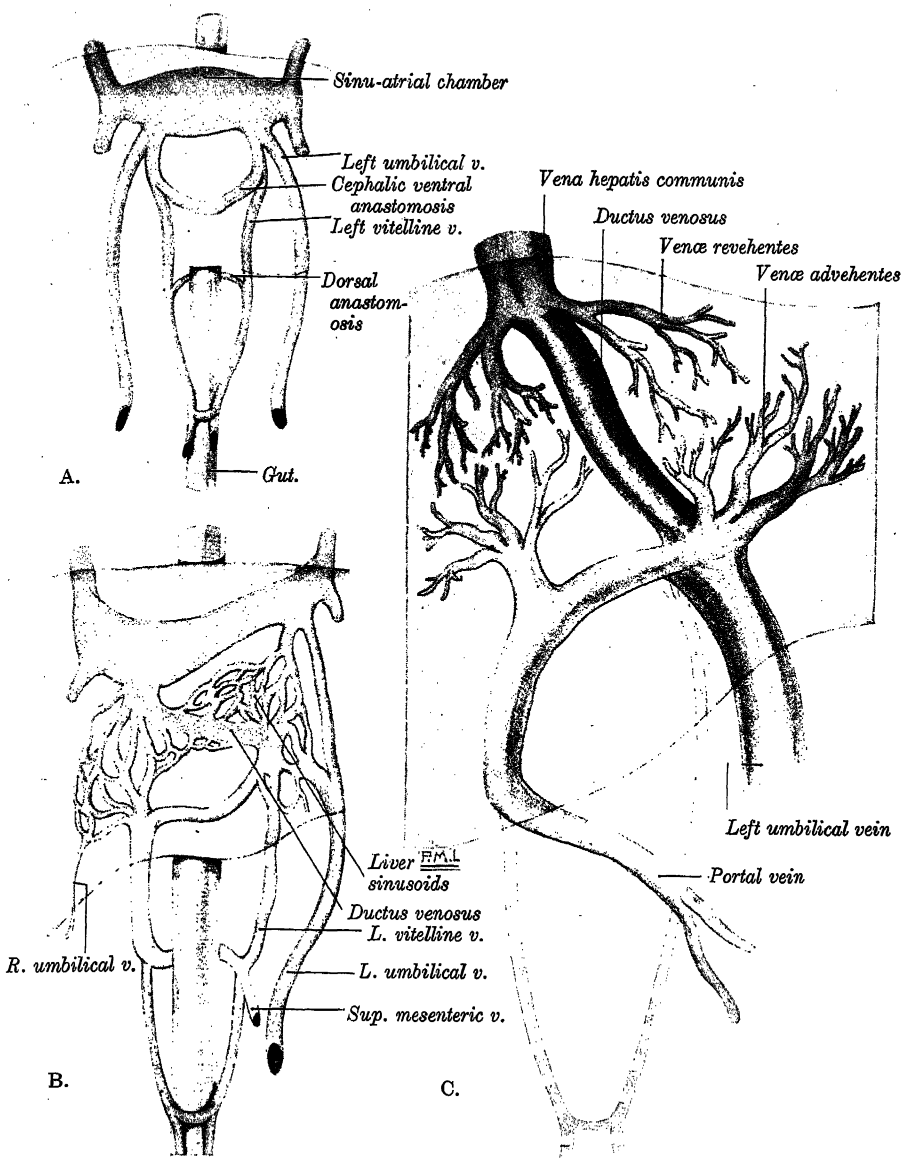
The proximal parts of the primitive posterior tibial and primitive peroneal arteries fuse, but their distal parts remain separate. Ultimately large portions of the axis artery and of the primitive peroneal artery disappear, although a

* H. D. Senior, *American Journal of Anatomy*, vol. xxv. 1919, and *Anatomical Record*, vol. xvii. 1920.

part of the former vessel is incorporated in the permanent peroneal artery. The changes are shown in greater detail in fig. 193.

The further development of the veins.—The principal veins of the embryo may be divided into two groups, visceral and parietal.

FIG. 194.—Three stages in the development of the veins of the liver.



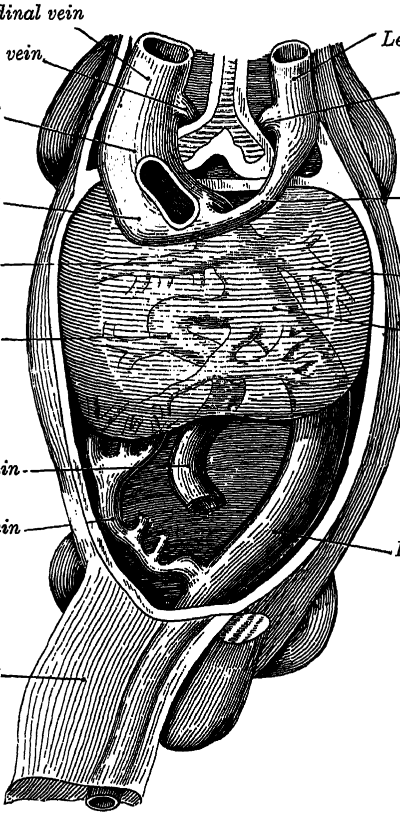
A. Pink = umbilical veins; mauve = vitelline veins.
B. Pink = umbilical veins and ductus venosus; mauve = vitelline veins and sinusoids of liver; blue = portions of vitelline veins later incorporated in the portal vein.
C. Blue = portal vein; interrupted mauve = portions of vitelline veins which disappear completely; pink = left umbilical vein and ductus venosus.

The visceral veins are the two vitelline veins bringing the blood from the yolk-sac, and the two umbilical veins returning the blood from the placenta; these four veins run through the septum transversum, and open into the sinus venosus.

The vitelline veins run upwards at first in front, and subsequently one on each side, of the digestive tube. They soon unite on the ventral surface of

the tube, and beyond this are connected to one another by two anastomotic branches, one on the dorsal and the other on the ventral surface of the duodenal portion of the intestine, which is thus encircled by two venous rings forming the figure 8 (fig. 194). The portions of the vitelline veins within the septum transversum become surrounded by the trabeculæ of the developing liver and broken up into a plexus of small capillary-like vessels, which are termed the liver *sinusoids*. Like the vitelline veins, the umbilical veins, running headwards from the umbilicus, traverse the septum transversum on their way to the sinus venosus and become involved in the growing liver. After a time the right umbilical vein entirely disappears, but the left umbilical vein, which retains

FIG. 195.—A human embryo with the heart and ventral body wall removed to show the sinus venosus and its tributaries. (After His.)

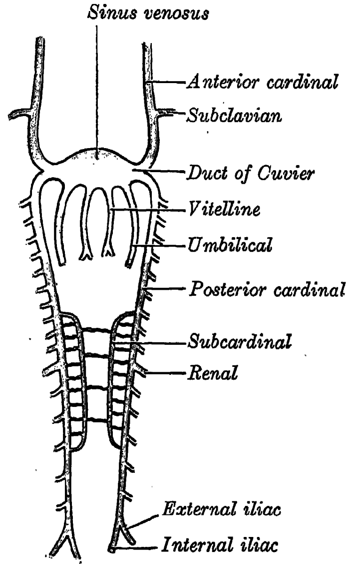


for a period its direct connexion with the left horn of the sinus venosus, pours its blood into the liver sinusoids. From the cardiac end of this vascular network, the blood flows into the horns of the sinus venosus through right and left venæ revehentes. In association with the establishment of the pulmonary circulation, venous channels develop which convey the blood from the left side of the liver to the right horn of the sinus venosus, where a large *common hepatic vein* now opens. The sinusoidal condition of the liver becomes condensed into a series of afferent vessels (*venœ advehentes*) and a series of efferent vessels (*venœ revehentes*) now leading to the common hepatic vein. In the process an oblique channel is formed which conveys most of the blood brought by the umbilical vein to the common hepatic vein. This vessel is the *ductus venosus* (fig. 194, *C*), and it plays a very important part in the fœtal circulation.

The superior mesenteric vein joins the left vitelline vein near the left extremity of the dorsal anastomosis. Later it is joined by the splenic vein, and the portal vein is thus established. Portions of the right and left vitelline veins disappear (fig. 194, *C*) and the portal vein is continued through the dorsal anastomosis, and the cephalic part of the right vitelline vein to the liver. The

intrahepatic part of the right vitelline vein becomes the right branch of the portal vein, while the cephalic ventral anastomosis and the intrahepatic part of the left vitelline vein form its left branch. The (left) umbilical vein joins the left branch of the portal vein, to which the ductus venosus is also connected. Some of the blood conveyed to the liver by the umbilical vein passes through the left venæ advehentes, but the great majority of it finds its way through the ductus venosus to the vena hepatis communis (which later forms the upper end of the inferior vena cava) and so to the right horn of the sinus venosus.

FIG. 196.—A scheme of the arrangement of the parietal veins.



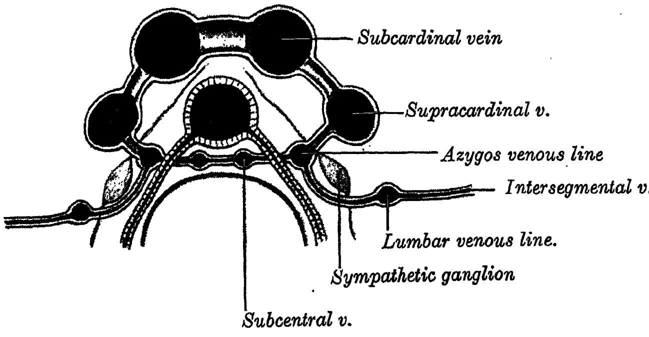
The venous drainage of the body-wall is effected at first by two large veins on each side, termed the *anterior* and *posterior cardinal veins*; the former drains the cephalic half of the embryo, and the latter the caudal half. These two veins unite to form a short vessel, termed the *duct of Cuvier*, which passes ventrally, lateral to the pleuropericardial canal (fig. 226), to gain the heart, where it joins the corresponding horn of the sinus venosus.

The *inferior vena cava* of the adult is a composite vessel, and the precise mode of development of its postrenal segment is still somewhat uncertain. Its earliest forerunner is the posterior cardinal vein, which receives the venous drainage of the lower limb bud and the pelvis and runs in the dorsal part of the mesonephric (Wolffian) ridge, receiving tributaries from the body-wall (intersegmental veins) and from the mesonephros.

A second longitudinal vein, termed the *subcardinal vein*, forms in the ventrimedial part of the mesonephric ridge and becomes connected to the posterior cardinal vein by a number of vessels which traverse the medial part of the ridge. The two subcardinal veins communicate with each other by a *preaortic anastomosis*, which later constitutes that portion of the left renal vein which crosses in front of the abdominal aorta.

The establishment of a cross anastomosis between the iliac veins, which forms a large part of the left common iliac vein in the adult, results in the preponderance of the right over the left longitudinal veins and helps to account for the subsequent disappearance of the latter.

FIG. 197.—Scheme of a composite transverse section to show the relative positions of some of the longitudinal somatic veins in the lumbar region.

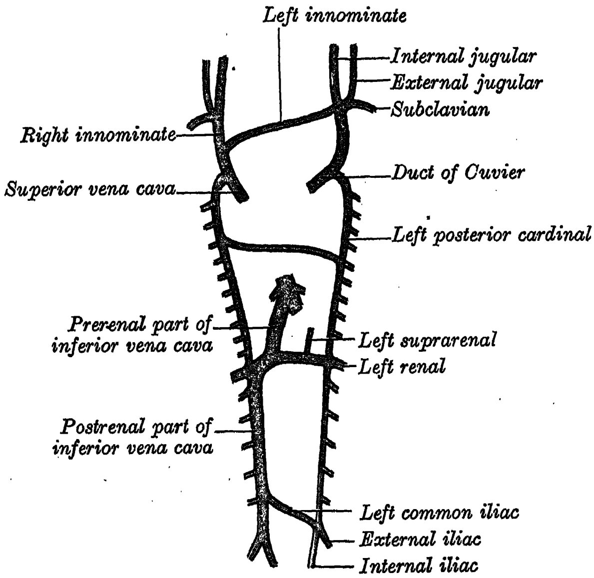


At its headward end the subcardinal vein receives the suprarenal vein on each side, but on the right side it comes into intimate relationship with the

liver. An extension of the vessel takes place in a cephalic direction and meets and establishes continuity with a corresponding new formation which is growing tailwards from the vena hepatis communis. In this way a more direct route is established to the heart and the prerenal segment of the inferior vena cava is formed.

The enlargement of the metanephros thrusts the posterior cardinal vein out of its course and the venous drainage of the mesonephric ridge is taken over by the subcardinal vein. At the same time new longitudinal channels form which take over the intersegmental venous drainage, and the whole of the posterior cardinal vein disappears with the exception of its extreme cephalic and caudal ends. These new channels are four in number on each side, but, so far as is known at the present time, only two of them persist as large vessels in the adult: (1) A longitudinal channel forms dorsilateral to the aorta and lateral to the sympathetic trunk and its branches, and takes over the intersegmental venous drainage from the posterior cardinal vein. This is the *thoraco-lumbar*

Fig. 198.—A diagram showing the development of the main cross branches between the longitudinal somatic veins.



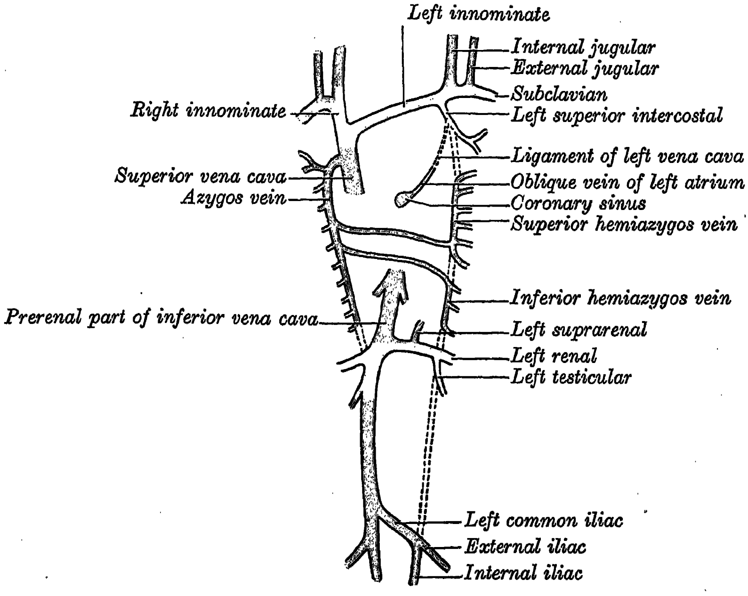
line (of Reagan). (2) A second channel is formed, also dorsilateral to the aorta but medial to the sympathetic trunk and the branches which it sends to the preaortic plexuses. This vessel constitutes the *azygos line* and, in turn, it takes over the intersegmental venous drainage from the thoraco-lumbar line. The intersegmental veins now, for the first time, reach their longitudinal channel by passing deep (medial) to the sympathetic trunk, the relationship which the lumbar and intercostal veins exhibit in the adult. At its cephalic end the azygos line joins the persistent cephalic part of the posterior cardinal vein. (3) Two *subcentral veins* are laid down directly dorsal to the aorta in the interval between the origins of the paired intersegmental arteries. These veins communicate freely with each other and with the azygos lines, and these connexions ultimately form the retro-aortic parts of the left lumbar veins. (4) The *supracardinal veins* are laid down lateral to the aorta and lateral to the sympathetic trunk and its branches to the preaortic plexuses, which therefore intervene between them and the azygos lines. These veins communicate caudally with the iliac veins and cephalically with the subcardinal veins in the neighbourhood of the preaortic intersubcardinal anastomosis. In addition, the supracardinal veins communicate freely with each other through the medium of the azygos lines and the subcentral veins. The most cranial of these connexions, together with the suprasubcardinal and intersubcardinal anastomosis, complete a venous

ring around the aorta below the origin of the superior mesenteric artery, termed by Huntington and McClure * the "*renal collar*" (fig. 197).

The right supracardinal vein persists and forms the greater part of the postrenal segment of the inferior vena cava, the continuity of the vessel being maintained by the persistence of the anastomosis between the right supracardinal and the right subcardinal in the "renal collar." The left supracardinal disappears, but the portion of the "renal collar" formed by the left supra-subcardinal anastomosis in part persists in the left renal vein.

The inferior vena cava is therefore formed, from below upwards, by (1) the right supracardinal vein, (2) an anastomosis between the right supra- and sub-

Fig. 199.—A diagram showing the completion of the development of the parietal veins.



cardinal veins, (3) the right subcardinal vein, (4) a new formation which connects the right subcardinal and the common hepatic veins, and (5) the common hepatic vein.† It should be noted that only the supracardinal part of the inferior vena cava receives the intersegmental venous drainage, and that the postrenal segment of the inferior vena cava is on a plane which lies dorsal to the plane of the prerenal segment. On this account the right inferior phrenic, suprarenal and renal arteries, which represent persistent mesonephric arteries, pass behind the inferior vena cava, while the testicular (or ovarian), which has a similar developmental origin, passes in front of it.

In some animals the right posterior cardinal vein constitutes a large part of the postrenal segment of the inferior vena cava. In these cases the right ureter, on leaving the kidney, passes medially dorsal to the vessel and then, curving round its medial side, crosses its ventral aspect. Very rarely a similar condition is found in the human subject, and indicates persistence of the right posterior cardinal vein and failure of the right supracardinal to play its normal part in the development of the vessel.

Summary of the history of the embryonic abdominal and thoracic longitudinal somatic veins.

(1) The posterior cardinal vein disappears entirely on the left side, but on the right side its cephalic end persists and forms the terminal portion of the vena azygos.

(2) The caudal part of the subcardinal vein is partly incorporated in the testicular (or ovarian) vein (McClure and Butler ‡) and partly disappears. The cephalic end of the right subcardinal vein is incorporated in the inferior vena cava and forms the right suprarenal

* S. S. Huntington and C. F. W. McClure, *Anatomical Record*, 1920.

† For a detailed account, see R. J. Gladstone, *Journal of Anatomy*, vol. lxiv. 1929.

‡ C. F. W. McClure and E. G. Butler, *American Journal of Anatomy*, vol. xxxv. 1925.

vein. The cephalic end of the left subcardinal vein is incorporated in the left renal vein and forms the left suprarenal vein.

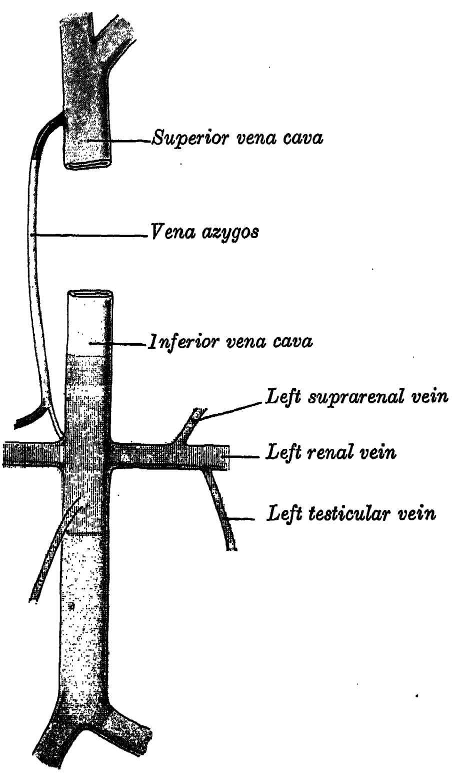
(3) The right supracardinal vein forms the postrenal segment of the inferior vena cava. The left supracardinal vein disappears entirely.

(4) The right azygos line persists in its thoracic portion to form all but the terminal part of the vena azygos. Its lumbar part can usually be identified as a small vessel which leaves the vena azygos on the body of the twelfth thoracic vertebra and descends on the vertebral column, deep to the right crus of the diaphragm, to join the posterior aspect of the inferior vena cava at the upper end of its postrenal segment. The left azygos line forms the hemiazygos veins.

(5) The subcentral veins are responsible for the formation of the retro-aortic parts of the left lumbar veins.

(6) The later history of the thoraco-lumbar lines is uncertain.

FIG. 200.—Diagram of the constituent parts of the inferior vena cava.



The supracardinal segment is shown in blue: the supra-cardinal-subcardinal segment in pink: the subcardinal segment in mauve: the subcardinal-hepatic segment in green: the hepatic segment in yellow.
The persistent part of the right posterior cardinal vein is shown in black.

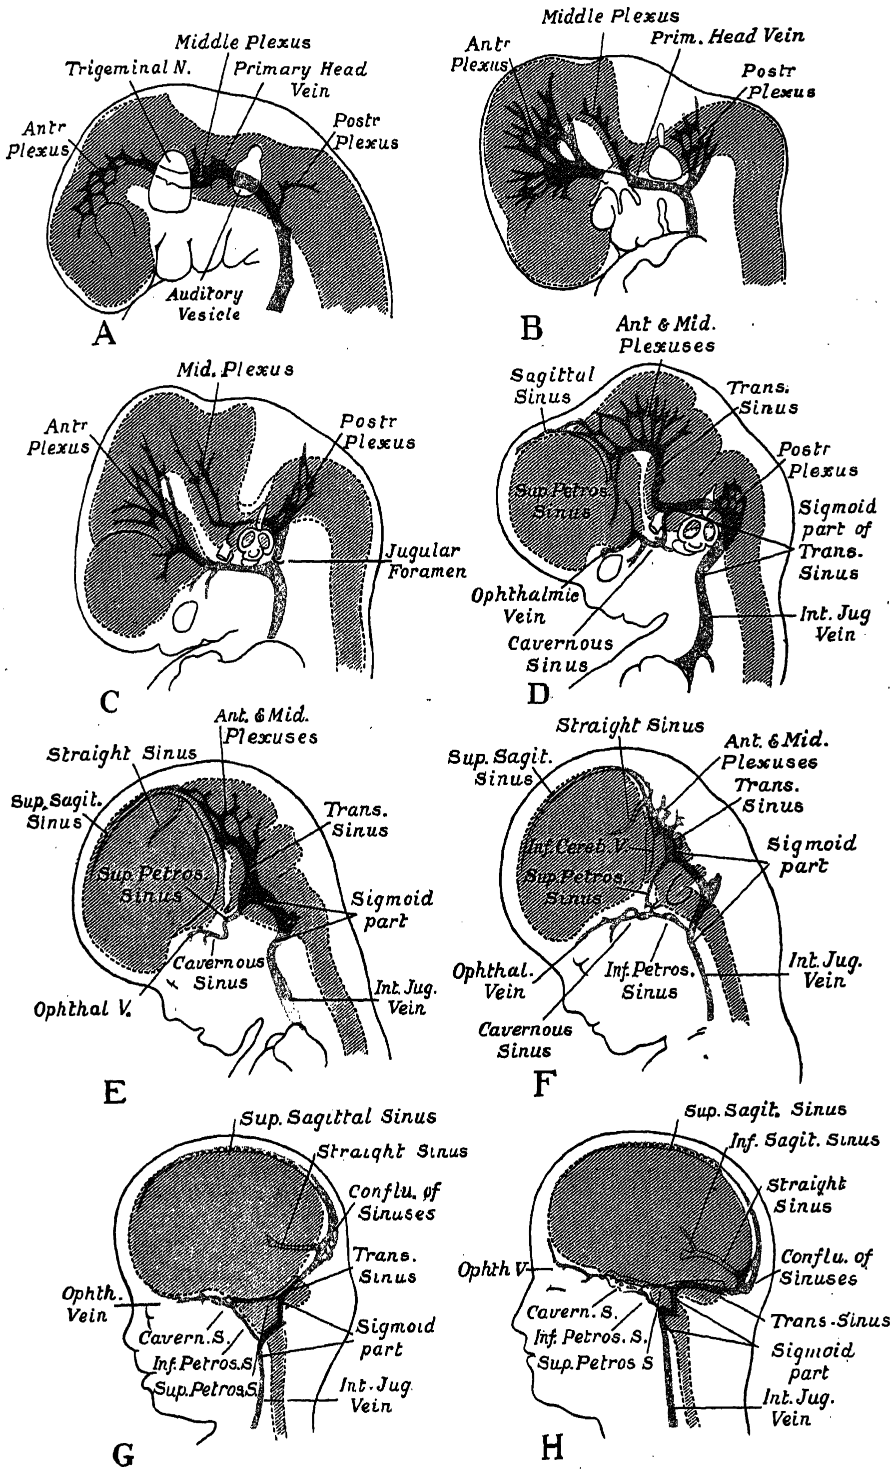
Owing to the rapid development of the head and brain the *anterior cardinal veins* become enlarged. They are further augmented by receiving the veins (*subclavian*) from the upper limb buds, and so come to form the chief tributaries of the ducts of Cuvier; these ducts gradually assume an almost vertical position in consequence of the descent of the heart into the thorax. The right and left ducts of Cuvier are originally of the same diameter, and are frequently termed the *right* and *left superior venæ cavæ*. By the development of a transverse branch (the *left innominate vein*) between the two anterior cardinal veins, the blood is carried across from the left to the right anterior cardinal (figs. 198, 199). The portion of the right anterior cardinal vein between the left innominate and the azygos vein forms the upper part of the superior vena cava of the adult; the lower part of the latter vessel (i.e. below the entrance of the azygos vein) is formed by the right duct of Cuvier. Below the left innominate vein the left anterior cardinal vein and left duct of Cuvier atrophy, the former constituting the upper part of the left superior intercostal vein, while the latter is represented by the ligament of the left vena cava and the oblique vein of the left atrium (fig. 199). The oblique vein of the left atrium passes downwards across the back of the left atrium to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus. Right and left superior venæ cavæ are present in some animals, and are occasionally found in the adult human being.

The venous sinuses of the dura mater. The following description is based on that given by Streeter.*

The primary blood-vessels of the head consist of a close-meshed capillary plexus which is drained by anastomosing loops into a pair of veins, named the *primary head veins*. Each primary head vein (fig. 201, *A*) begins on the diencephalon, and courses along the side of the brain running medial to the trigeminal (semilunar) ganglion and lateral to the auditory vesicle; on reaching the vagus nerve it turns sharply downwards and opens into the duct

* George L. Streeter, *American Journal of Anatomy*, vol. xviii. 1915.

FIG. 201.—Profile drawings showing the development of the venous sinuses of the dura mater in human embryos from 4 mm. to birth. Their adaptation to the growth and changes in the form of the brain should be noted. A. Embryo of 4 mm.; B. Embryo of 14 mm.; C. Embryo of 18 mm.; D. Embryo of 21 mm.; E. Embryo of 35 mm.; F. Embryo of 50 mm. crown-rump length; G. Embryo of 80 mm. crown-rump length; H. At birth. (George L. Streeter.)



of Cuvier. The part of the vein which is caudal to the vagus nerve is the anterior cardinal vein, the cephalic portion of which forms the internal jugular vein. At a later stage the greater part of the original capillary plexus assumes the form of three secondary plexuses —anterior, middle and posterior (fig. 201, *B*, *C*); the middle and posterior plexuses each open by a single vein into the primary head vein. Some tributaries from the ventral part of the head also enter this vein; the most important of these are the channels from the eye-region, and these later become the ophthalmic veins.

The development of the cranium and of the brain membranes introduces further changes: the three main secondary plexuses are largely retained in association with the dura mater, while superficial portions are split off to drain the surface of the head, and deeper portions are specialized for the drainage of the brain-stem. The next series of modifications is largely due to the increase in the size of the internal ear. An anastomosing channel between the middle and posterior plexuses forms on the dorsal aspect of the auditory vesicle, and the anterior and middle plexuses unite with one another (fig. 201, *C*, *D*). A single large vein, which is the commencement of the transverse sinus, drains the anterior and middle plexuses into the new anastomosing channel (fig. 201, *D*). The posterior part of the primary head vein, i.e. the part connected with the internal jugular vein, disappears, but the anterior portion, in the region of the trigeminal nerve, is retained as the cavernous sinus, and into this the ophthalmic veins open (fig. 201, *D*, *E*). The original stem of the middle plexus, between the new anastomosing channel and the primary head vein, undergoes atrophy, but later is re-established as the superior petrosal sinus (fig. 201, *E*, *F*, *G*). The inferior petrosal sinus is a new formation, developed from a small plexus between the cavernous sinus and the internal jugular vein (fig. 201, *F*, *G*).

The transverse and sigmoid sinuses at this stage can be recognized as a composite vessel derived from (1) the stem of the conjoined anterior and middle plexuses, (2) the anastomosing channel dorsal to the auditory vesicle, and (3) the stem of the posterior plexus continued into the internal jugular vein; the second and third portions together form the sigmoid sinus.

Between the growing cerebral hemispheres extensions of the anterior and middle plexuses of both sides meet and form the *sagittal plexus*, a curtain of capillary veins which hangs down in the position of the future falx cerebri. Along the dorsal margin of this curtain the superior sagittal sinus is evolved, and this sinus usually joins the right transverse sinus; along the ventral free edge of the curtain the inferior sagittal sinus and the straight sinus are formed, the latter passing into the left transverse sinus. When the cerebral hemispheres grow backwards they carry with them the sagittal sinus; the straight sinus extends backwards through a plexus in the tentorium cerebelli, and the transference of both sinuses is continued until they arrive at their adult positions with their point of junction at the confluence of the sinuses. The posterior plexus establishes a secondary connexion with the confluence of the sinuses, loses its connexion with the sigmoid sinus, and is retained as the occipital sinus.

The external jugular vein at first drains the region behind the ear (posterior auricular) and enters the anterior cardinal as a lateral tributary. A group of veins from the face and lingual region converge to form a common vein, termed the linguofacial,* which also ends in the anterior cardinal vein. Later, cross communications develop between the external jugular and the linguofacial, with the result that the posterior group of facial veins is transferred to the external jugular vein. The cephalic vein is, for a time, a tributary of the external jugular vein, but is later diverted into the axillary vein.

At first the heart is placed directly under the head and is relatively of large size. Later it assumes its position in the thorax, but lies at first in the median plane; towards the end of pregnancy it gradually becomes oblique in direction. The atrial portion is at first larger than the ventricular part, and the two atria communicate freely through the foramen ovale. In consequence of the communication, through the ductus arteriosus, between the pulmonary artery and the aorta, the contents of the right ventricle are mainly carried into the latter vessel instead of to the lungs, and hence the wall of the right ventricle is more muscular than that of the left, a condition which persists throughout intra-uterine life. After birth more work is thrown on the left ventricle and its walls rapidly become much thicker than those of the right ventricle.

The fœtal circulation and the changes which take place in the circulation after birth are described in the section on Angiology.

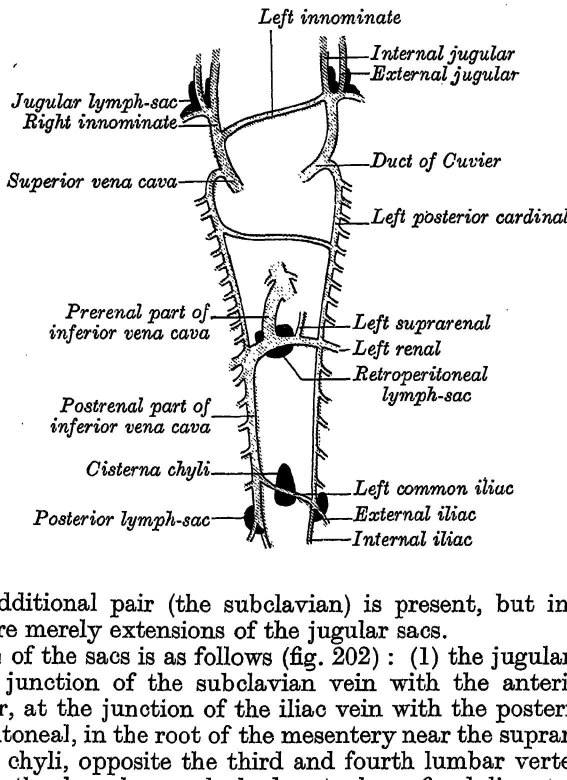
The lymphatic system.—Two different views are still current as to the initial stages in the development of the lymphatic system. According to the view

* Lewis, *American Journal of Anatomy*, vol. ix. 1909.

put forward by Huntington and McClure lymphatic spaces appear as clefts in the mesenchyme, and their lining cells take on the characters of endothelium. These spaces form capillary plexuses from which certain lymph-sacs, to be noted later, are derived. The connexions of the lymphatic with the venous system are entirely secondary. According to Sabin, however, the earliest lymph vessels arise as capillary offshoots from the endothelium of the veins, which form capillary plexuses. These plexuses lose their connexions with the venous system and become confluent to form lymph-sacs. The balance of the evidence suggests that the lymphatic system originates independently of the venous system and only acquires connexions with it at a later stage.

In the human embryo the lymph-sacs from which the lymph vessels are derived are six in number; two paired (the jugular and the posterior lymph-sacs) and two unpaired (the retroperitoneal and the cisterna chyli). In lower

FIG. 202.—A scheme showing the relative positions of the primary lymph-sacs. (Based on the description given by Florence Sabin.)



mammals an additional pair (the subclavian) is present, but in the human embryo these are merely extensions of the jugular sacs.

The position of the sacs is as follows (fig. 202): (1) the jugular, the first to appear, at the junction of the subclavian vein with the anterior cardinal; (2) the posterior, at the junction of the iliac vein with the posterior cardinal; (3) the retroperitoneal, in the root of the mesentery near the suprarenal glands; (4) the cisterna chyli, opposite the third and fourth lumbar vertebræ. From the lymph-sacs the lymph vessels bud out along fixed lines corresponding more or less closely with the course of the embryonic blood-vessels, but many arise *de novo* in the mesenchyme and establish connexions with existing vessels. In the body-wall and in the wall of the intestine,* the deeper plexuses are the first to be developed; by continued growth of these the vessels in the superficial layers are gradually formed. The thoracic duct is, phylogenetically, a bilateral structure. In man it comprises the caudal part of the right vessel, a transverse anastomosis and the cephalic part of the left vessel. According to Sabin it is formed from anastomosing outgrowths from the jugular sac and cisterna chyli. At its connexion with the cisterna chyli it is at first double, but the vessels soon join. Numerous valves are laid down in the duct during the fifth month, but many of them disappear prior to birth. Those which persist are formed in situations where the duct may

* Heuer, *American Journal of Anatomy*, vol. ix. 1909.

be subjected to pressure, e.g. where it is crossed by the œsophagus and the aortic arch.

All the lymph-sacs except the cisterna cyli are, at a later stage, divided up by a number of slender connective tissue bridges. Later they are invaded by lymphocytes and transformed into groups of lymph glands ; the lymph sinuses representing portions of the original cavity of the sac. The lower portion of the cisterna chyli is similarly converted, but its upper portion remains as the adult cisterna.

THE DEVELOPMENT OF THE DIGESTIVE AND RESPIRATORY APPARATUS

The **digestive tube.**—As already indicated (p. 69), the primitive digestive tube consists of three parts, viz. : (1) the *fore-gut,* within the head-fold and dorsal to the heart ; (2) the *hind-gut,* within the tail-fold (fig. 93, A) ; and (3) the *mid-gut,* which is intermediate in position. At first the fore-gut and hind-gut end blindly ; the cephalic end of the fore-gut is closed by the buccopharyngeal membrane ; the hind-gut ends in the cloaca, which is closed by the cloacal membrane. Both the buccopharyngeal and the cloacal membranes consist of ectodermal and entodermal layers in direct apposition with each other without the intervention of mesoderm. The wide communication between the mid-gut and the yolk-sac is gradually narrowed and drawn out to form the *vitello-intestinal duct.*

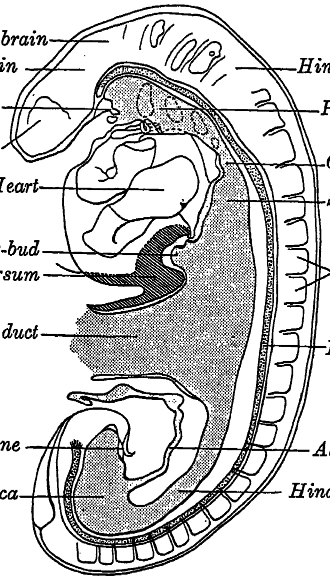
The **mouth** is developed partly from the stomodæum, and partly from the floor of the cephalic portion of the fore-gut. By the growth of the head-end of the embryo, and the formation of the head-fold, the pericardial area and the buccopharyngeal membrane come to lie on the ventral surface of the embryo (p. 69). With the further expansion of the brain, and the bulging of the pericardium, the buccopharyngeal membrane is depressed between these two prominences. This depression constitutes the *stomodæum* or *primitive mouth* (fig. 203). It is lined with ectoderm, and is separated from the cephalic end of the fore-gut by the buccopharyngeal membrane, which is formed by the apposition of the stomodæal ectoderm with the fore-gut entoderm ; at the end of the fourth week the membrane disappears, and a communication is established between the primitive mouth and the cephalic end of the fore-gut or future pharynx. No trace of the membrane is found in the adult ; and the communication just mentioned must not be confused with the permanent oro-pharyngeal isthmus (isthmus faucium). The lips, teeth, and gums are formed from the walls of the stomodæum, but the tongue is developed in the floor of the mouth and pharynx.

The visceral arches grow in a ventral direction and come to lie between the stomodæum and the pericardium ; with the completion of the mandibular arch and the development of the maxillary processes, the opening of the stomodæum assumes a pentagonal form, bounded on its cephalic side by the frontonasal process, caudally by the mandibular arches, and laterally by the maxillary processes (fig. 204). With the inward growth and fusion of the palatine processes (figs. 127, 129), the stomodæum is divided into a nasal and a buccal part. Along the free margins of the processes bounding the mouth cavity a shallow groove appears ; this is termed the *primary labial groove,* and from its floor a downgrowth of ectoderm into the underlying mesoderm takes place. Owing to the degeneration of the central cells of this ectodermal downgrowth the groove is deepened and a *secondary alveolo-labial groove* is formed, which separates the lips and cheeks from the alveolar processes of the maxillæ and mandible.

The **salivary glands** arise from the epithelial lining of the mouth. The *parotid gland* can be recognised in human embryos 8 mm. long as an elongated furrow running dorsally from the angle of the mouth between the mandibular arch and the maxillary process. The groove, which is converted into a tube, loses its connexion with the epithelium of the mouth except at its anterior end and grows dorsally into the substance of the cheek. The tube persists as the

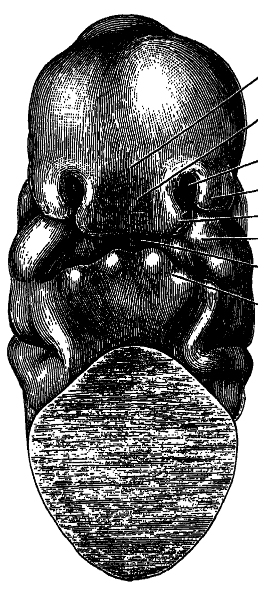
parotid duct and its blind end proliferates to form the gland. Subsequently the size of the oral fissure is reduced, and the duct opens thereafter on the inside

FIG. 203.—The digestive tube of a human embryo 2·5 mm. long. (Peter Thompson.)



of the cheek at some distance from the angle of the mouth. The *submandibular gland* (submaxillary gland) is present in human embryos, 13 mm. long, as an epithelial outgrowth from the floor of the alveololingual groove (p. 164). It increases rapidly in size by giving off numerous branching processes, which later acquire lumina. The original connexion with the floor of the mouth gradually moves ventrally, as the walls of the groove in which it lies come together at its dorsal end and the process extends ventrally to form the tubular submandibular duct (Frazer). The *sublingual gland* arises at the end of the second month as a number of small epithelial thickenings in the alveololingual groove lateral to the submandibular outgrowth.

FIG. 204.—The head-end of a human embryo in the sixth week. Ventral aspect. (From a model by K. Peter.)



The **tongue**.—Before the visceral arches meet one another at their ventral ends, a small median elevation, named the *tuberculum impar*, appears in the entodermal floor of the pharynx, and it subsequently becomes incorporated in the anterior part of the tongue. A little later two oval *lingual swellings* appear on the entodermal aspect of the mandibular arches. They meet each other in front, and caudally they converge on the tuberculum impar, with which they fuse (figs. 205, 206). A

sulcus forms along the ventral and lateral margins of this elevation and deepens to form the *alveololingual groove*, while the elevation constitutes the anterior or buccal part of the tongue.

Caudal to the tuberculum impar, a second median elevation, termed the *hypobranchial eminence* (Frazer) (*copula* of His), forms in the floor of the pharynx, and it receives the ventral ends of the fourth, the third and, later, the second visceral arches. A transverse groove separates off the caudal portion of the eminence to form the epiglottis, while its ventral portion ap-

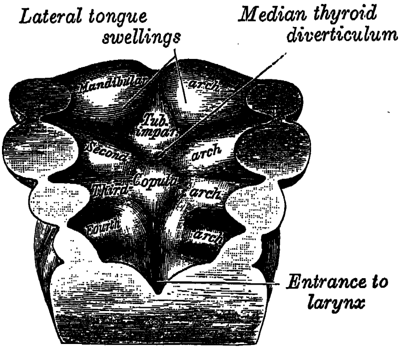


Fig. 205.—The floor of the pharynx of a human embryo in the fifth week. (From a model by K. Peter.)

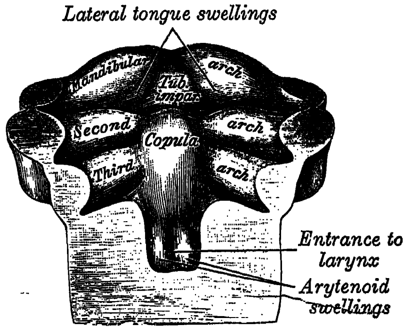

Fig. 206.—The floor of the pharynx of a human embryo at the beginning of the sixth week. (From a model by K. Peter.)

proaches the tongue rudiment, spreading ventrally in the form of a V, and blends with it to constitute the posterior or pharyngeal part of the tongue. In the process the third arch elements grow over and bury the elements of the second arch, excluding it from the tongue. As a result the mucous membrane of the pharyngeal part of the tongue receives its sensory supply from the glossopharyngeal, the nerve of the third arch. In the adult the union of the anterior and posterior parts of the tongue is marked by the V-shaped sulcus terminalis, the apex of which is at the foramen cæcum, a pit-like depression produced at the time of fusion of the constituent parts of the tongue, but also marking the site of the out-growth of the diverticulum which forms the thyroid gland.

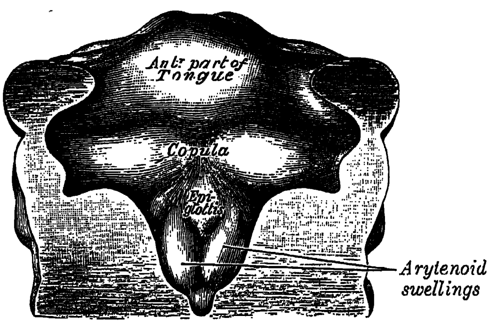

Fig. 207.—The floor of the pharynx of a human embryo, about six weeks old. (From a model by K. Peter.)

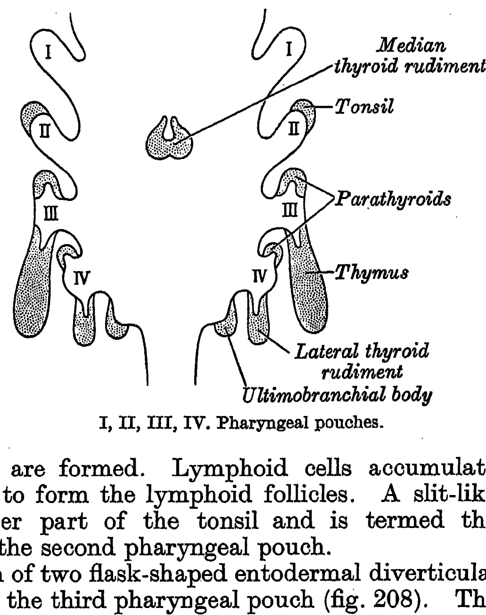
At first the tongue consists of a mass of mesoderm covered on its free surface by entoderm. During the second month the occipital myotomes migrate from their original position on the lateral aspect of the myelencephalon and invade the tongue to form its musculature. They pass ventrally round the wall of the pharynx to reach its floor and they are accompanied, necessarily, by their nerve of supply (the hypoglossal nerve), which therefore crosses superficial to both the internal carotid (dorsal aorta) and the external carotid arteries.

The composite character of the tongue is indicated by its adult innervation. The anterior or buccal part receives sensory branches from (*a*) the lingual nerve, which is derived from the (post-trematic) nerve of the first arch (mandibular nerve); and (*b*) the chorda tympani, which is the pretrematic nerve of the first arch. The posterior or pharyngeal part of the tongue receives its innervation from the glossopharyngeal, which is the nerve of the third arch. The muscles of the tongue are myotomic in origin and receive their nerve

supply from the hypoglossal nerve, which is serially homologous with the anterior nerve roots of the spinal nerves.

The **thyroid gland** is developed from a median diverticulum, which appears about the fourth week in the furrow immediately caudal to the tuberculum impar (fig. 205). It grows caudally as a tubular duct, which bifurcates and subsequently divides into a series of cellular cords, from which the isthmus and portions of the lateral lobes of the thyroid gland are developed. From the region of the ventral end of the fourth pharyngeal pouch an entodermal diverticulum grows caudally and medially. After losing its connexion with the pharnyx, it comes into contact and fuses with the dorsal and medial aspects of the lateral portion of the median thyroid rudiment. It constitutes the lateral thyroid rudiment and both median and lateral rudiments help to form the (lateral) lobe of the adult gland.* The connexion of the median diverticulum with the pharynx is termed the *thyroglossal duct*; it is obliterated at a very early stage, but the site of its connexion with the epithelial floor of the mouth is marked by the foramen cæcum. The pyramidal lobe is probably a secondary extension upwards from the developing isthmus. Occasionally portions of the thyroglossal duct persist and give rise to the formation of cysts in the median line of the neck.

FIG. 208.—A scheme showing the development of the branchial epithelial bodies. (Modified from Kohn.)



I, II, III, IV. Pharyngeal pouches.

The **tonsils** (palatine tonsils) are developed from the parts of the second pharyngeal pouches which lie between the tongue and the soft palate. The entoderm lining these pouches grows in the form of a number of solid buds into the surrounding mesoderm. These buds are excavated by the degeneration and shedding of their central cells, and by this means the tonsillar pits (crypts) are formed. Lymphoid cells accumulate around the pits, and are grouped to form the lymphoid follicles. A slit-like fissure, which cuts into the upper part of the tonsil and is termed the *intratonsillar cleft*, is a remnant of the second pharyngeal pouch.

The **thymus** appears in the form of two flask-shaped entodermal diverticula, which arise, one on each side, from the third pharyngeal pouch (fig. 208). The ventral end of each pouch gives origin to a hollow diverticulum which grows caudally into the surrounding mesoderm. In front of the aortic sac (p. 147) the two thymic rudiments meet and are subsequently united by connective tissue, but the rudiments themselves never fuse. The connexion with the third pouch is soon lost, but the stalk may persist for some time as a solid, cellular cord. By further proliferation of the cells lining the diverticula, solid buds are formed, which become surrounded and isolated by the invading mesoderm. Lymphocytes penetrate the solid lobules and soon preponderate over the epithelial elements, which later give rise to the concentric corpuscles.

The thymic rudiment closely resembles the lateral thyroid rudiment in its mode of origin. At birth the thymus weighs about 13 grams, and it increases in size up to puberty, when it averages 37·52 grams (Hammar). After puberty the gland undergoes a slow reduction in size.

The **parathyroid glands** are also derivatives of the pharyngeal entoderm. After the appearance of the thymic rudiment from the third pharyngeal pouch, the epithelium on the dorsal aspect of its neck-like connexion with the pharynx differentiates to form the *inferior parathyroid gland*. Although the connexion between the pouch and the pharynx is soon lost, the connexion between the

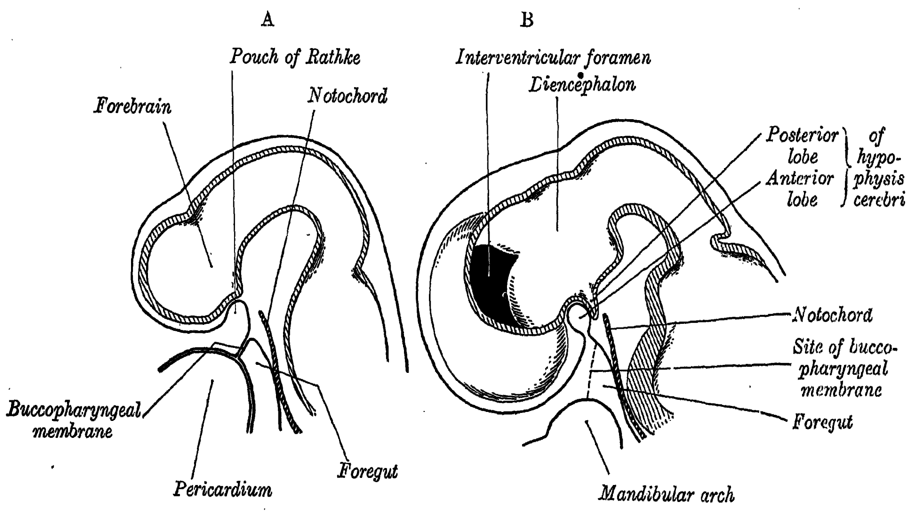
* The description of the development of the thyroid gland given here is based on the work of G. Louis Weller, jr., *Contributions to Embryology*, vol. xxiv. 1933.

thymic and parathyroid rudiments persists for some time, with the result that the latter is drawn caudally with the developing thymus. The *superior parathyroid gland* develops in a similar manner in association with the lateral thyroid rudiment and so may be ascribed to the fourth pharyngeal pouch.

It is uncertain whether the diverticulum derived from the fifth pouch and termed the *ultimobranchial body* is a distinct entity; if so, it disappears entirely at an early stage.

The **hypophysis cerebri** (pituitary body) consists of an anterior and a posterior lobe; the former is derived from the ectoderm of the stomodæum, the latter from the floor of the fore-brain. Previous to the rupture of the buccopharyngeal membrane a pouch-like diverticulum appears in the ectodermal lining of the roof of the stomodæum. This diverticulum (*pouch of Rathke*) (fig. 209) is the rudiment of the anterior lobe of the hypophysis; arising immediately ventral to the cephalic border of the buccopharyngeal membrane, it extends upwards in front of the cephalic end of the notochord, and comes into contact with the under surface of the fore-brain. It is then constricted off to form

FIG. 209.—Schematic sagittal sections of heads of early embryos to show first stages in the development of the hypophysis cerebri.



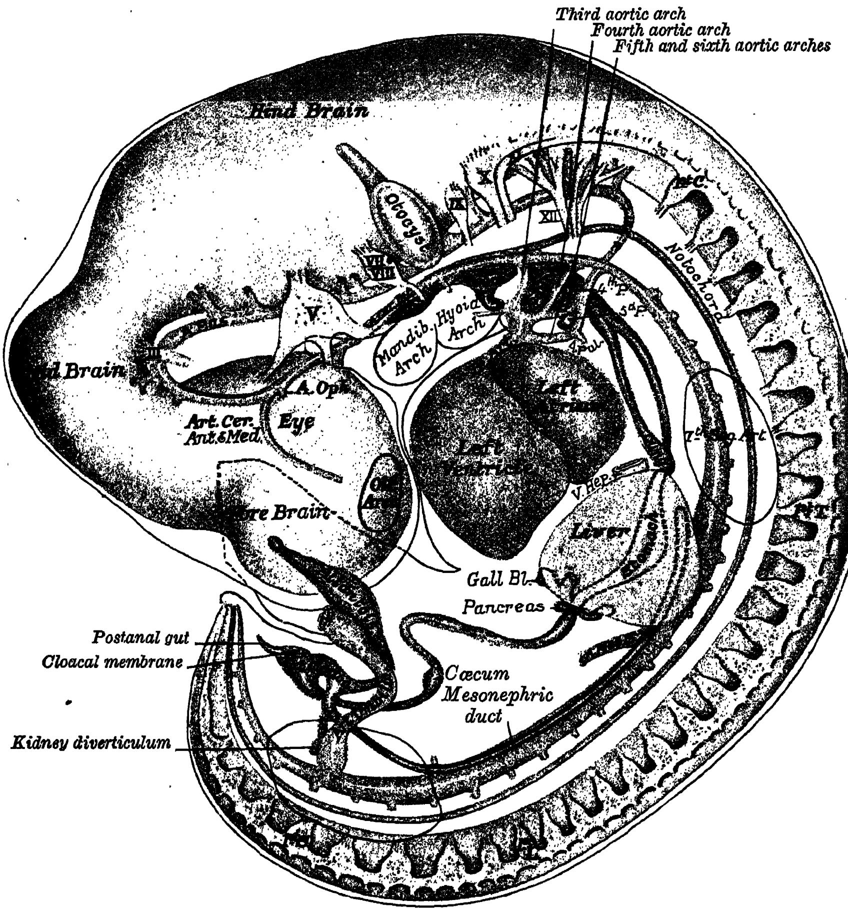
a closed vesicle, but remains for a time connected to the ectoderm of the stomodæum by a solid cord of cells. Masses of epithelial cells form on each side and in the ventral wall of the vesicle, and by the growth of a stroma from the mesenchyme between the masses the development of the anterior lobe of the hypophysis is completed. A canal (*craniopharyngeal canal*) sometimes runs from the anterior part of the hypophyseal fossa of the sphenoid bone to the under surface of the skull, and marks the original position of Rathke's pouch; and traces of the stomodæal end of the pouch are occasionally present at the junction of the septum of the nose with the palate (Frazer). Just behind Rathke's pouch a hollow diverticulum grows towards the mouth from the floor of the diencephalon. This neural outgrowth forms a funnel-shaped sac, the walls of which increase in thickness so as to obliterate the contained cavity except at its upper end, where it persists as the *infundibular recess* of the third ventricle. Formed in this way the *posterior lobe* of the hypophysis becomes invested by the anterior lobe, which extends dorsally on each side of it. In addition, the anterior lobe gives off two processes from its ventral wall which grow along the infundibulum and fuse to surround it, coming into relation with the tuber cinereum and constituting the *tuberal portion* of the hypophysis. The original cavity of the stomodæal diverticulum remains as a cleft and can be identified readily in sagittal sections through the gland in the adult. The dorsal wall of the stomodæal part, which remains thin, fuses with the adjoining part of the posterior lobe and forms the *pars media*. In

some of the lower animals the posterior lobe contains nerve-cells and nerve-fibres, but in man and the higher vertebrates it consists only of neuroglial tissue.

A small entodermal diverticulum, named *Seessel's pouch,* projects towards the brain from the cephalic end of the fore-gut, close to the buccopharyngeal membrane. In some marsupials this pouch forms a part of the hypophysis but, in man, it disappears entirely.

The **pharynx** is formed from the cephalic end of the fore-gut, and the visceral arches and pharyngeal pouches play an important part in its development. The

FIG. 210.—A human embryo of 7 mm. greatest length. Left lateral aspect. (From a reconstruction by P. Thompson.)



entodermal aspect of the mandibular arch in its dorsal part contributes to the formation of the lateral wall of the nasal pharynx in front of the orifice of the pharyngo-tympanic (auditory) tube. The ventral end of the first pouch becomes obliterated, but its dorsal end persists and deepens as the head enlarges. It remains in close relationship with the ectoderm of the dorsal end of the first cleft (p. 97) and, together with the adjoining lateral part of the pharynx and dorsal part of the second pharyngeal pouch, constitutes the *tubotympanic recess,* which forms the tympanic cavity and the pharyngo-tympanic tube (p. 131). The site of the second arch is partly indicated by the palato-glossal arch, but its dorsal end is separated from its ventral end by the forward growth of the third arch, which obliterates the intermediate part (Frazer). It is believed that the site of the second pharyngeal pouch is represented by the intratonsillar cleft, around which the tonsil is developed. This cleft is sometimes incorrectly termed the supratonsillar fossa. The third arch forms the pharyngo-epiglottic fold, and its dorsal end takes part in the formation of the floor of the pharyngo-

tympanic tube (Frazer). From the third pouch the thymus and the inferior parathyroid are developed (p. 165). The ventral ends of the fourth arches fuse with the posterior part of the hypobranchial eminence and so contribute to the formation of the epiglottis (p. 164). The adjoining portion becomes connected to the arytenoid swelling and may be identified in the aryepiglottic fold.

After the caudal portion of the hypobranchial eminence has been separated from the dorsal part of the tongue (p. 164), it is in continuity with two linear ridges which appear in the ventral wall of the pharynx, the whole forming an inverted U, regarded by His as an independent formation and called by him the *furcula*. Frazer identifies these vertical ridges as the sixth arches, placed very obliquely owing to the shortness of the pharyngeal floor compared with the greater extent of its roof. The contained groove of the furcula is carried downwards on the ventral wall of the fore-gut as the *laryngotracheal groove*, from which the lower part of the larynx, the trachea, bronchi and lungs are developed (p. 179). At the cephalic end of the groove paired arytenoid swellings arise which convert the slit-like upper aperture of the respiratory system into a T-shaped opening. The aryepiglottic folds can now be recognised extending from the arytenoid swellings to the epiglottis.

The **further development of the digestive tube.**—The portion of the fore-gut which succeeds the pharynx remains tubular, and is elongated to form the œsophagus. About the fourth week the stomach can be recognised as a fusiform dilatation (fig. 211), and beyond this the gut opens into the yolk-sac; this opening is at first wide, but is gradually narrowed into a tubular stalk (the *vitelline* or *vitello-intestinal duct*), which soon loses its connexion with the digestive tube (fig. 210). At this stage the stomach is placed in the median plane, and ventrally it is separated from the pericardium by the septum transversum (p. 72), which extends on to the cephalic side of the vitello-intestinal duct. Dorsally, the stomach is related to the dorsal aorta and, owing to the presence of the pleuroperitoneal canals on each side, it is connected to the body wall by a short dorsal mesentery, termed the *dorsal mesogastrium*. This mesentery is directly continuous with the dorsal mesentery of the gut. The liver develops as a hollow diverticulum from the ventral aspect of the fore-gut and grows headwards into the substance of the septum transversum (fig. 211), and it is this part of the latter which is sometimes termed the *ventral mesogastrium*.

In the human embryo, at the 10 mm. stage, the curvatures of the stomach are defined. Growth proceeds more actively along the dorsal border of the viscus; its convexity is notably increased and the rudiment of the fundus appears. As a result of the more rapid growth of the dorsal border the pyloric end of the stomach is carried ventrally and the concavity of the lesser curvature becomes apparent (fig. 210). At this stage the stomach presents right and left surfaces, to which the right and left vagus nerves are distributed.

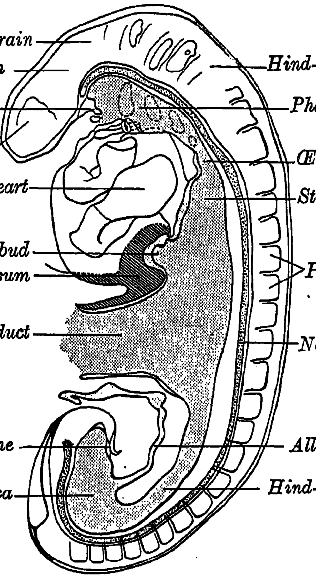
While these changes are occurring in the stomach, the gut increases in length more rapidly than the vertebral column, and forms a U-shaped loop, which acquires a dorsal mesentery as it lengthens, and projects into the cœlomic cavity (fig. 210). The rapidly growing liver and the developing mesonephroi encroach on the available space in the cœlom so much that the U-loop is extruded into the portion of the extra-embryonic cœlom which becomes included in the umbilical cord (p. 74). *This umbilical hernia is a normal condition in human embryos between the* 10 *mm.* (*sixth week*) *and the* 40 *mm. stage* (*third month*); under abnormal conditions it may be present at birth.

Partly as a result of the active growth of the fundus and the greater curvature, and partly influenced by the pressure exerted by the growing liver, the stomach becomes displaced to the left and rotated so that its right surface is directed dorsally and its left surface ventrally. In this way the omental bursa, which was hitherto a simple recess in the dorsal mesogastrium (p. 174), comes to lie dorsal to the stomach and may now be termed the *lesser sac* of the peritoneum.

The rotation of the stomach reacts on the position of the duodenum, which is also carried dorsally and to the right. At this stage the duodenum possesses a thick mesentery, which is continuous with the dorsal mesogastrium, on the one hand, and the mesentery of the U-loop, on the other (fig. 213). At a later

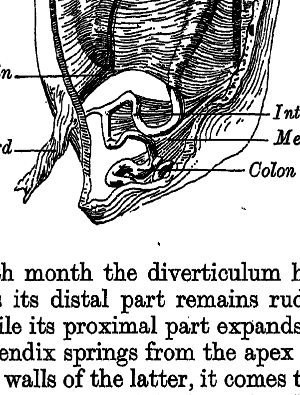
stage the approximation of the duodenum to the dorsal abdominal wall leads first to the adhesion of the right layer of its mesentery to the parietal peritoneum, and later to the absorption of both layers. In this way the duodenum comes to be retroperitoneal.

FIG. 211.—The digestive tube of a human embryo 2·5 mm. long. (Peter Thompson.)



At the 5 mm. stage a small diverticulum appears on the caudal limb of the U-loop (fig. 210) and is later differentiated into the cæcum and the vermiform appendix. Thereafter it is possible to distinguish the large from the small

FIG. 212.—The primitive mesentery of a human embryo. Half-schematic. (Kollmann.)

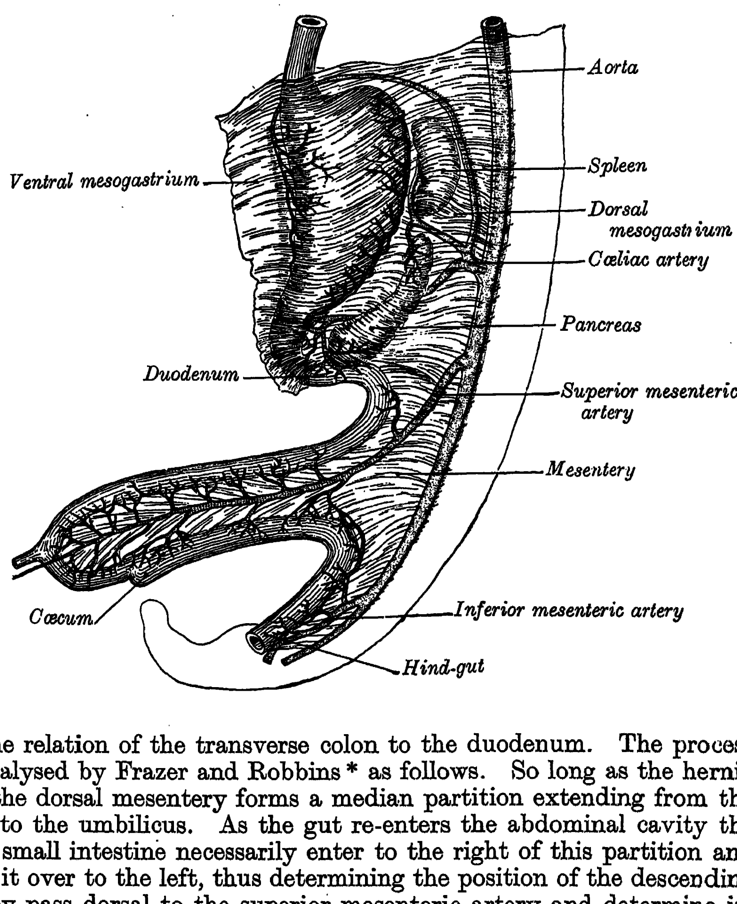


intestine. Until the fifth month the diverticulum has a conical outline, but from that time onwards its distal part remains rudimentary and forms the vermiform appendix, while its proximal part expands to form the cæcum. At birth the vermiform appendix springs from the apex of the cæcum, but, owing to unequal growth in the walls of the latter, it comes to open on its medial side.

When the U-loop enters the umbilical cord it has already been rotated

through an angle of 90°, so that the proximal limb lies to the right and the distal limb to the left (fig. 214). This relative position is maintained so long as the hernia persists, but during this period the portion which forms the small intestine becomes elongated and coiled, and the mesentery adapts itself to the changes in the gut. The colic part of the hernia elongates less rapidly and has no tendency to become coiled. By the time the embryo has attained a length of 40 mm. (middle of third month), the peritoneal cavity has enlarged sufficiently to contain all the abdominal viscera, and the hernia undergoes rapid reduction. The manner in which this occurs is important, for it is at this stage that the gut undergoes a process of *rotation,* which results in the establishment of the very constant relationships which the large intestine shows in the adult,

Fig. 213.—The abdominal part of the digestive tube and its attachment to the dorsal common mesentery. From a human embryo, six weeks old. (After Toldt.) (From Kollmann's Entwickelungsgeschichte.)



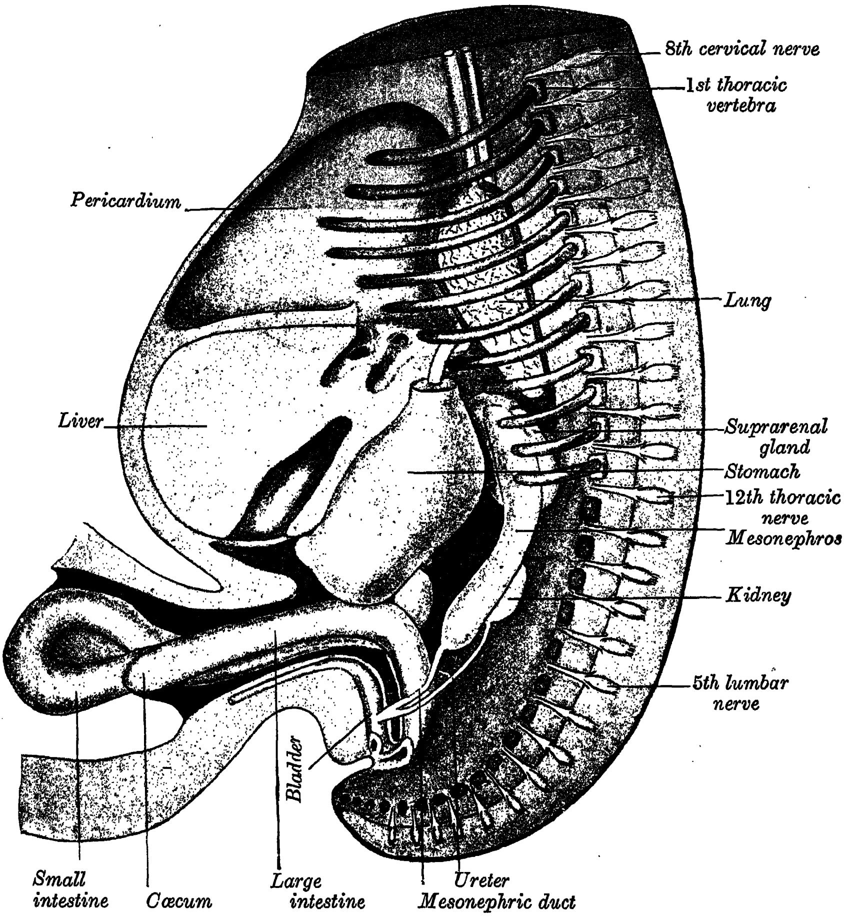
including the relation of the transverse colon to the duodenum. The process has been analysed by Frazer and Robbins * as follows. So long as the hernia is present, the dorsal mesentery forms a median partition extending from the dorsal wall to the umbilicus. As the gut re-enters the abdominal cavity the coils of the small intestine necessarily enter to the right of this partition and they thrust it over to the left, thus determining the position of the descending colon. They pass dorsal to the superior mesenteric artery and determine its adult relationship to the third part of the duodenum. The cæcum is the last part to re-enter the abdomen, and it lies at first on the surface of the coils of the ileum. The subsequent growth changes soon carry the cæcum dorsally and to the right, where it lies in contact with the caudal aspect of the liver. The portion of the colon which adjoins the cæcum now lies ventral to the duodenum and the rotation of the gut has been completed.

As a result of the manner in which the coils of small intestine re-enter the abdominal cavity the mesentery of the descending colon is thrust against the dorsal abdominal wall and the opposed peritoneal surfaces become adherent and are gradually absorbed. In this way the descending colon loses its mesentery and becomes retroperitoneal. Since this change takes place towards

* J. E. Frazer and R. H. Robbins, *Journal of Anatomy and Physiology,* vol. l.

the end of the third month the left colic vessels, whose position on the posterior abdominal wall is secondary, must lie in front of such structures as the left ureter and testicular or ovarian vessels, which are associated with the posterior wall originally. At the same time the proximal part of the colon is carried behind the lesser sac, and fusion takes place between the transverse mesocolon and the dorsal wall of the sac (fig. 215). During the later months of fœtal life the cæcum descends into the right iliac fossa, and the ascending colon so formed loses its mesentery in the same way and with the same results as happened in the case of the descending colon.

FIG. 214.—The trunk of a human embryo 17 mm. long. (After a reconstruction by Mall.) (From Quain's Elements of Anatomy, vol. i., Embryology.)

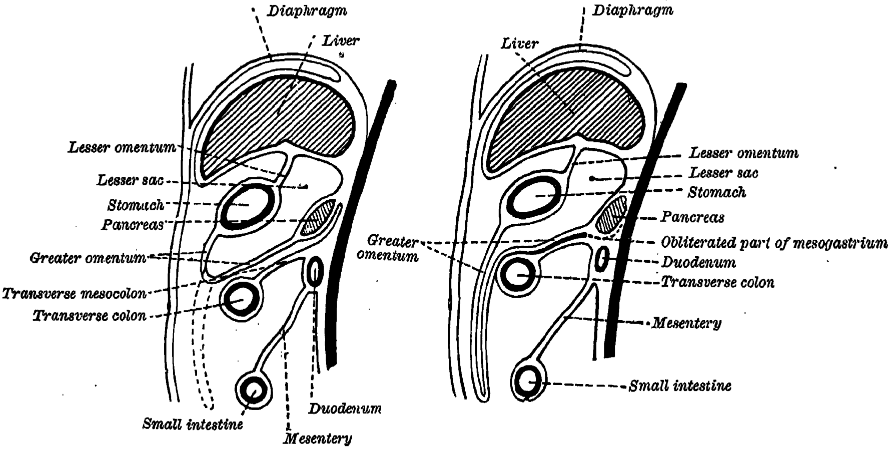


The rectum and anal canal.—With the formation of the tail-fold and the definition of the hind-gut (p. 71), the body-stalk is carried headwards on to the ventral surface of the body, and a bend is formed at the junction of the hind-gut and allantoic canal. Caudal to this bend the hind-gut dilates to form a pouch, which constitutes the *entodermal cloaca* ; into its dorsal part the hind-gut opens, and from its ventral part the allantoic canal passes into the body-stalk. At a later stage the mesonephric (Wolffian) and paramesonephric (Müllerian) ducts open into the ventral portion of the cloaca. Over the mid-ventral wall of the cloaca the entoderm comes into direct contact with the surface ectoderm without the interposition of mesoderm, and this area is termed the *cloacal membrane*. At first it extends on to the dorsal aspect of the body-stalk (fig. 96) but it undergoes real shortening (p. 71) and later the distance between it and the umbilicus gradually increases owing to the formation of the lower part of the abdominal wall. It should be noted that the cloacal membrane, in which the urogenital

and anal orifices subsequently develop, lies in the line of the primitive streak, which is carried round on to the ventral aspect of the body by the formation of the tail-fold. By the growth of the surrounding tissues the cloacal membrane comes to lie at the bottom of a depression, which is lined by ectoderm and named the *ectodermal cloaca* (fig. 216).

At the time when the mesonephric ducts enter the cloaca its ventral part is

FIG. 215.—Diagrams to illustrate the development of the greater omentum and the transverse mesocolon.



wider from side to side than its dorsal part, which remains very narrow. The mesoderm outside the line of union of these two parts grows rapidly and thrusts the entodermal epithelium inwards. As a result the two walls come into apposition and fuse. This process commences opposite the connexion of the allantoic canal with the cloaca and is continued caudally to form a septum, termed the *urorectal septum*, which separates the dorsal segment or rectum from the ventral segment which forms the urinary bladder and the urogenital sinus. At its

FIG. 216.—The tail-end of a human embryo, about four weeks old. (From a model by Keibel.)

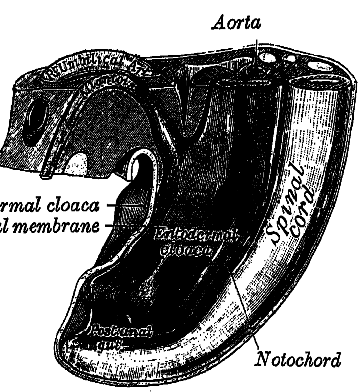


FIG. 217.—The cloaca of a human embryo, at the end of the fifth week. (From a model by Keibel.)

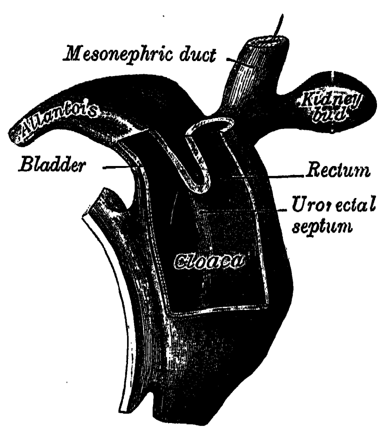
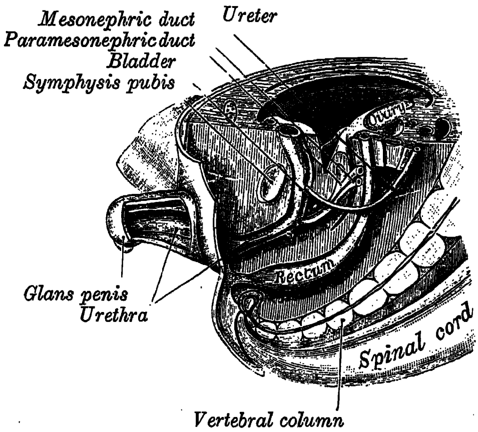


caudal end the urorectal septum reaches the cloacal membrane and divides it into an *anal* and *a urogenital membrane*. For a time a communication, named the *cloacal duct*, exists between the two parts of the cloaca caudal to the urorectal septum; this duct occasionally persists as a passage between the rectum and the bladder or urethra. By the upgrowth of anal tubercles * the anal part of the cloacal membrane comes to lie at the bottom of a depression, termed the

* Consult "Development of the anus in the human embryo," by Ellsworth M. Tench, *The American Journal of Anatomy*, vol. 59.

proctodœum. On the absorption and disappearance of this membrane the rectum communicates with the exterior (fig. 218). The lower part of the anal canal is formed from the proctodæum, but its upper part is entodermal in origin and is derived from the caudal end of the dorsal subdivision of the cloaca; the line of union corresponds with the edges of the anal valves in the adult. A small part of the hind-gut projects tailwards beyond the anal membrane; it is named the *post-anal gut* (fig. 210), and usually becomes obliterated and disappears.*

Fig. 218.—The tail-end of a human embryo, eight and a half to nine weeks old. (From a model by Keibel.)



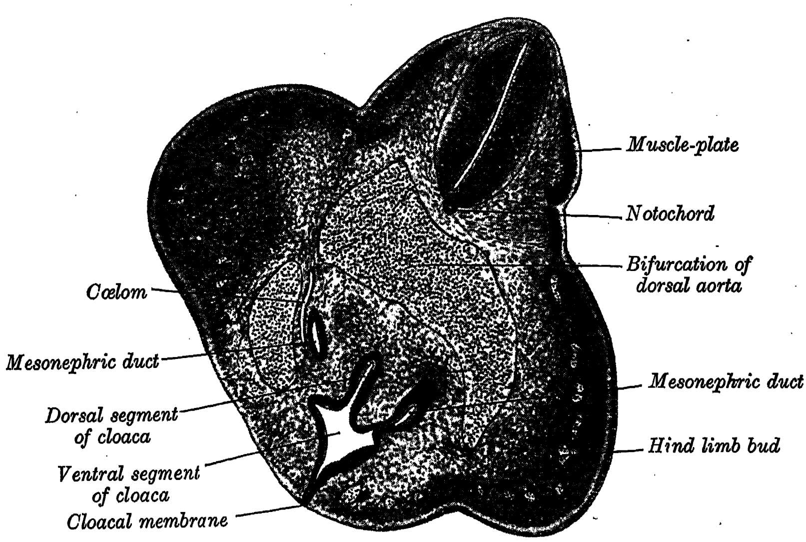
Applied Anatomy.—Abnormalities in the development of the digestive tube may lead to various disturbances which become apparent at birth or shortly after. Of these the following are the most common:

The closure of the laryngo-tracheal groove (p. 179) may be effected in such a way that the œsophagus is divided into two portions, viz. an upper, which communicates with the mouth above and ends blindly below in the neighbourhood of the tracheal bifurcation, and a lower, which communicates below with the stomach and above with the trachea.

Congenital stricture of the small intestine is usually due to exuberant overgrowth of the lining epithelium and the formation of adhesions. This overgrowth is a normal occurrence at one stage in the development of the duodenum, but the lumen is soon restored.

The umbilical hernia which is found between the 10 mm. and the 40 mm. stage (p. 168) may not be reduced and may be present at birth.

Fig. 219.—Oblique transverse section through a mole embryo, 5 mm. long, at the level of the bifurcation of the aorta. (Drawn from a microphotograph.)



The vitello-intestinal duct (p. 168) may remain patent as a constituent of the umbilical cord or its proximal part may persist as a "Meckel's diverticulum," which may or may not be anchored to the umbilicus by a fibrous band. In its simplest form a "Meckel's diverticulum" is a short, sac-like protrusion from the antimesenteric border of the ileum about three feet above the ileo-colic valve.

Rotation of the gut (p. 170) may fail to occur. In these cases the colon occupies the left,

* Consult in this connexion: "A Contribution to the Morphology of the Human Urogenital Tract," by D. Berry Hart, *Journal of Anatomy and Physiology,* vol. xxxv.

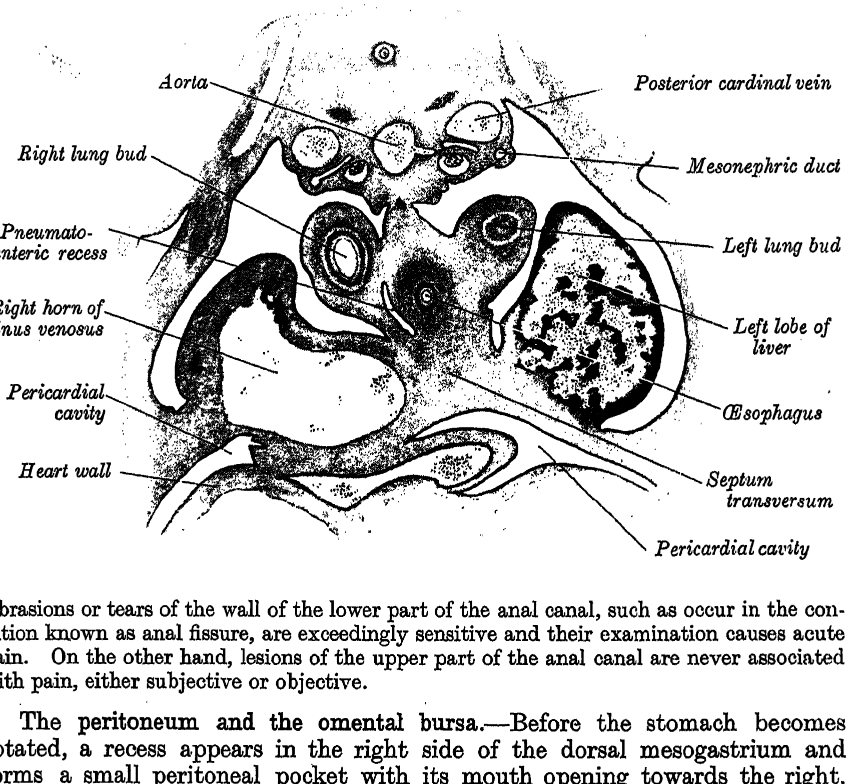
lower portion of the abdominal cavity and has no connexion with the greater omentum : the duodenum may be spirally coiled and the superior mesenteric vessels pass either behind it or to its left side.

The cæcum may retain its fœtal form with an apical vermiform appendix. It may fail to descend and is then found in front of the right kidney in close relation to the visceral surface of the liver. Occasionally it lies in the transverse mesocolon.

The separation of the entodermal cloaca into ventral and dorsal portions may be incomplete. The rectum then opens into the bladder, urethra or vagina and the anus is imperforate. The condition of imperforate anus may occur without other abnormalities. In some cases it is due to persistence of the anal membrane (p. 172) ; in others, the colon may end blindly, considerably above the level of the pelvic floor. The proctodæum may or may not be present.

On account of its mode of development the anal canal is lined in its lower part by modified skin, and in its upper part by mucous membrane which is entodermal in origin.

FIG. 220.—Transverse section of a human embryo 8 mm. long, showing the right pneumato-enteric recess. ×50.



Abrasions or tears of the wall of the lower part of the anal canal, such as occur in the condition known as anal fissure, are exceedingly sensitive and their examination causes acute pain. On the other hand, lesions of the upper part of the anal canal are never associated with pain, either subjective or objective.

The peritoneum and the omental bursa.—Before the stomach becomes rotated, a recess appears in the right side of the dorsal mesogastrium and forms a small peritoneal pocket with its mouth opening towards the right. This recess is termed the *bursa omentalis*, but it only corresponds to the inferior recess of the lesser sac of the adult. The recess does not involve the thick mesoduodenum, and its mouth extends from the œsophageal end of the stomach to the duodenum, occupying the position of the gastro-pancreatic folds of the adult.

A second, smaller recess appears at an early stage in the mesoderm covering the right side of the œsophagus (fig. 220). This is the *right pneumato-enteric recess*, and its mouth opens caudally, close to the mouth of the bursa omentalis. A similar recess develops on the left side, but it soon becomes closed and leaves no trace. The right pneumato-enteric recess becomes extended in a downward direction by the *hepato-enteric recess* which is formed during the growth of the right lobe of the liver (fig. 221). In its growth, the upper part of the right lobe of the liver invades the lower part of the right wall of the pneumato-enteric recess and then grows caudally along the line of the inferior vena cava (p. 155). A recess which is bounded ventrally by the caudate lobe of the liver is thus formed. It is continuous at its cephalic end with the right pneumato-enteric

recess and caudally it communicates with the cephalic part of the bursa omentalis. It is now possible to refer to a " lesser sac " and an " aditus to the lesser sac " (epiploic foramen) (fig. 222), although the caudal boundary of the

FIG. 221.—Transverse section through the same embryo as fig. 220, but 530μ more caudally. Note that rotation of the stomach has taken place and that the sinusoidal spaces in the liver communicate freely with one another. ×34.

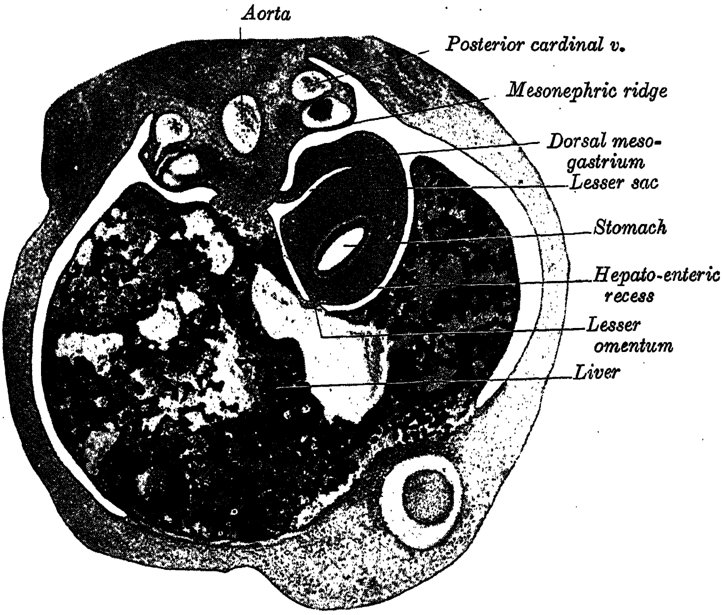


FIG. 222.—Transverse section through the same embryo as fig. 221, but 150μ more caudally. Observe that the " lesser sac " communicates with the general peritoneal cavity. ×34.

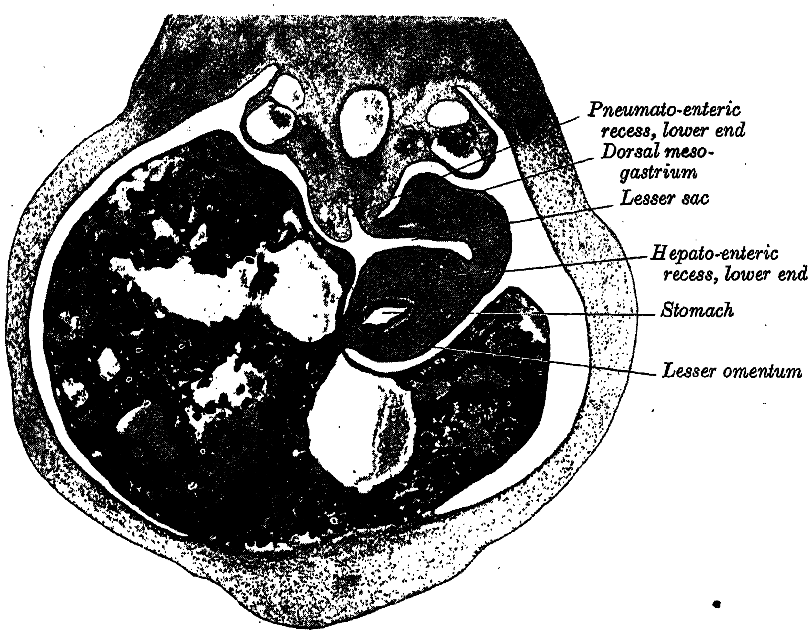

latter lacks definition until the mesoduodenum has disappeared. The cephalic part of the pneumato-enteric recess becomes cut off by the development of the diaphragm but sometimes remains as the *bursa infracardiaca*, a small serous

sac which lies medial to the basal part of the right lung, posterior to the inferior vena caval notch.

As the stomach enlarges the bursa omentalis keeps pace with it, and when

FIG. 223.—Diagram to show the fusion of the proximal part of the dorsal mesogastrium with the peritoneum on the posterior abdominal wall. Note also the conversion of the dorsal mesogastrium into the gastro-splenic and lieno-renal ligaments.

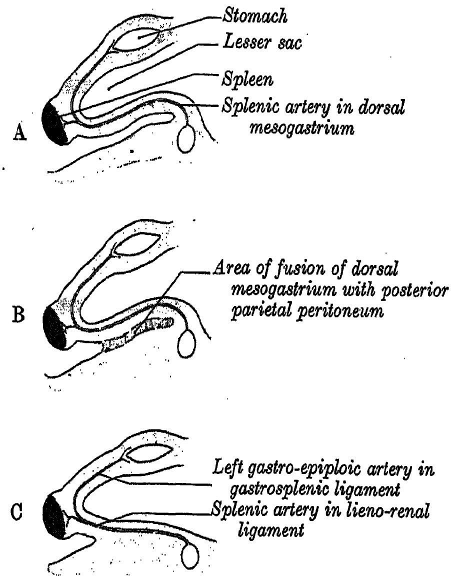

FIG. 224.—Diagrams to illustrate two stages in the development of the digestive tube and its mesentery. The arrow indicates the entrance to the bursa omentalis.

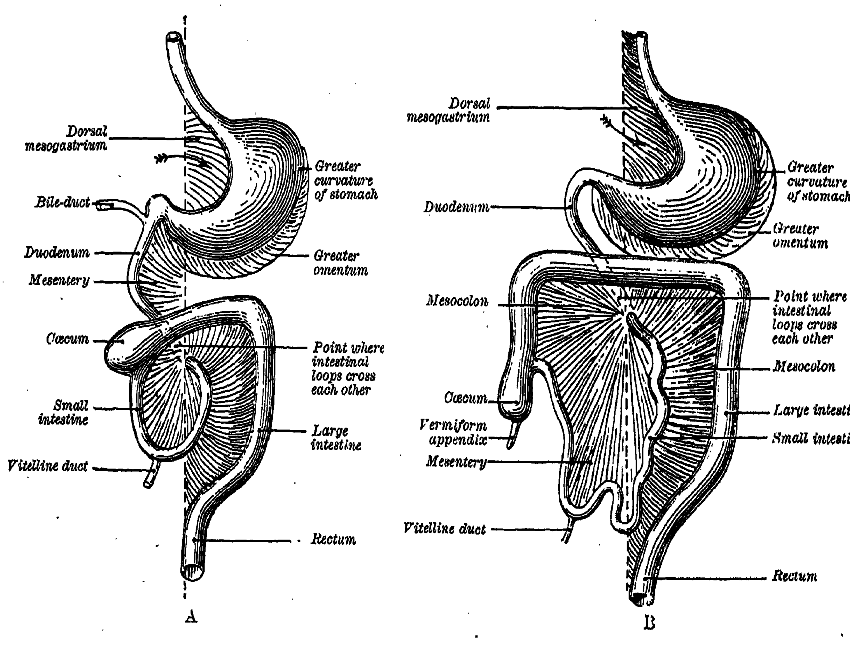


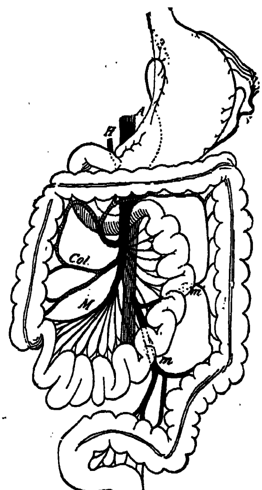
the intestines return to the abdominal cavity they come to lie caudal and dorsal to its caudal part. The dorsal wall of the cephalic part of the bursa becomes pressed against the dorsal abdominal wall and the opposed peritoneal layers fuse (fig. 223). Up to this time the dorsal mesogastrium has been attached in

the median plane, but as the result of the fusion the root of the mesogastrium acquires a new, curved attachment to the dorsal wall. From the œsophagus this attachment passes tailwards and to the left, giving the gastrophrenic and lienorenal ligaments of the adult, and then turns to the right and runs somewhat caudally and to the right along the line of the pancreas (fig. 215).

The development of the spleen in the cephalic part of the dorsal mesogastrium (p. 179) subdivides that part of it into a lienorenal and a gastroplenic ligament. The caudal part of the dorsal wall of the bursa remains free and grows caudally overlapping the transverse colon and the underlying coils of small intestine, forming the greater omentum. Later the two layers of the transverse mesocolon fuse with the overhanging dorsal surface of the greater omentum, so that the adult condition is attained (fig. 215).

The **liver** arises as a diverticulum from the ventral surface of the fore-gut at the point where the latter joins the vitelline duct (fig. 211). This diverticulum is lined with entoderm, and grows ventrally and headwards into the septum transversum, giving off two solid buds of cells, which represent the right and the left lobes of the liver. The solid buds of cells grow into columns or cylinders, termed the *hepatic cylinders*, which branch and anastomose to form a close meshwork. This network invades the vitelline and umbilical veins, and breaks them up into a series of capillary-like vessels termed *sinusoids* (Minot), which ramify in the meshes of the cellular network (fig. 221). By the continued growth and ramification of the hepatic cylinders the mass of the liver is gradually formed, but its connective tissue stroma is derived from included mesenchymal cells of the septum transversum. The original diverticulum from the duodenum forms the bile duct, and from its distal part the cystic duct and gall bladder arise as a solid outgrowth which later acquires a lumen. The opening of the bile duct is at first in the ventral wall of the duodenum; later, it is carried to the left across the dorsal (originally right) surface of the duodenum to the position which it occupies in the adult on the medial (or mesenteric) border. This migration of the orifice is effected by differences in the rate of growth in different parts of the walls of the duodenum.

FIG. 225.—The final disposition of the intestines and their vascular relations. (Jonnesco.)



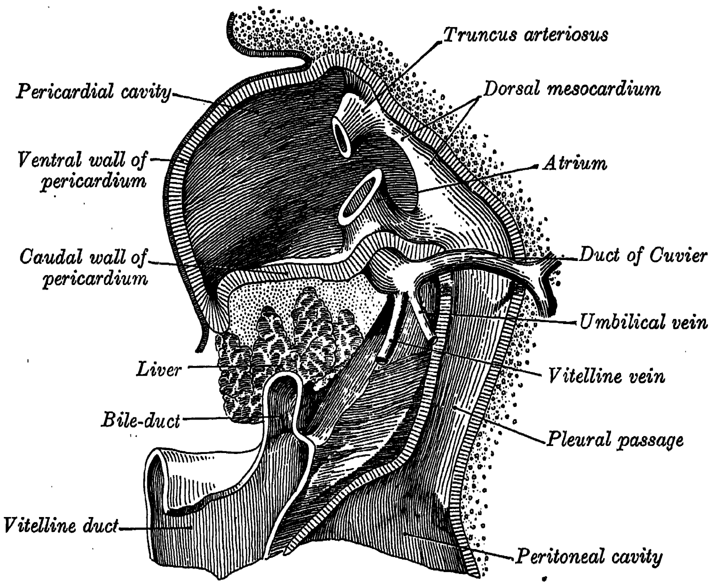
A, Aorta. *H*, Hepatic artery. *M*, *Col.* Branches of superior mesenteric artery. *m*, *m′*. Branches of inferior mesenteric artery. *S.* Lienal artery.

As the liver undergoes enlargement, both it and the ventral mesogastrium are gradually differentiated from the septum transversum; and from the caudal surface of the latter the liver projects tailwards into the abdominal cavity. By the growth of the liver the ventral mesogastrium is divided into two parts, of which the ventral forms the falciform and coronary ligaments and the dorsal the lesser omentum. About the third month the liver almost fills the abdominal cavity, and its left lobe is nearly as large as its right. From this period the relative development of the liver is less active, more especially that of the left lobe, which actually undergoes some degeneration and becomes smaller than the right; but up to the end of fœtal life the liver remains relatively larger than in the adult.

The **pancreas** (figs. 227, 228).—The pancreas is developed in two parts, a dorsal and a ventral. The former arises as a diverticulum from the dorsal wall of the duodenum a short distance headwards of the hepatic diverticulum, and, growing headwards and dorsally in the mesoduodenum, enters that part of the dorsal mesogastrium which is forming the dorsal wall of the bursa omentalis. It forms the whole of the neck, body and tail of the pancreas and a part of the head. The ventral part appears in the form of a diverticulum from the primitive bile duct at the spot where the latter opens into the duodenum.

This diverticulum is at first double, but the two outgrowths soon fuse, and the diverticulum, now a single mass, grows round the gut into the mesoduodenum, where it enlarges to form the remainder of the head of the gland.* The duct of the dorsal part (accessory pancreatic duct) therefore opens directly into the duodenum, while that of the ventral part (pancreatic duct) opens with the bile duct. About the seventh week the two parts of the pancreas meet and

FIG. 226.—The liver with the septum transversum. Human embryo, 3 mm. long. (After a model and figure by His.)



fuse, and a communication is established between their ducts. After this has occurred the terminal part of the accessory duct, i.e. the part between the duodenum and the point of meeting of the two ducts, undergoes little or no enlargement, while the duct of the ventral part increases in size and forms the main duct of the gland. The opening of the accessory duct into the

FIG. 227.—The pancreas of a human embryo, six weeks old. (Kollmann.)

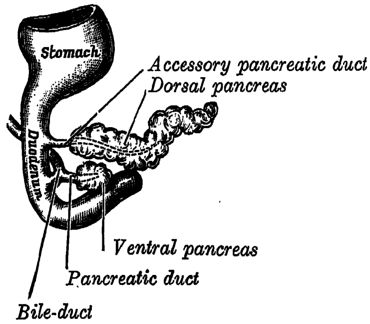


FIG. 228.—The pancreas of a human embryo, at the end of the seventh week. (Kollmann.)

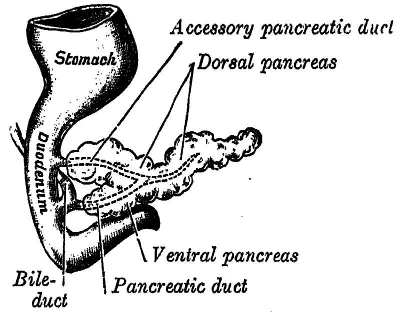


duodenum is sometimes obliterated, and, even when it remains patent, it is probable that the whole of the pancreatic secretion is conveyed through the main duct.

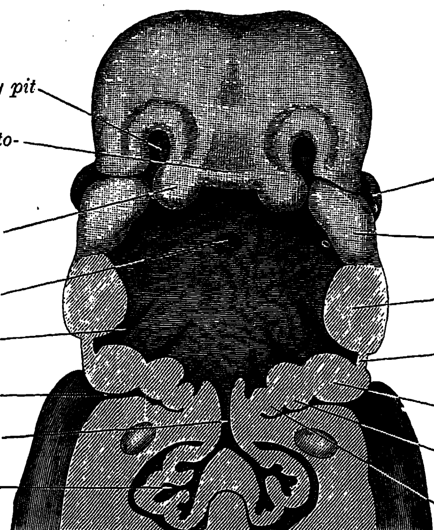
At first the body of the pancreas is directed headwards and dorsally between the two layers of the dorsal mesogastrium, in the dorsal wall of the bursa omentalis. When this wall fuses with the dorsal parietal peritoneum the

* P. N. B. Odgers, *Journal of Anatomy*, vol. lxv. October, 1930.

process extends tailwards as far as the caudal (inferior) border of the pancreas, and thus, in the adult, the gland becomes retroperitoneal.

The spleen (fig. 213).—Although the spleen belongs to the group of ductless glands, its development may be conveniently referred to here. It appears about the sixth week as a localised thickening of the cœlomic epithelium of the dorsal mesogastrium in its cephalic portion, and the proliferating cells invade the underlying mesenchyme, which has become condensed and vascularised. The process occurs simultaneously in several adjoining areas which soon fuse to form a lobulated spleen, derived in part from the cœlomic epithelium and in part from the mesenchyme in the dorsal mesogastrium. As the organ enlarges it projects to the left, so that its surfaces come to be covered with the peritoneum of the greater sac. When fusion occurs between the dorsal wall of the lesser

FIG. 229.—The head and neck of a human embryo in the sixth week. Ventral aspect. The floor of the mouth and the ventral wall of the pharynx have been removed. (His.)



sac and the dorsal parietal peritoneum, the process does not extend so far to the left as the spleen (fig. 223), which remains connected to the dorsal abdominal wall by a short lienorenal ligament, while its primitive connexion with the stomach forms the gastrosplenic ligament. The earlier lobulated character of the organ disappears but is indicated by the presence of notches on its upper border in the adult.

The respiratory organs.—The rudiment of the respiratory organs appears in the fifth week as a median *laryngo-tracheal groove* in the ventral wall of the pharynx. The groove deepens and its lips fuse to form a septum, which converts the groove into a tube, termed the *laryngo-tracheal tube* (fig. 229), which opens into the pharynx by a slit-like aperture formed by the edges of the persistent cephalic part of the groove. The process of fusion commences at the caudal end of the groove and extends headwards. The tube is lined with entoderm, and from this the epithelial lining of the respiratory tract is developed. The cephalic part of the tube forms the larynx, and its next succeeding part the trachea, while from its caudal end two lateral outgrowths arise and form the right and left *lung-buds*. The latter are surrounded by mesenchyme, from which the connective tissue of the bronchi and lungs is developed.

The first rudiment of the larynx consists of the cephalic end of the laryngo-tracheal groove, bounded ventrally by the caudal part of the hypobranchial eminence (p. 164) and on each side by the ventral ends of the sixth arch (Frazer). Two arytenoid swellings appear, one on each side of the groove, and, as they enlarge, they become approximated to each other, and to the caudal part

of the hypobranchial eminence, from which the epiglottis is developed. The upper aperture of the larynx is at first a vertical slit, which is converted into a T-shaped cleft by the enlargement of the arytenoid swellings; the vertical limb of the T lies between the two arytenoid swellings and its horizontal limb between them and the epiglottis. Soon after its appearance the epithelial walls of the cleft adhere to each other, and the aperture of the larynx remains occluded until the third month, when its lumen is regained. The upgrowth of the arytenoid swellings and the deepening of the primitive aryepiglottic folds form the walls of the vestibule and leave its aperture above the level of the primitive aperture, which now corresponds to the level of the glottis. The arytenoid swellings are differentiated into the arytenoid and corniculate cartilages, and the folds joining them to the epiglottis form the aryepiglottic folds in which the cuneiform cartilages are developed as derivatives of the epiglottis. The thyroid cartilage is developed from the ventral ends of the

Fig. 230.—The lung-buds from a human embryo, about five weeks old, showing commencing lobulation. (His.)

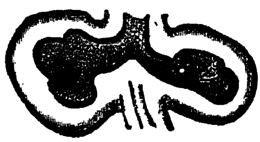


Fig. 231.—The lungs of a human embryo more advanced in development. (His.)

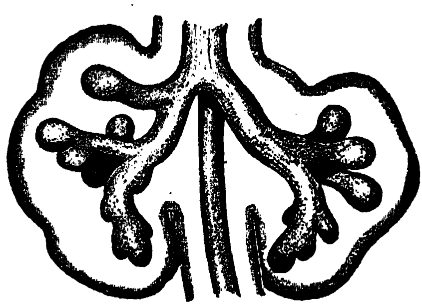


cartilages of the fourth and fifth branchial arches; it appears as two lateral plates, each chondrified from two centres and united in the midventral line by membrane in which an additional centre of chondrification develops. The cricoid cartilage arises from two cartilaginous centres, which soon unite ventrally and gradually extend and ultimately fuse on the dorsal surface of the tube.*

The right and left lung-buds make their appearance before the laryngotracheal groove is converted into a tube. They grow out caudal to the ducts of Cuvier, and divide into lobules, three appearing on the right, and two on the left, lung-bud; these subdivisions are the early indications of the corresponding lobes of the lungs (figs. 230, 231). The buds undergo further subdivision and ramification, and ultimately end in minute expanded extremities—the infundibula of the lung. After the sixth month the air-sacs begin to make their appearance on the infundibula in the form of minute pouches. The pulmonary arteries are derived from the sixth aortic arches. During the course of their development the lungs migrate in a caudal direction, so that by the time of birth the bifurcation of the trachea is opposite the fourth thoracic vertebra. As the lungs grow they project into the pleural passages, or parts of the cœlom which will ultimately form the pleural sacs, and the splanchnic mesoderm enveloping the lung rudiment expands on the growing lung and is converted into the pulmonary pleura.

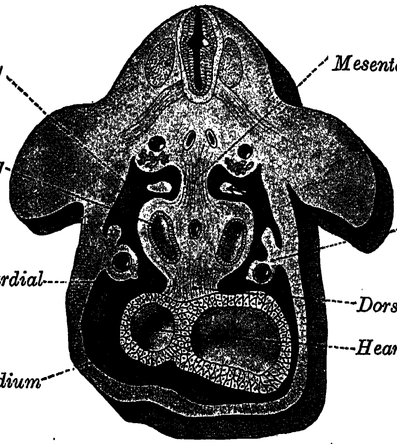
THE DEVELOPMENT OF THE BODY-CAVITIES

The appearance of the intra-embryonic cœlom and the manner in which it communicates with the extra-embryonic cœlom have already been described (p. 66). Prior to the formation of the head-fold the pericardium lies at the headward end of the embryonic area and communicates caudally, on each side of the median plane, with the rest of the cœlom. After the formation of the

* E. Fawcett, *loc. cit.*

head-fold the pericardium communicates dorsally with the pleural passages by means of two pleuropericardial canals (fig. 226); and the pleural passages open caudally into the peritoneal cavity. The duct of Cuvier crosses the lateral aspect of the pleuropericardial canal, as it passes ventrally to reach the sinus venosus, which is imbedded in the septum transversum (p. 136).

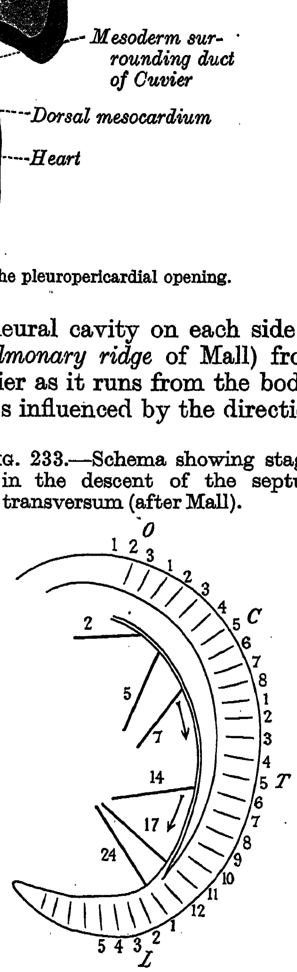
FIG. 232.—A transverse segment through the upper part of the cœlom of a human embryo, 7·5 mm. long. (Kollmann.)



The upper arrow is in the pleuroperitoneal, the lower in the pleuropericardial opening.

The separation of the pericardial from the pleural cavity on each side is effected by the growth of a ridge of tissue (*pulmonary ridge* of Mall) from the mesenchyme associated with the duct of Cuvier as it runs from the body-wall to the septum transversum, but the process is influenced by the direction in which the developing lung-buds enlarge. They project at first into the pleural passage, but, as growth proceeds, they extend in a lateral direction, *caudal to the ducts of Cuvier* and the pulmonary ridges. As the apical part of the lung forms, it does not grow headwards in the pleural passage but invades the body-wall and ascends *on the lateral aspect of the duct of Cuvier.* The pleuropericardial canal still lies medial to the vessel, which intervenes between it and the developing apical part of the pleural sac. It is reduced to a narrow slit, which is soon obliterated by the apposition of its walls (fig. 183).

FIG. 233.—Schema showing stages in the descent of the septum transversum (after Mall).



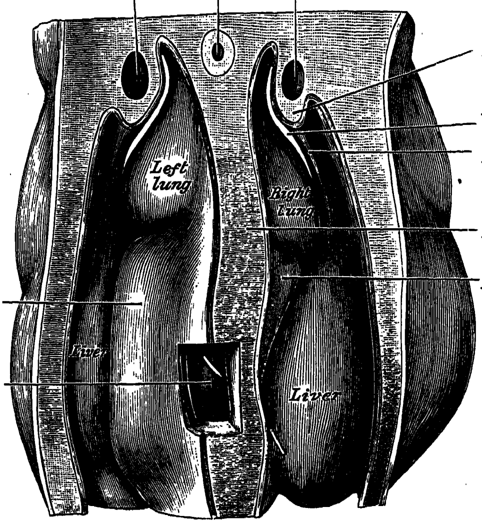
The numerals on the heavy lines indicate the length of the embryo in mm., and the position of the occipital, cervical, thoracic and lumbar segments is also shown.

In addition to its extension in a headward direction the lung enlarges ventrally and medially, and the pleura is therefore carried into the body-wall over the surface of the pericardium, thus separating it from the lateral thoracic walls (fig. 235).

The separation of the pleural and peritoneal cavities from each other is effected on each side by the formation of a *pleuro-peritoneal fold* or *membrane.* This fold is commonly described as an active ingrowth from the body-wall, but it may be attributed to the influences exerted by the growing lung-bud and the growing liver. As the latter enlarges, it projects into the peritoneal cavity and acquires, on each side of its connexion with the septum transversum, a cephalic peritoneal-covered surface. At the same time the body-wall is growing rapidly in order to provide the increase in the diameters of the trunk rendered

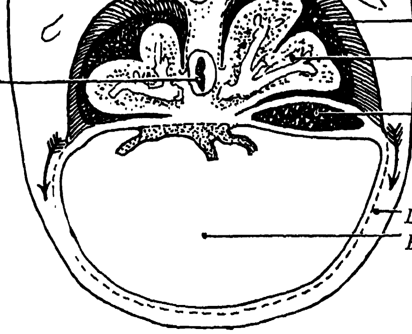
necessary by the growth of the liver. Just as the enlargements of the lung headwards and ventrally were effected by a process of burrowing into the body-wall, so its caudal enlargement is effected in the same way. The expanding and

Fig. 234.—The upper part of the cœlom of a human embryo of 6·8 mm. long. Dorsal aspect. (From a model by Piper.)



elongating lung-base grows into the body-wall and its peripheral part becomes separated from the peritoneal-covered right (or left) lobe of the liver by a crescentic fold of body-wall, which constitutes the pleuroperitoneal fold or membrane. On each side the free, inner edge of this fold forms the dorsilateral

Fig. 235.—A diagram of a transverse section through a rabbit embryo. (After Keith.)

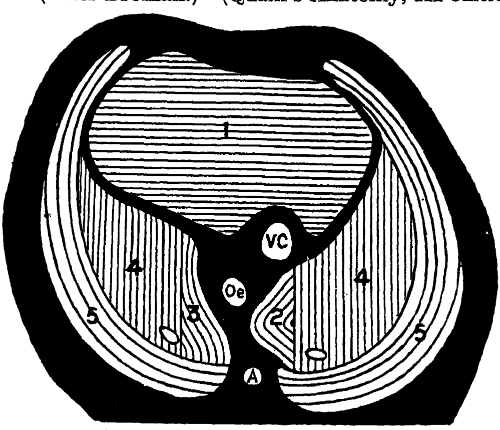


boundary of the communication between the pleural sac and the peritoneal cavity, the other boundaries being formed by the dorsilateral part of the septum transversum and the lateral aspect of the dorsal mesentery of the caudal end

of the œsophagus. On the right side the mass of the right lobe of the liver blocks the communication and renders easy the approximation of the boundaries of the opening. Closure therefore occurs earlier on the right than on the left side, where the position is complicated by the fact that the left lobe of the liver is smaller, and the left suprarenal gland, which projects at first into the caudal part of the left pleural sac dorsimedially, occupies the rest of the gap. It is therefore on the left side that an abnormal communication between the pleural and the peritoneal cavities most frequently is found. The further development of the peritoneal cavity has already been described (p. 174).

While these changes are in progress, the septum transversum undergoes a progressive alteration in position. In a human embryo, 2 mm. long, the dorsal border of the septum transversum lies opposite the second cervical segment, but as the embryo grows, and the heart enlarges, it migrates in a caudal direc-

FIG. 236.—Diagram to show the elements which contribute to the formation of the diaphragm. (After Broman.) (Quain's Anatomy, XI edition, vol. i.)



1, part derived from septum transversum ; 2 and 3, parts derived from the dorsal mesentery ; 4, parts derived from the pleuroperitoneal membranes ; 5, parts derived from the body-wall.

tion. At first the ventral border moves more rapidly than the dorsal border, but after the embryo has attained a length of 5 mm. it is the dorsal border which migrates more rapidly (fig. 233). When the dorsal border of the septum transversum lies opposite the fourth cervical segment, the phrenic nerve (*C* 3, 4 and 5) and portions of the corresponding myotomes grow into it and accompany it in its later migrations. It is not until the end of the second month that the dorsal border of the septum transversum comes to lie opposite the last thoracic and first lumbar segments, the position which is occupied by its derivative, the diaphragm, in the adult.

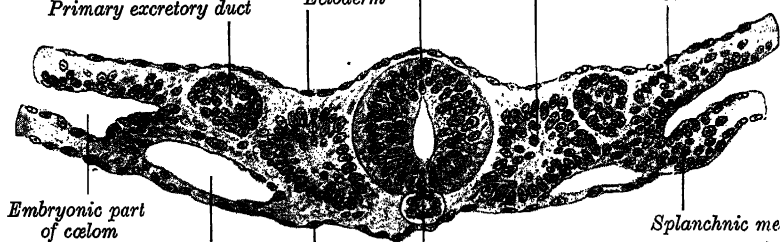
The development of the diaphragm.—The closure of the pleuroperitoneal openings completes a mesodermal partition which separates the thoracic from the abdominal viscera and occupies the position of the diaphragm in the adult. This partition has a composite origin ; its ventral and median portion is derived from the septum transversum, its dorsal portion from the dorsal mesentery, and its dorsilateral portions from the pleuroperitoneal folds. According to Broman the lateral body-wall makes a mesodermal contribution to the partition along the outer margins of the pleuroperitoneal folds and the septum transversum. Premuscle tissue, derived principally from the fourth cervical myotome, invades the septum transversum as already described and from this position extends into the rest of the partition, giving rise to the muscular diaphragm (fig. 236).

THE DEVELOPMENT OF THE UROGENITAL ORGANS

The excretory and reproductive organs are developed from the mesoderm of the intermediate cell-mass (p. 65) and they are intimately associated with

one another, especially in the earlier stages of their development. The excretory organs are noteworthy in that three distinct sets of them appear in the course of development, viz.: the pronephros, the mesonephros and the metanephros. The pronephros disappears entirely, but its duct persists and becomes the duct of the mesonephros. Most of the mesonephros undergoes degenerative changes and disappears, but some of its tubules play an important part in connexion

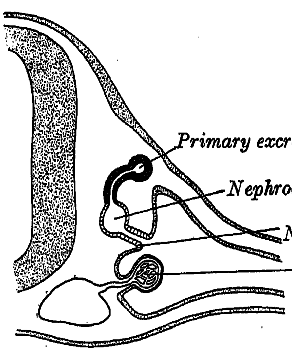
FIG. 237.—A transverse section through a ferret embryo. (A. Robinson.)



with the male sexual gland. The metanephros is the last to appear, and it persists as the permanent kidney.

The **pronephros** is a very rudimentary and transient organ in the human embryo; it begins to appear in embryos of 1·7 mm. length and, as a rule, with the exception of its duct, no trace is left by the time the embryo has attained a length of 5 mm. It is found in the intermediate cell-mass of the seventh to the fourteenth segments (lower cervical and upper thoracic regions) and consists of six or seven horizontal tubules, which usually show a distinctly segmental character. The tubules open into the dorsal part of the cœlom by means of *nephrostome canals*, while their originally blind ends turn caudally and link up with one another to form a longitudinal duct, termed the pronephric or *primary excretory duct*. Medial to the opening of the nephrostome canal the cœlomic epithelium shows a small tuft-like protrusion into which the aorta sends one of its lateral branches, converting it into an *external glomerulus* (fig. 238). A typical pronephric tubule shows a localised dilatation, termed the *nephrocoele*, into which, in some animals though not in man, internal glomeruli project.

FIG. 238.—Diagram of a pronephric segment. (After Felix.)

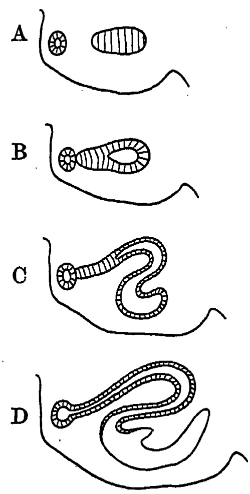


The primary excretory duct lies immediately under the surface ectoderm and grows tailwards, curving ventrally to reach the side of the entodermal cloaca, into which it opens in 4·3 mm. embryos. Caudal to the tenth segment the duct grows tailwards more rapidly than the process of segmentation. The mesoderm into which it extends is in line with the intermediate cell-mass and forms an unsegmented column, termed the *nephrogenic cord*.

The **mesonephros (Wolffian body)**, which succeeds the pronephros, differs from it in two important particulars; (*a*) such nephrostomes as may develop are few in number and transitory, and they never establish connexions with the mesonephric tubules; (*b*) the glomeruli are all *internal* and secrete directly into the tubules.

The mesonephros extends from the sixth cervical segment to the third lumbar so that its cephalic end overlaps the caudal end of the pronephros. The organ occupies the greater part of the nephrogenic cord, lying medial to the primary excretory duct. It consists of about seventy to eighty tubules and a corresponding number of internal glomeruli, which are not segmental in their arrangement. All of these tubules, however, are not present at the same time, and it is rare to find more than thirty to forty in any individual embryo, for the cephalic tubules and glomeruli atrophy and disappear before the development of those which are situated more caudally. Each tubule first appears as a solid mass of cells, which later becomes hollowed in the centre (fig. 239); one end grows towards and finally opens into the primary excretory duct, which thus becomes the *mesonephric* (Wolffian) *duct*, while the other end becomes dilated and is invaginated by a tuft of vessels derived from a lateral branch of the aorta, the whole constituting an *internal glomerulus*. By the end of the sixth week the mesonephros forms an elongated, spindle-shaped organ, which projects into the cœlomic cavity on each side of the dorsal mesentery, from the septum transversum to the third lumbar segment. This projection is termed the *mesonephric* (Wolffian) *ridge* (fig. 221), and the genital glands are developed on its medial surface.

FIG. 239.—Diagram showing stages in the development of the tubules and Malpighian corpuscles of the mesonephros. (After Felix.)



In *A* the tubule is a solid epithelial mass having no connexion with the primary excretory duct. In *B* it has acquired a lumen and is in contact with the duct. In *D* it has opened into the duct, while its opposite extremity has been invaginated by a vascular tuft (not shown in the diagram) and has been converted into a Malpighian corpuscle.

In fishes and amphibians the mesonephros persists and forms the permanent kidney, but in reptiles, birds and mammals it is replaced, as the principal excretory organ, by the metanephros. In both sexes the cephalic end of the mesonephros atrophies and disappears, and in embryos of 20 mm. length the organ is found only in the first three lumbar segments, although it may still possess as many as twenty-six tubules. Of these tubules the cephalic six to twelve persist to form the *efferent ducts of the testis*, in the male, and the tubules of the *epoöphoron* in the female; the caudal tubules form the *ductus aberrans* and the *paradidymis*, in the male, and the *paroöphoron*, in the female.

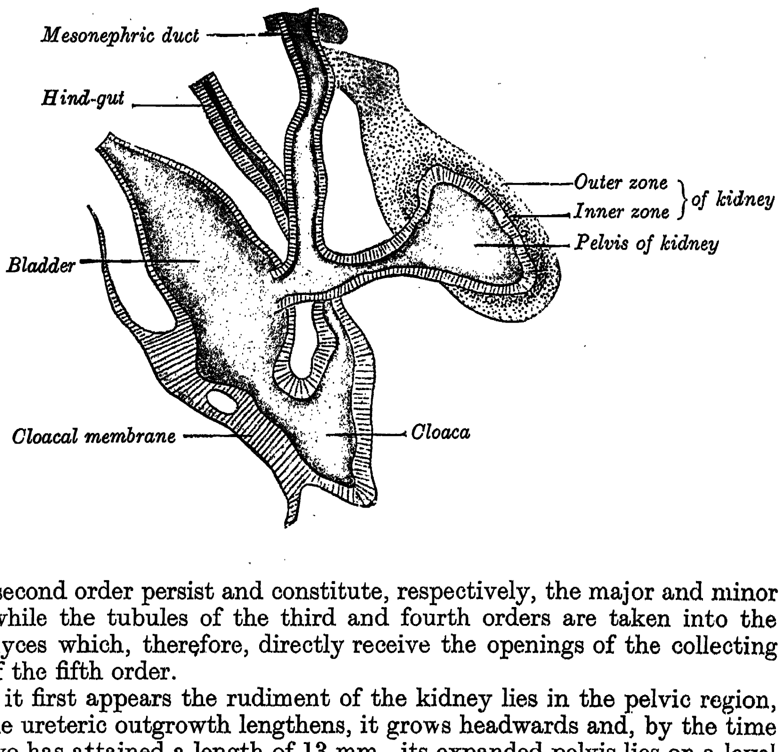
The *mesonephric duct* runs tailwards in the lateral part of the mesonephric ridge and, at the caudal end of the mesonephros, is projected into the cavity of the cœlom in the free border of a mesodermal fold (fig. 241). As the ducts approach the urogenital sinus the two folds fuse with each other, between the bladder ventrally, and the rectum, dorsally, forming a transverse partition across the cavity of the pelvis which is termed the *genital cord* (fig. 242). In the male the peritoneal fossa between the bladder and the genital cord becomes obliterated, but it persists in the female as the uterovesical pouch. The mesonephric duct itself becomes the canal of the epididymis, the vas deferens (ductus deferens) and the ejaculatory duct in the male, and it later gives rise to a diverticulum which forms the seminal vesicle. In the female it constitutes the horizontal duct of the epoöphoron.

The **metanephros**, or permanent kidney, has a twofold origin. At about the 5 mm. stage an outgrowth forms from the dorsal and medial aspect of the mesonephric duct, near the point at which it opens into the cloaca. This outgrowth is the *ureteric diverticulum*, and it travels dorsally at first and then inclines headwards. Its blind extremity, which grows into the caudal end of the nephrogenic cord, becomes expanded and the adjoining mesoderm condenses around it to form the *metanephrogenic cap* (fig. 240). The stalk of the ureteric diverticulum becomes the ureter, and its expanded end gives origin not only

to the pelvis of the ureter and the calyces but also to the collecting tubules of the kidney. The secreting and convoluted tubules and the renal corpuscles are all derived from the metanephrogenic cap. As a result, the blind ends of the secreting tubules must establish communication with the blind ends of the collecting tubules; should they fail to do so, congenital cysts of the kidney will be formed.

The expanded extremity of the ureter gives origin to four collecting tubules of the first order and itself forms the primitive renal pelvis. Each of these tubules ends in an ampullated extremity, which gives rise to collecting tubules of the second order. These, in turn, give rise to collecting tubules of the third order, and so on. In some animals the four collecting tubules of the first order are taken into the renal pelvis, which then presents a single renal papilla and no subdivision into calyces. In man, however, the collecting tubules of the

FIG. 240.—The primitive kidney and the bladder, from a reconstruction. (After Schreiner.) (From Quain's Elements of Anatomy, vol. i., Embryology.)



first and second order persist and constitute, respectively, the major and minor calyces, while the tubules of the third and fourth orders are taken into the minor calyces which, therefore, directly receive the openings of the collecting tubules of the fifth order.

When it first appears the rudiment of the kidney lies in the pelvic region, but, as the ureteric outgrowth lengthens, it grows headwards and, by the time the embryo has attained a length of 13 mm., its expanded pelvis lies on a level with the second lumbar vertebra. During this period the developing kidney receives its blood-supply from arteries in its immediate neighbourhood, the middle sacral and common iliac arteries, but the definitive renal artery is not recognisable until the beginning of the third month. It arises from the most caudal of the three suprarenal arteries, all of which represent persistent mesonephric or lateral splanchnic arteries (p. 150). Additional renal arteries are by no means uncommon. They may enter at the hilum or at the upper or lower pole of the gland, and they also represent persistent mesonephric arteries.

At an early stage the kidney is a lobulated organ, a condition which persists throughout fœtal life and only disappears after birth.

The ureter undergoes little alteration, save that it grows in length in conformity with the embryo. Two fusiform enlargements appear subsequently, one affecting its lumbar and the other its pelvic portion. The lumbar enlargement appears during the fifth month, but the pelvic enlargement does not develop until the ninth month and is not constant. As a result the ureter

shows a constriction at its upper end and another as it crosses the brim of the pelvis. A third constriction is always present at its lower end, and is caused by the growth of the bladder wall.

At first the ureter is connected to the dorsal and medial aspect of the

FIG. 241.—Transverse section through the lower abdomen of a human embryo, nine weeks old, to show the connexions and relative positions of the structures derived from the Wolffian ridge.

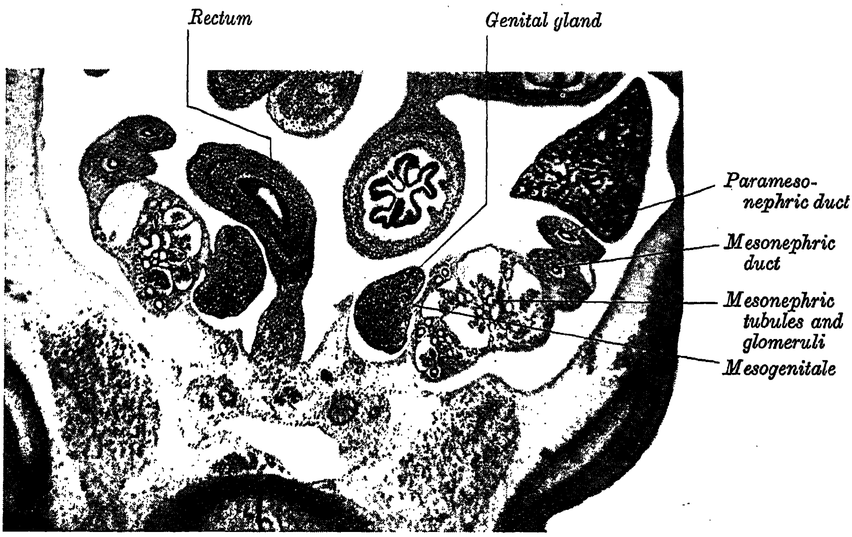


FIG. 242.—Transverse section through the pelvic part of a human embryo, to show the formation of the genital cord and the inguinal folds. (From Quain's Elements of Anatomy, II edition, vol. i., Embryology.)

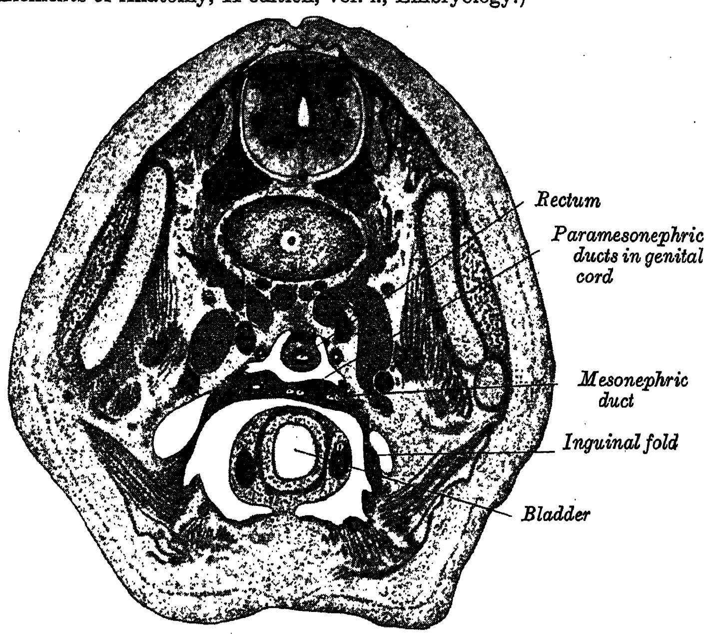
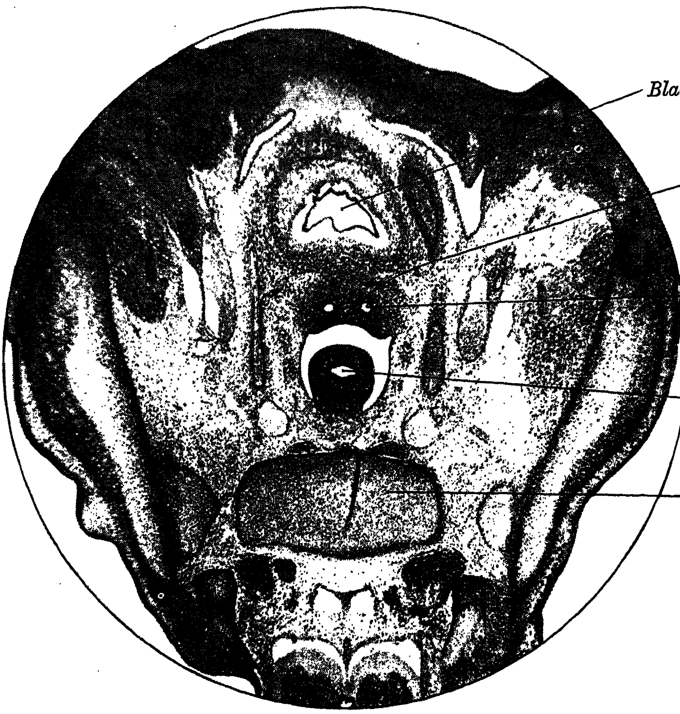


mesonephric duct but, owing to differences in rate of growth, it comes to be connected to the lateral aspect of that structure. Thereafter the caudal end of the mesonephric duct becomes incorporated in the developing bladder and the orifice of the ureter opens into the bladder on the lateral side of the opening

of the duct. Later the two orifices become separated still further and, although the ureter retains its point of entry into the bladder, the mesonephric duct opens

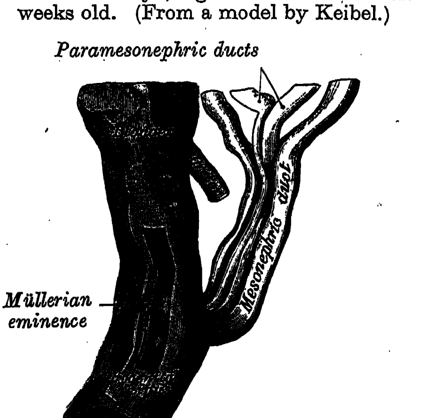
FIG. 243.—Transverse section through the pelvis of a nine weeks old human embryo, male, showing the approximation of the genital cord to the dorsal wall of the urogenital sinus.



into that part of the urogenital sinus which subsequently becomes the prostatic urethra.

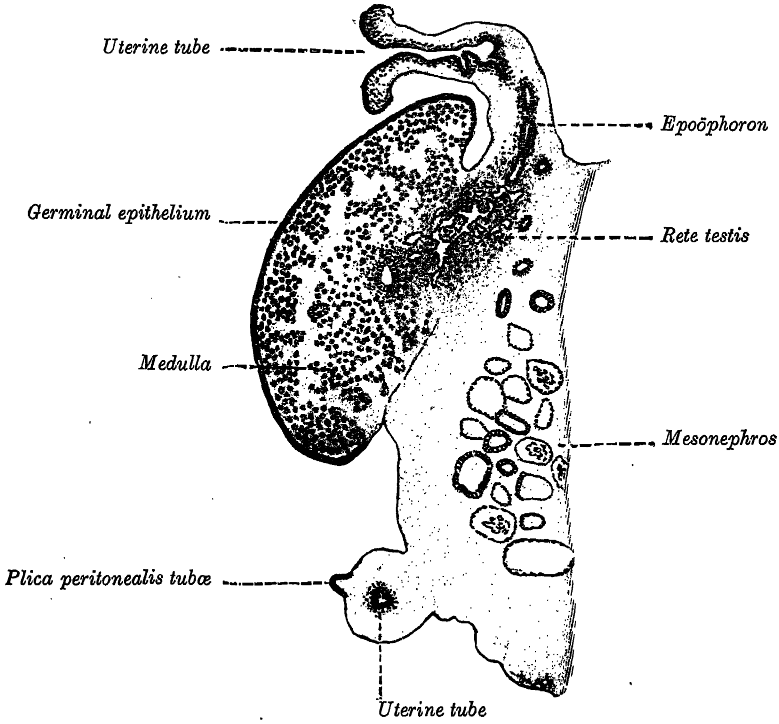
The **paramesonephric** (Müllerian) **ducts**, which are destined to play a very important part in the development of the reproductive system in the female, do not develop until the embryo reaches a length of 10-12 mm. (sixth week). Each commences as a groove-like invagination of the cœlomic epithelium on the dorsilateral aspect of the mesonephric ridge near its cephalic end, and its blind end grows tailwards as a solid rod of cells which acquires a lumen as it lengthens. Throughout the extent of the mesonephros it lies on the lateral side of the mesonephric duct. At the caudal end of the mesonephros, which it reaches in the eighth week, it bends medially (fig. 248, I.) and crosses ventral to the mesonephric duct to enter the genital cord (fig. 242), where it bends caudally in close apposition with its fellow of the opposite side. The two ducts reach the dorsal wall of the urogenital sinus during the third month, and their blind ends produce an elevation on it termed the *Müllerian tubercle* or *eminence* (fig. 244). Each paramesonephric duct consists of an upper vertical, an intermediate horizontal, and a lower vertical portion. The upper vertical part forms the

FIG. 244.—The urogenital sinus of a female human embryo, eight and a half to nine weeks old. (From a model by Keibel.)



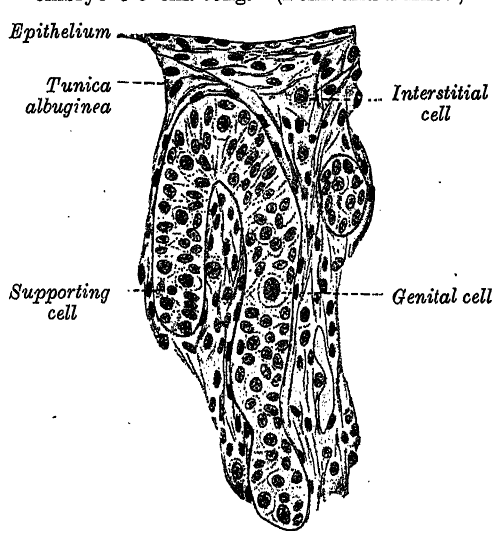
uterine tube, and the original cœlomic invagination remains as the pelvic opening of the tube, the fimbriae becoming defined as the cephalic end of the

FIG. 245.—A longitudinal section of the ovary of a cat embryo, 9·4 cm. long. Schematic. (After Coert, from Hertwig's Handbuch der Entwickelungslehre.)



mesonephros degenerates. The lower vertical parts of the two ducts fuse with each other to form the *uterovaginal canal*, and as the uterine section enlarges it

FIG. 246.—A section through a testis cord of the testis of a human embryo 3·5 cm. long. (Felix and Bühler.)



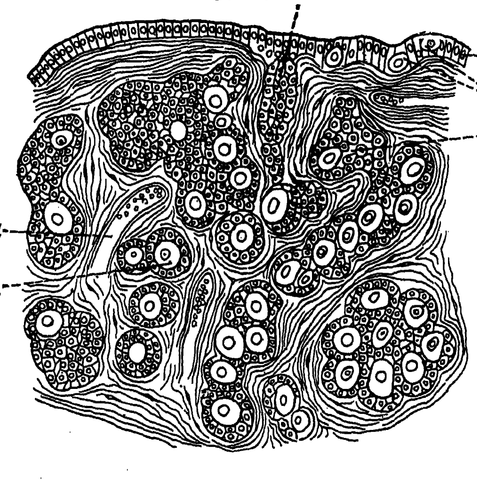
takes in the horizontal parts to form the fundus and most of the body of the adult uterus.

The caudal end of the uterovaginal canal becomes occluded by the proliferation of its lining epithelium, which gives rise to the formation of a central and two lateral vaginal bulbs.* These solid epithelial masses extend tailwards, increasing the size of the area of contact of the vagina with the urogenital sinus and forming a conspicuous projection on the dorsal wall of the latter. The vagina grows much more rapidly than the surrounding parts and, owing to the way in which its caudal end enlarges and encroaches on the dorsal wall of the urogenital sinus, that structure becomes definitely shortened. The vaginal invagination, covered on the one hand by sinus epithelium and on the other by vaginal epithelium, constitutes the *hymen,* and it later breaks down centrally to form the hymeneal orifice.

In the male the paramesonephric (Müllerian) duct atrophies, but a vestige of its cephalic end persists as the *appendix testis.* The fused terminal portions of the two ducts (fig. 243) form the *prostatic utricle,* which opens into the floor of the prostatic part of the urethra.

The genital glands.—The first indication of the formation of the genital gland is the appearance of an area of thickened epithelium on the medial side

Fig. 247.—A section through the ovary of a new-born child. (Waldeyer.)



of the mesonephric ridge in the fifth week. Elsewhere on the surface of the ridge the cœlomic epithelium is one or two cells thick, but over the genital area it is many layered. The thickening rapidly extends in a longitudinal direction until it covers nearly the whole of the medial surface of the ridge. The thickened epithelium continues to proliferate, displacing the Malpighian corpuscles of the mesonephros in a dorsilateral direction, and forming a projection into the cœlomic cavity which is termed the *genital ridge.* Surface depressions form along the limits of the ridge, which is thus connected to the mesonephros by an originally broad *mesogenitale.* In this way the mesonephric ridge becomes subdivided into a lateral part, containing the mesonephros and the mesonephric (Wolffian) and paramesonephric (Müllerian) ducts, which is termed the *mesonephric fold*, and a medial part, termed the *genital fold* (fig. 241).

Up to the seventh week the genital gland possesses no differentiating features. The epithelium proliferates and sends a number of cellular cords into the underlying mesoderm of the mesonephric ridge. In the male all the progenitors of the definitive sex cells are to be found in the cords, but in the female a large number remain behind in the surface epithelium. An ingrowth of mesenchyme occurs at this stage in the male, cutting off the *testis cords* from the surface and rapidly thickening to form the *tunica albuginea.* In the female this

* J. Ernest Frazer and Alice Bloomfield, *Journal of Anatomy*, vol. lxii. *See also* Arthur K. Koff, *Contributions to Embryology*, vol. xxiv. 1933.

mesenchymal ingrowth is much less obvious and offers a feature which serves to distinguish the testis from the ovary.

The **testis**.—The cellular cords enlarge and their inner ends converge towards the site of the hilum, where they unite in a network which ultimately becomes the *rete testis*. The outer parts of the testis cords become the seminiferous tubules, but certain epithelial derivatives occupy the intervals between the cords and subsequently form the interstitial cells. The cords of the rete

testis become connected to the five to twelve persisting cephalic tubules of the mesonephros (p. 185), which constitute the efferent ducts of the testis. The seminiferous tubules do not acquire lumina until the seventh month, but the rete tubules acquire theirs at a somewhat earlier stage.

According to the above description the rete testis is derived from the epithelium of the genital ridge, but the view is widely held that the rete testis is derived from outgrowths from the tubules of the mesonephros or from the capsules of the Malpighian corpuscles, and becomes secondarily connected to the testis cords. However this may be, it is clear that the seminiferous tubules are brought into communication with the cephalic end of the mesonephric duct through the five to twelve most cephalic of the persisting tubules, which become exceedingly convoluted and form the lobules of the head of the epididymis. The mesonephric duct, which was the primitive ureter of the mesonephros, becomes the canal of the epididymis and the vas deferens of the testis.

The **ovary**.—The cellular cords, which appear in the indifferent stage of the genital gland, are termed the *medullary cords* of the ovary, and the sex cells which they contain, proliferate and develop into oöcytes, but although these oöcytes undergo the initial changes leading to maturation, they never form mature ova. It is said that all the sex cells derived from the medullary cords undergo degenerative changes and disappear. A second invasion of the underlying mesenchyme now occurs, and new cords grow in from the surface epithelium. All the sex cells are included in this new ingrowth, and the ova become separated from one another by an irregularly arranged growth of connective tissue. Each ovum assumes a covering of connective tissue cells, and in this way the rudiments of the ovarian follicles are formed.

It is generally believed that the primary sex cells or *gonocytes* are differentiated at an early stage in the development of the embryo, and that, prior to the appearance of the genital ridge, they are situated in the wall of the yolk-sac at the margins of the embryonic area. From this position they migrate to the root of the dorsal mesentery and thence to the genital ridge. Arrived at their destination the primary sex cells lose all their characteristic features, and become indistinguishable from the neighbouring cells of the cœlomic epithelium. Probably the definitive sex cells are derived partly from the primary sex cells, and partly from the epithelial cells.

The descent of the testis.—At first the testis lies on the dorsal abdominal wall, but, as it enlarges, its cephalic end degenerates, and the whole organ therefore assumes a more caudal position. The testis is attached to the mesonephric fold by a peritoneal fold, termed the *mesorchium* (fig. 241) (the mesogenitale of the undifferentiated genital gland), which contains the testicular vessels and nerves together with a quantity of undifferentiated mesenchyme. In addition, it acquires a secondary attachment to the ventral abdominal wall, which has a considerable influence on its subsequent movements. At the point where it bends medially to form the genital cord (p. 185), the mesonephric fold becomes connected to the lower part of the ventral abdominal wall by a fold of peritoneum which is termed the *inguinal fold* (fig. 242). The mesenchymal cells included in the inguinal fold form a cord, which extends from that part of the skin which later forms the scrotum, through the inguinal fold and the mesorchium to the lower pole of the testis. This cord later becomes a fibromuscular bundle and is termed the *gubernaculum testis*. It traverses the site of the future inguinal canal, which is formed around it by the muscles of the abdominal wall as they become differentiated. At the end of the second month the caudal part of the ventral abdominal wall is horizontal but, after the return of the intestines to the peritoneal cavity (p. 170), it grows in length and assumes a vertical position. As a result the umbilical artery pulls up a sickle-shaped peritoneal fold, as it runs ventrally from the dorsal to the ventral wall, and this fold forms the medial boundary of a peritoneal fossa into which the testis projects. This fossa is termed the *saccus vaginalis* and its lower end protrudes down the inguinal canal along the gubernaculum, forming the *processus vaginalis*. The lower pole of the testis is retained in apposition with the deep inguinal ring by the gubernaculum until the seventh month, when it suddenly and rapidly passes through the inguinal canal and gains the scrotum. As it descends it is necessarily accompanied by its peritoneal covering and the adjoining peritoneum from the iliac fossa is drawn down into the processus vaginalis. The distal end of the processus vaginalis, into which the testis projects, forms the tunica vaginalis testis, but the portion associated with the spermatic cord in the scrotum and in the inguinal canal normally becomes obliterated.

The actual cause of the descent of the testis is still uncertain. It has been ascribed, by different investigators, to shortening and active contraction of the gubernaculum, to increased intra-abdominal pressure, to a simple growth process, and to the effect on the convex surface of the gland of the active contraction of the lower fibres of the internal oblique muscle, which squeezes it through the canal.

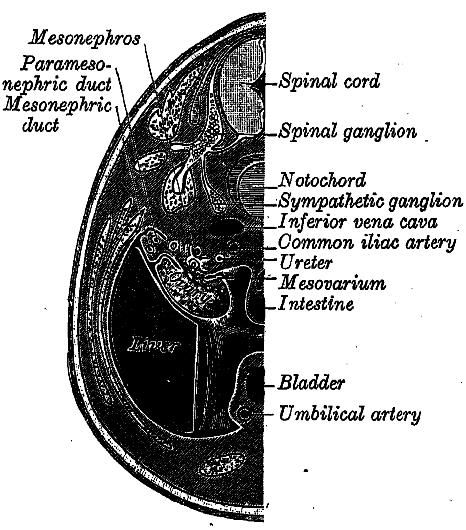
Various abnormalities may occur in connexion with the descent of the testis and the obliteration of the processus vaginalis. The testis may be retained in the abdomen, or it

may fail to reach the scrotum and may then lie in any of the following situations :—(1) in the perineum, (2) at the root of the penis, (3) at the superficial inguinal ring, (4) in the upper part of the thigh. These malpositions are associated with certain additional connexions of the bundles of the gubernaculum testis. The largest bundle normally passes to the scrotum and smaller bundles gain attachment to the perineum, the root of the penis, the pubis, the inguinal ligament, and the neighbourhood of the saphenous opening (fossa ovalis). The testis must follow the processus vaginalis and, should the latter for any reason follow any but the scrotal bundle of the gubernaculum, malposition of the testis will result.

The processus vaginalis may remain completely patent, or its obliteration may be incomplete. When it retains a connexion with the general peritoneal cavity it provides a preformed sac for a potential oblique inguinal hernia. It may be occluded at its upper end and may be shut off from the tunica vaginalis and yet remain patent in the intervening section. The patent portion may become distended with fluid, constituting an encysted hydrocele of the spermatic cord.

The descent of the ovary.—Like the testis, the ovary lies at a lower level in the adult than it does in the early months of fœtal life, but it does not leave the pelvis to enter the inguinal canal save under abnormal conditions. Connected to the medial portion of the mesonephric fold by the mesovarium, which is homologous with the mesorchium, the ovary is also attached to the ventral abdominal wall through the medium of the inguinal fold. In this fold the fibro-muscular gubernaculum develops and, as it traverses the mesonephric fold, it acquires an additional attachment to the cornu of the uterus ; its lower portion forms the round ligament of the uterus and its upper part the ligament of the ovary, these two structures together being homologous with the gubernaculum testis in the male. This new attachment serves to anchor the ovary and to restrict its movements. At first the ovary is attached to the medial side of the mesonephric fold, but owing to the way in which the two mesonephric folds unite to form the genital cord (p. 185) it is found connected to the posterior layer of the broad ligament of the uterus in the adult.

Fig. 249.—A transverse section through a human embryo, eight and a half to nine weeks old. (From a model by Keibel.)



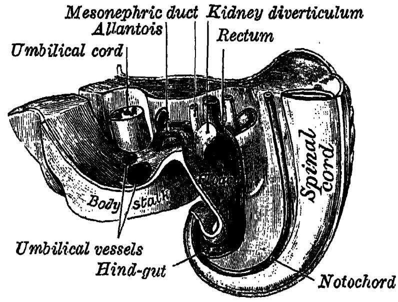
The saccus vaginalis forms in the female as in the male ; its prolongation into the inguinal canal, which is termed the *canal of Nuck*, normally undergoes complete obliteration, but it may remain patent and form the sac of an oblique inguinal hernia. At birth the ovary and the corresponding end of the uterine tube lie in the false pelvis, and they do not sink down into the true pelvis until it enlarges sufficiently to contain both them and the bladder together with the other pelvic viscera.

The **urinary bladder** is formed partly from the entodermal cloaca and partly from the ends of the mesonephric (Wolffian) ducts. After the separation of the rectum from the cloaca (p. 171), the ventral part of the latter becomes subdivided into three portions : (1) a cephalic *vesico-urethral portion*, continuous with the allantoic canal—into this portion the mesonephric ducts open ; (2) a middle, narrow channel, the *pelvic portion* ; and (3) a caudal, broad, *phallic portion*, closed externally by the urogenital membrane (fig. 252). The second and third parts together constitute the *urogenital sinus*. The vesico-urethral portion incorporates the caudal ends of the mesonephric ducts and the associated ends of the ureteric diverticula, and these give rise to the trigone of the bladder and part of the prostatic urethra. The remainder of the vesico-urethral portion

forms the body of the bladder and part of the prostatic urethra ; its apex is prolonged to the umbilicus as a narrow canal. In postnatal life the urachus is drawn downwards as the bladder descends, but its blind upper end remains connected to one or both of the obliterated umbilical arteries. Its lumen is retained throughout life, and its lower end frequently communicates with the bladder near its vertex.*

The **prostate** arises during the third month as a number of outgrowths from the proximal part of the urethra. These outgrowths, some fourteen to twenty

FIG. 250.—The tail-end of a human embryo, about thirty-five days old. (From a model by Keibel.)

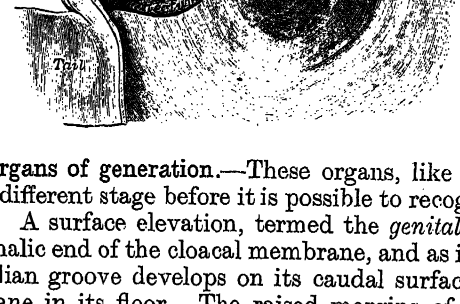


in number, arise mainly from the lateral aspects of the tube, but some develop from its dorsal aspect and a few from its ventral aspect. Most of these outgrowths occur caudal to the orifices of the mesonephric (Wolffian) ducts, but about one-third occur on the cephalic side. The outgrowths, which are at first solid, become tubular and invade the surrounding mesenchyme, which is being differentiated into muscular tissue.

Similar outgrowths occur in the female, but they remain in a rudimentary condition and form the para-urethral ducts.

The *bulbo-urethral glands* in the male, and *greater vestibular glands* in the female, arise as diverticula from the epithelial lining of the urogenital sinus.

FIG. 251.—The tail-end of a human embryo, about six weeks old. (From a model by Keibel.)



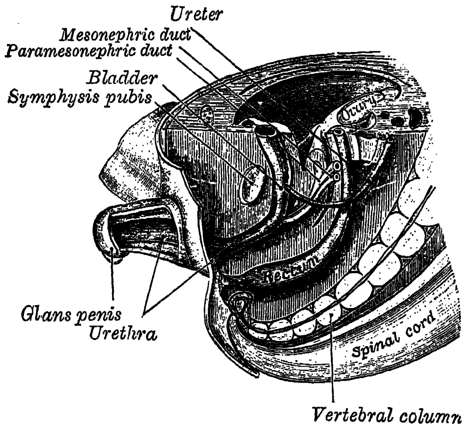
The **external organs of generation**.—These organs, like the genital glands, pass through an indifferent stage before it is possible to recognise distinguishing sexual characters. A surface elevation, termed the *genital* or *cloacal tubercle*, appears at the cephalic end of the cloacal membrane, and as it lengthens to form the *phallus*, a median groove develops on its caudal surface and includes the urogenital membrane in its floor. The raised margins of the groove, which are named the *genital folds* (fig. 254), terminate behind in a transverse ridge, situated immediately in front of the anus.† In the majority of cases in male

* R. C. Begg, *Journal of Anatomy*, vol. lxiv. 1930.

† According to Ellsworth M. Tench (*loc. cit.*) the genital folds are continuous behind with the anal tubercles, which do not fuse with each other in front of the anus until a later stage.

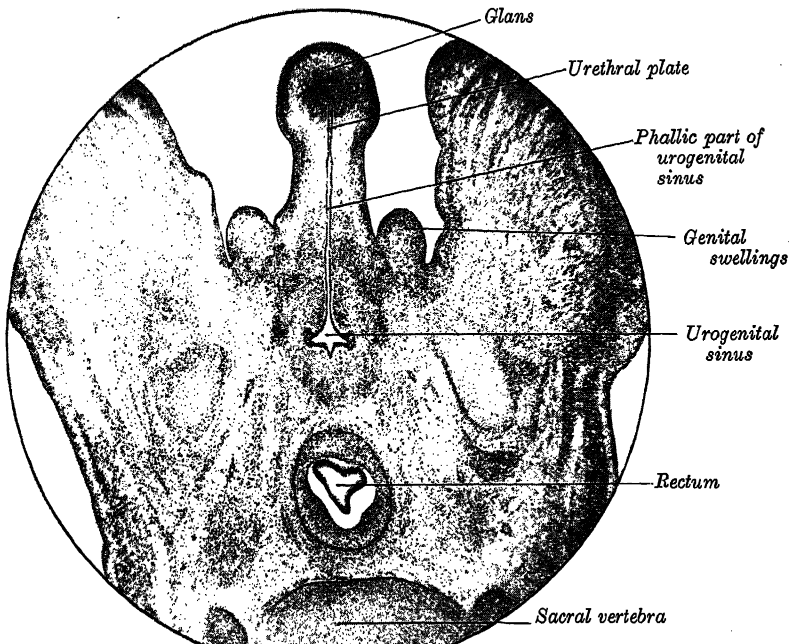
embryos the groove reaches the apex of the phallus, whereas in female embryos it does not extend so far.* By this feature the sex of an embryo may frequently, but not invariably, be determined as early as the seventh week.

FIG. 252.—The tail-end of a human embryo, eight and a half to nine weeks old. (From a model by Keibel.)



Prior to the rupture of the urogenital membrane the urogenital sinus extends ventrally into the phallus and is continued to its apex as a sagitally placed epithelial plate, termed the *urethral plate* (fig. 253). The rupture of the urogenital membrane provides a common perineal orifice for both the generative and the urinary tracts, and this orifice is bounded at the sides by the genital folds.

FIG. 253.—Transverse section through the lower part of the pelvis of a nine weeks old human embryo.

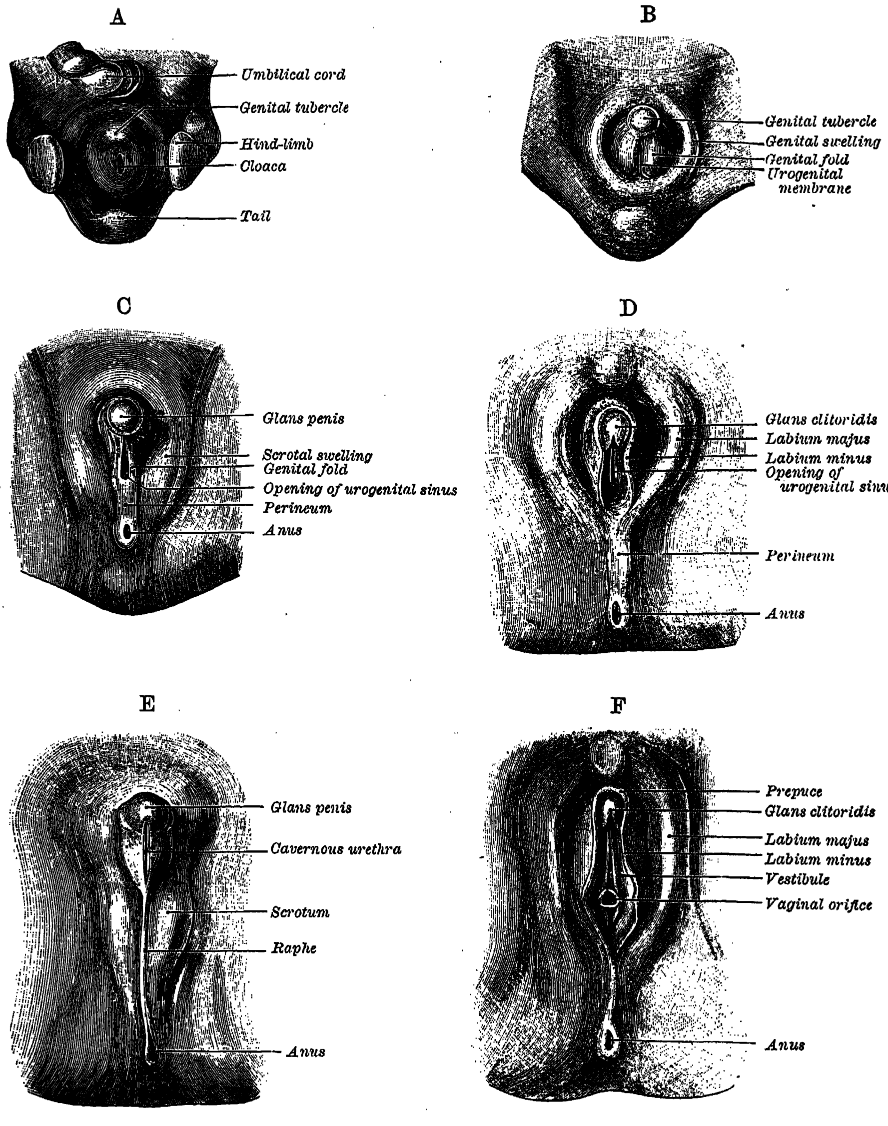


* M. H. Spaulding, *Contributions to Embryology*, No. 61, 1921; K. M. Wilson, *Contributions to Embryology*, No. 91, 1926; A. Szenes, *Morphol. Jahrbuch*, Bd. 54.

While these changes are in progress two *genital swellings* (labioscrotal folds) appear, one on each side of the base of the phallus, and extend caudally, separated from the genital folds by distinct grooves (fig. 254).

In the male, the phallus enlarges to form the penis, and its apex constitutes the glans. The genital swellings meet each other ventral to the anus and unite to form the scrotum. The genital folds fuse with each other from behind

Fig. 254.—Stages in the development of the external sexual organs in the male and female. (From the Ecker-Ziegler models.)



forwards, enclosing the penile part of the urethra and completing the ventral aspect of the penis. In this way, as the phallus lengths, the urogenital orifice is carried onwards until it reaches the base of the glans, where it forms a primary meatus. The urethral plate splits and a trough is formed, which extends from the primary meatus forwards to the apex of the glans. The primary meatus becomes closed and the margins of the trough unite from behind forwards, until only the definitive (secondary) meatus remains. The *prepuce* is formed by the ingrowth of a ring-like plate of ectoderm which burrows into the superficial part of the glans. The ring is deficient ventrally

and the gap indicates the site of the frenulum. By the breaking down of its central cells the plate is split into two lamellæ, and a cutaneous fold, the prepuce, is liberated to form a hood-like covering for the glans. 'Adherent prepuce is not an adhesion really, but a hindered central desquamation' (Berry Hart).

In the female the phallus, which exceeds the male phallus in length in the early stages, becomes the clitoris. The genital swellings remain separate as the labia majora and the genital folds also remain ununited, forming the labia minora. The perineal orifice of the urogenital sinus is retained as the cleft between the labia minora, above which the urethra and vagina open. The prepuce of the clitoris develops in the same way as the homologous structure in the male.

The **urethra.**—In the female, the whole of the urethra is derived from the vesico-urethral portion of the cloaca (p. 193). It is homologous with that part of the prostatic urethra in the male which lies headwards of the orifices of the prostatic utricle and the ejaculatory ducts.

In the male, the prostatic part of the urethra headwards of the orifice of the prostatic utricle is derived from the vesico-urethral portion of the cloaca and the incorporated caudal ends of the mesonephric ducts. The remainder of the prostatic part, the membranous part and probably the part within the bulb, are all derived from the urogenital sinus. The succeeding portion, as far as the glans, is formed by the fusion of the genital folds, while the section within the glans is formed from the urethral plate.

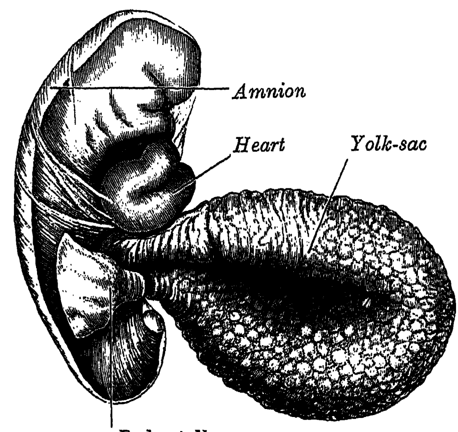
The subjoined table shows the homologies of the various parts of the urogenital system in the male and in the female (fig. 248).

Indifferent	Male	Female
Genital gland	Testis	Ovary
Gubernacular cord	Gubernaculum testis	Ligament of ovary Round ligament of uterus
Mesonephros (Wolffian body)	(?) Appendix of epididymis	(?) Appendices vesiculosæ
	Efferent ducts of testis	Epoöphoron
	Coni vasculosi of head of epididymis	
	Paradidymis	Paroöphoron
	Ductuli aberrantes	
Mesonephric duct (Wolffian duct)	Duct of epididymis	Duct of epoöphoron
	Ductus deferens	
	Ejaculatory duct	
	Part of bladder and prostatic urethra	Part of bladder and urethra
Paramesonephric ducts (Müllerian ducts)	Appendix of testis	Uterine tubes
		Uterus
	Prostatic utricle	Vagina
Allantoic canal	(?) Urachus	(?) Urachus
Cloaca, dorsal portion of	Rectum and upper part of anal canal	As in male
ventral portion of	Most of the urinary bladder and part of prostatic urethra	Most of the urinary bladder, and the urethra
urogenital sinus	Prostatic urethra (below prostatic utricle)	Bulbo-vestibular glands
	Bulbo-urethral glands	
	Remainder of urethra	Vestibule
Genital swellings	Scrotum	Labia majora
Genital folds	Ventral aspect of penis	Labia minora
Genital tubercle	Penis	Clitoris

Congenital defects of the urethra, due to arrests of development, are not uncommon in the male. The urethra may open on the ventral aspect of the penis at the base of the glans, and the portion of the urethra which is normally derived from the urethral plate is absent. This constitutes the simplest form of *hypospadias*. In more severe cases the genital folds fail to fuse, and the urethra opens on the ventral aspect of a malformed penis just in front of the scrotum. A still greater degree of this malformation is accompanied by failure of the genital swellings to unite with each other. In these cases the scrotum is divided and, as the testes are frequently undescended, the resemblance to the labia majora is very striking. Male children suffering from this deformity are often mistaken for girls.

Maldevelopment of the cloacal or urogenital membranes is a less common condition, but three varieties of it can be distinguished. (1) In *epispadias* the urethra opens on the dorsal aspect of the penis at its junction with the anterior abdominal wall. (2) In *extroversion of the bladder* * the lower part of the anterior abdominal wall is occupied by an irregularly oval area, covered with mucous membrane, on which the two ureters open. Around its periphery this extroverted area, which is lined by transitional epithelium, becomes continuous with the skin. (3) In *extroversion of the cloaca* the condition is very similar,

FIG. 255.—A human embryo, 2·6 mm. long. (His.)



but is complicated by the presence of intestinal openings in the median plane. In (3) the cloacal membrane is probably abnormally elongated and ruptures prematurely and throughout its whole extent, prior to the formation of the urorectal septum. In (2) the maldevelopment occurs after the separation of the ventral from the dorsal part of the cloaca. The urogenital membrane extends further headwards than it does in normal cases and the genital tubercle forms at its caudal limit. Rupture of the membrane throws the bladder open to the exterior. In (1) a similar condition exists, but rupture of the urogenital membrane is localised so that the anterior wall of the bladder is not affected.

THE FORM OF THE EMBRYO AT DIFFERENT STAGES OF ITS GROWTH

To determine the precise age of any given human embryo is a matter of great difficulty, especially in the earlier stages, even when the date of the fertilising coitus is known. In 1899 Peters † described a specimen, the age of which he computed at from three to four days, but Bryce and Teacher,‡ in the light of the specimen described by them, have estimated its age as from thirteen and a half to fourteen and a half days. A very young human embryo was found by Miller in 1913 in tissue removed by curettage. The sections have been examined by Streeter,§ who estimates the age at from ten to eleven days. There were no chorionic villi but the amniotic vesicle was present and a rudiment of the entodermal vesicle was recognisable. Stieve ** has recently described an ovum (Embryo Werner) which he

* G. M. Wyburn, *Journal of Anatomy*, vol. lxxi. 1937.

† Hubert Peters, *Die Einbettung des menschlichen Eies*, 1899.

‡ Bryce and Teacher. (*Early Development and Imbedding of the Human Ovum*, 1908.)

§ Streeter, G. E. *Contributions to Embryology*, No. 92, 1927.

** H. Stieve. *Zeitschrift für Mikroskopisch-Anatomische Forschung*, Bd. 40, 1936.

regards as representing an intermediate stage between the Miller ovum and the Peters ovum. Primary chorionic villi are present and a trophoblastic shell limits a blood-filled intervillous space. The ectodermal vesicle is present and its ventral surface is in relation with a single layer of cells which is regarded as representing the roof of the entodermal

Fig. 256.—A human embryo, 4·2 mm. long. (His.)

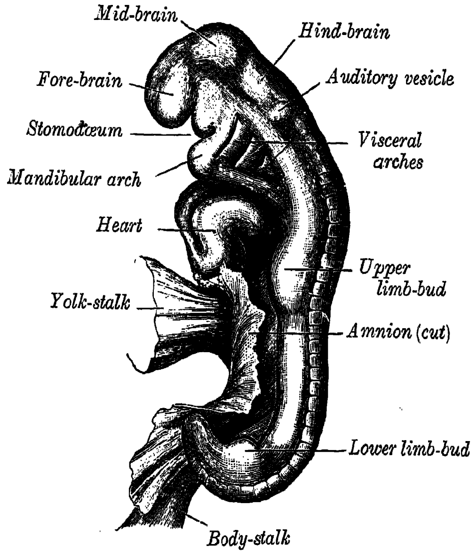


Fig. 257.—A human embryo, about 8 mm. long. (Drawn from a stereoscopic photograph taken before fixation.)

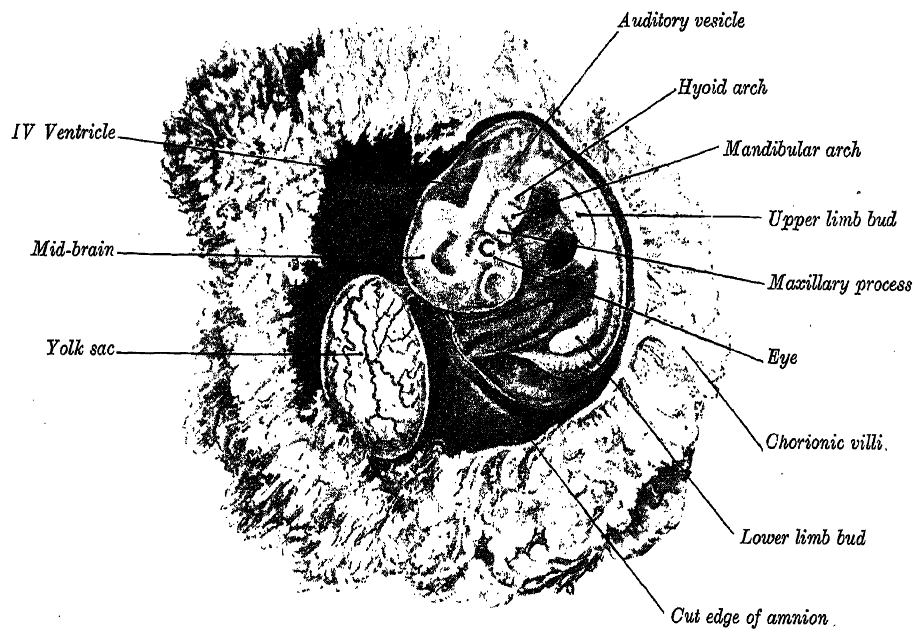


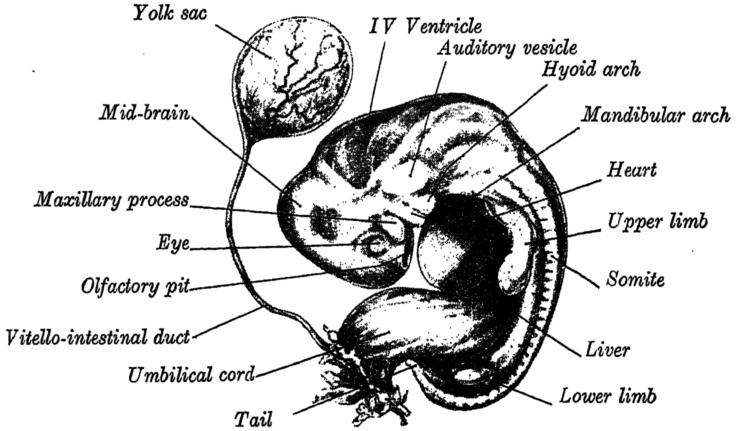
vesicle. The rest of the vesicle is outlined in the magma cavity but its wall is not cellular (see p. 55, footnote *). Bryce and Teacher, Grosser,* and von Mollendorff † have all described early human embryos of approximately the same stage. The Teacher-Bryce

* Grosser, O. *Zeitschrift für Anatomie und Entwickelungsgeschichte,* 1922.

† von Mollendorff, W. *Zeitschrift für Anatomie und Entwickelungsgeschichte,* 1921.

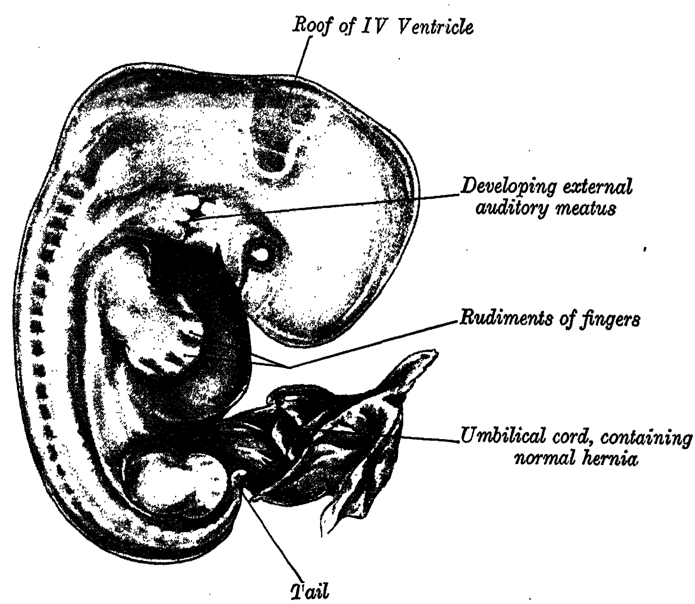
ovum (T.B.I.) was the product of an early abortion, and the ovum was discharged completely enveloped by decidua. The authors estimate its age as from thirteen to fourteen days. It took the form of a blastocyst (fig. 74) with a diameter of approximately 6 mm., which was surrounded by a well-developed, reticular plasmodial trophoblast lined by

FIG. 258.—Human embryo, about 9 mm. long. (Drawn from a stereoscopic photograph.)



cytotrophoblast. Within the blastocyst was contained the embryonic rudiment, which consisted of two small vesicles; the larger of the two was identified as the ectodermal or amnio-embryonic vesicle, and the smaller as the entodermal vesicle or yolk-sac. The primary mesoderm, which filled the blastocyst and surrounded the vesicles, consisted of a fluid matrix containing numerous cellular elements. The cells of the ectodermal vesicle

FIG. 259.—Human embryo, about 15 mm. long. (Drawn from a stereoscopic photograph.)



showed no differentiation into the amnion and the embryonic area, so that the specimen was definitely younger than the Peters ovum, in which the embryonic ectoderm was already defined.

During the third week differentiation commences in the embryonic area. The primitive streak and node, the head process and the neural groove appear. The allanto-enteric diverticulum is present and, by the end of the period, head and tail folds are in process of formation (fig. 95).

During the fourth week the head and tail folds are completed. The primary cerebral vesicles can be recognised and the neural groove commences to close (fig. 255). The auditory vesicle appears, but as yet the face is unrecognisable and the neck is not apparent. The heart forms a prominent elevation, immediately caudal to the stomodæum, and segmentation of the mesoderm is begun. The vitello-umbilical veins communicate with the common sinu-atrial chamber and the embryonic circulation is established; at the end of the period the embryo is about 2·5 mm. long.

In the fifth week the embryo becomes markedly curved on itself and becomes more definitely pinched off from the yolk-sac. The lens vesicle has closed and is separated from the covering ectoderm. The olfactory placodes are present, and the maxillary and fronto-

Fig. 260.—A human embryo, about 23 mm. long. (His.)

nasal processes can be recognised. The branchial arches and grooves appear, indicating the position of the neck, and the rudiments of the limb-buds can be identified (fig. 256). By the end of the period some thirty to thirty-six somites are present and the crown-rump length of the embryo has reached 5·5 mm.

In the sixth week the curvature of the embryo is further increased. The head is in contact with the umbilical cord and may almost meet the long, curved tail. The olfactory pits deepen, and the maxillary, lateral nasal and globular processes begin to fuse. The mandibular and hyoid arches meet their fellows in the median plane, and the neck commences to appear. The liver forms a surface prominence between the heart and the umbilical cord. The limb-buds increase in length and three segments can be recognised in each. By the end of the sixth week the embryo has increased to 11 mm. crown-rump length.

In the seventh and eighth weeks the flexure of the head is gradually reduced and the neck is somewhat lengthened. The upper lip is completed and the nostrils are directed forwards; the palate is not completely developed. The eyelids are present in the shape of folds above and below the eye, and the different parts of the auricle are distinguishable. The external genitalia are present and may show sexual differences by the end of the seventh week (p. 195). The tail begins to disappear. The fingers and toes can be recognised. By the end of the eighth week the embryo has attained a crown-rump length of about 25 mm. and now passes into the fœtal period.

In the third month the head is extended and the neck is lengthened. The eyelids meet and fuse, remaining closed until the end of the sixth month. The limbs are well developed and nails appear on the digits. The normal umbilical hernia is reduced and by the end of this month the crown-rump length of the fœtus is about 10 cm.

In the fourth month lanugo appears on the body, and by the end of the month the fœtus has reached a crown-rump length of about 14 cm., and a total length—i.e. including the legs—of about 22 cm.

During the fifth month the first movements of the fœtus are usually observed. The eruption of hair on the head commences, and the vernix caseosa begins to be deposited. By the end of this month the total length of the fœtus is nearly 30 cm.

In the sixth month the deposit of vernix caseosa is considerable. The papillæ of the skin are developed and the free borders of the nails project from the corium of the dermis. From vertex to heels the total length of the fœtus at the end of this month is about 33 cm. The weight is about 1 kilogram.

In the seventh month the pupillary membrane atrophies, and the eyelids are open. The testis descends with the vaginal sac of the peritoneum. The skin is red and wrinkled, giving the fœtus a prematurely aged appearance. From vertex to heels the total length at the end of the seventh month is about 40 cm. The weight is about 1·5 kilograms.

During the eighth month the skin is entirely coated with vernix caseosa, and the lanugo begins to disappear. Subcutaneous fat has been developed to a considerable extent, and the fœtus presents a plump appearance. The total length, i.e. from head to heels, at the end of the eighth month is about 45 cm., and the weight varies between 2 and 2·5 kilograms.

At the end of the ninth month the lanugo has largely disappeared from the trunk. The umbilicus is almost in the middle of the body and the testes are in the scrotum. The fœtus weighs from 3 to 3·5 kilograms, and measures from head to heels about 50 cm.

OSTEOLOGY

THE general framework of the body is built up mainly of a series of bones, supplemented in certain regions by pieces of cartilage; this bony and cartilaginous framework constitutes the *skeleton* (fig. 261).

In comparative anatomy the term skeleton has a wider application, for in some of the lower animals hard, protecting and supporting structures are developed in association with the skin. In such animals the skeleton comprises an internal or deep skeleton, termed the *endoskeleton*, and an external or superficial, termed the *exoskeleton*. In the human subject the exoskeleton is very rudimentary, its only important representatives being the nails and the enamel of the teeth, and therefore, in human anatomy, the term skeleton is confined to the endoskeleton; this is divisible into an *axial* part, which comprises the bones of the head and trunk, and an *appendicular* part, which comprises the bones of the limbs. The minute structure and the physical properties of bone, together with the process of bone formation and growth, are described on pages 18 to 27. The bones available for study in articulated skeletons and as separate entities have been subjected to a process of maceration, by which they are denuded of all the structures attached to them, viz., muscles, ligaments, periosteum and articular cartilage Subsequently they are allowed to dry for a prolonged period, with the result that the fat in the marrow drains away and what is left of the marrow itself shrivels up, leaving the bone clean, dry and easy to handle.

Function of bones.—Bones provide the central axis and give form to the body. Many of them are adapted to give support to the weight of the body, but they may fulfil some additional function, e.g. the thigh bones support the weight of the body in standing, walking and running, but they also provide the levers which are essential for locomotion. Other bones give protection to underlying or contained structures, e.g., the cranium protects the contained brain, and the sternum and ribs overlie the heart and lungs and give them some measure of protection. Others, again, afford areas for the attachment of muscles and provide the levers which facilitate speedy and efficient movements. Bones, therefore, constitute an important part of the locomotor apparatus of the body, but to enable them to function as levers for the production of movements they must be connected by muscles, and movable joints or articulations must be present where individual bones come into contact with one another.

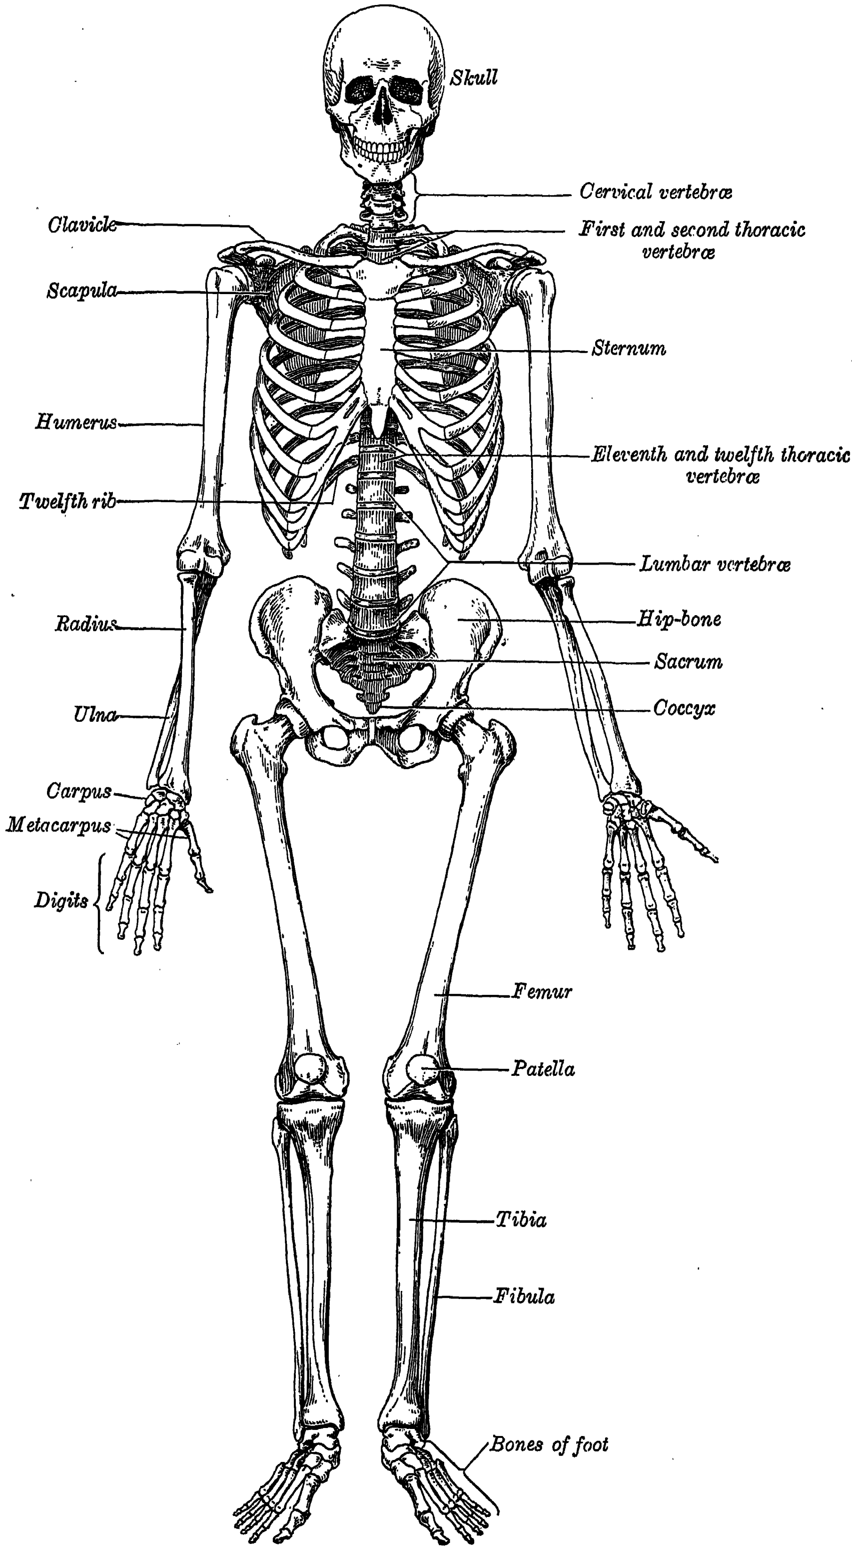
Bones are divisible into four classes: *long*, *short*, *flat*, and *irregular*.

The **long bones** are found in the limbs, where they form levers; each has a shaft and two ends. The *shaft* is tubular, and its central cavity is termed the *medullary cavity*; the wall consists of dense, compact substance of considerable thickness in the middle part of the shaft of the bone, but becoming thinner towards the ends; projecting into the medullary cavity there is some spongy substance, scanty in the middle of the body of the bone but plentiful towards the ends. The *ends* are usually expanded for purposes of articulation and muscular attachment; they consist of spongy substance covered by thin compact bone, and are usually developed from one or more secondary or *epiphyseal* centres of ossification (p. 25). The medullary cavity and the spaces in the spongy substance are filled with marrow (*medulla ossium*) (p. 27).

The **short bones.**—Where a part of the skeleton is intended for strength and compactness combined with limited movement it is constructed of a number of short bones, as in the *carpus* and *tarsus*. These bones consist of spongy substance surrounded by a thin crust of compact bone.

The **flat bones.**—Where the principal requirement of the skeleton is to protect delicate structures or provide broad surfaces for muscular attachment the bones are expanded into plates, as in the skull and the shoulder-blades, and are composed of two thin layers of compact bone separated by a variable quantity of spongy substance. In the cranial bones the layers of compact bone are known as the *tables* of the skull; the outer table is thick and tough, the inner thin, dense and brittle. The intervening spongy substance is called the *diploë*, and this, in certain regions of the skull, undergoes absorption, and air-filled spaces, termed *sinuses*, are left between the tables of the skull.

FIG. 261.—Front view of the skeleton. The right hand is in the prone position, the left in the supine position.



The **irregular bones**, from their peculiar form, cannot be grouped under the preceding heads. They consist of spongy substance enclosed within a thin layer of compact bone.

Surfaces of bones.—The surfaces of bones present many and variable features, which call for the use of a number of special descriptive terms. Smooth areas for articulation with other bones are known as *articular surfaces* and, when small, are frequently termed *facets*. A *condyle* is a smooth rounded projection, and a *trochlea* is a pulley-shaped surface; both are covered with articular cartilage in the recent state.

Depressions on bony surfaces are usually termed *fossæ*. They may be large or small, rough or smooth, non-articular or articular.

Any localised elevation or projection on a bony surface constitutes a *process*. A pointed process is called a *spine*, but the term is frequently applied to elongated processes with blunt extremities, e.g. the spines of the vertebræ. The terms *tubercle* and *tuberosity* are used, without much distinction, for localised, rounded elevations, which may possess smooth or roughened surfaces. An *epicondyle* is an elevation placed above an articular surface. A *hamulus* is a hook-like process, and a *cornu* a horn-like process. A sharp, distinct ridge, whether rough or smooth, is termed a *crest*, and if it is wide enough to possess borders they are known as *lips*. A low, narrow ridge is termed a *line*.

A hole in a bone is known as a *foramen*, and the term is often applied to the opening of a bony tunnel, which is termed a *canal*. A groove or furrow is frequently called a *sulcus*, a notch an *incisura*, a gap a *hiatus*, and a thin sheet or plate a *lamina*.

Many other terms are employed occasionally, but those already defined have the widest use.

THE VERTEBRAL COLUMN [COLUMNA VERTEBRALIS]

In all vertebrate animals the central axis of the body consists of a **vertebral column**. As it is essential that provision should be made for a considerable range of movement of the trunk, the column consists, not of a single elongated bone, but of a number of independent, irregular bones, termed the *vertebræ*, which are firmly connected to one another but are capable of a limited amount of movement on one another. The provision of a central axis is not the only function which the column has to subserve. It is built up so as to surround the spinal cord, to which it affords necessary protection. The human vertebral column must also support the weight of the trunk and transmit it to the lower limbs.

The vertebræ are grouped under the names *cervical*, *thoracic*, *lumbar*, *sacral* and *coccygeal* or *caudal*, according to the region in which they lie, but all the vertebræ, not only of man but also of all vertebrate animals, conform to a general plan, and although, at first sight, there may be little resemblance between a cervical vertebra of a giraffe and a human lumbar vertebra, the essential features of both will be found to be identical.

THE GENERAL CHARACTERISTICS OF A VERTEBRA

A **typical vertebra** (fig. 262) is made up of two principal parts, an anterior or ventral, termed the *body*, and a posterior or dorsal, termed the *vertebral arch*; these enclose a foramen, which is named the *vertebral foramen*.

In the articulated column the bodies and the intervertebral discs interposed between them form a continuous pillar, which constitutes the central axis of the body and, in man, supports and transmits the weight of the head and trunk. The vertebral foramina, placed one above another, constitute a canal in which the spinal cord is lodged and protected. Between contiguous vertebræ two *intervertebral foramina*, one on each side, open into the canal and serve for the transmission of the spinal nerves and vessels.

The **body** of a vertebra is more or less cylindrical, but is subject to a wide range of variation in size and shape in different animals and in different regions of the same animal. Its upper and lower surfaces are flattened and roughened to give attachment to the intervertebral discs. In front, it is convex from side to side and

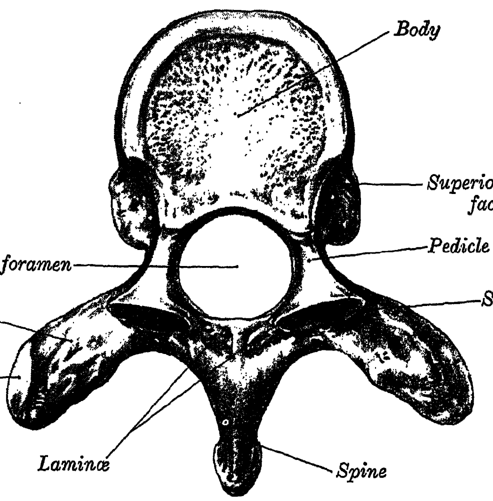
gently concave from above downwards; behind, it is flattened or slightly concave from side to side, and flat from above downwards. On its anterior surface there are a few small apertures for the passage of nutrient vessels; on its posterior surface there is a large irregular aperture (occasionally more than one) for the exit of the basivertebral veins (fig. 263).

The **vertebral arch** has a pair of *pedicles* and a pair of *laminæ*; it supports seven processes, viz., four *articular*, two *transverse* and one *spinous*.

The *pedicles* (*roots of the vertebral arches*) are a pair of short, thick processes, which project backwards from the body at the junctions of its lateral and posterior surfaces. The concavities above and below the pedicles are named the *vertebral notches*; and when the vertebræ are articulated with one another, the notches of contiguous vertebræ form the *intervertebral foramina*, to which reference has already been made.

The *laminæ* are broad plates directed backwards and medially from the pedicles. They fuse in the spine posteriorly, and so complete the posterior boundary of the vertebral foramen.

Fig. 262.—A typical thoracic vertebra. Superior aspect.



The *spine* (*spinous process*) is directed backwards and downwards from the junction of the laminæ, and serves for the attachment of muscles and ligaments. The spines are subject to great variations in size, shape and direction; they provide a series of levers for the movement of extension, or straightening, of the vertebral column and, to a lesser degree, for the movement of rotation.

The *articular processes*, two superior and two inferior, spring from the junctions of the pedicles and laminæ. The superior processes project upwards, and their articular surfaces face more or less backwards; the inferior project downwards, and their articular surfaces face more or less forwards. These processes meet the corresponding processes of the adjoining vertebræ and, while permitting a certain degree of movement, definitely control and restrict its range.

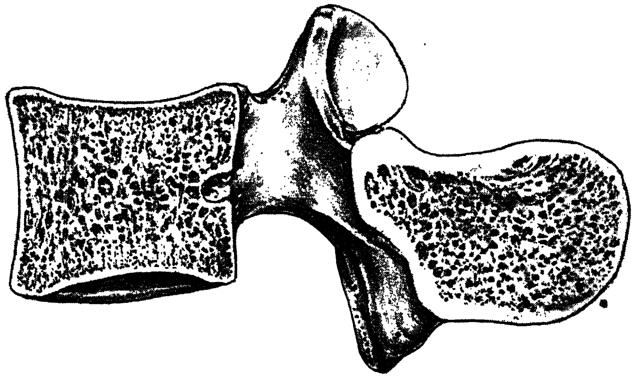
The *transverse processes* project laterally from the junctions of the pedicles and laminæ; they serve for the attachment of muscles and ligaments and are the levers by means of which the rotatory and lateral movements of the vertebræ can be effected. In addition, in the thoracic region they articulate with and limit the movements of the ribs.

The *costal elements* develop as essential constituent parts of each vertebral arch. In certain regions (in man, the thoracic region only) they become independent units—the *ribs*—which articulate with the vertebral column. In other regions they remain stunted and, almost unrecognisable in form, become fused with the vertebræ. Originally protective in function, in higher forms they also act as levers which play an important part in the movements of respiration.

Structure of a vertebra (fig. 263).—The body of a vertebra is composed of

spongy substance covered by a thin coating of compact bone, which presents numerous orifices for the passage of vessels; the interior of the body is traversed by one or two large canals, for the transmission of veins, which converge towards the large aperture on the posterior surface of the body. In the vertebral arch and the processes projecting from it the compact substance is thicker than it is in the body.

FIG. 263.—A median sagittal section through a lumbar vertebra.



THE INDIVIDUAL VERTEBRÆ

In the light of this description of a typical vertebra it is now possible to study the individual vertebræ of the human vertebral column, and observe how the essential features are modified in the different regions. In each region the vertebræ exhibit certain group characters, but atypical characters make their appearance at the upper and lower limits of each region for the purpose of adapting the vertebræ concerned to their neighbours.

In man the cervical vertebræ are seven in number; the thoracic, twelve; the lumbar, five; the sacral, five; and the coccygeal, four; making a total of thirty-three. The cervical, thoracic and lumbar vertebræ are separate bones throughout life and are therefore known as the *movable vertebræ*; the sacral and coccygeal, on the other hand, are termed *fixed vertebræ*, because, owing to the necessity for stability in this part of the column in man, they are united in the adult to form two bones, viz. the *sacrum* and the *coccyx.*

THE CERVICAL VERTEBRÆ [VERTEBRÆ CERVICALES]

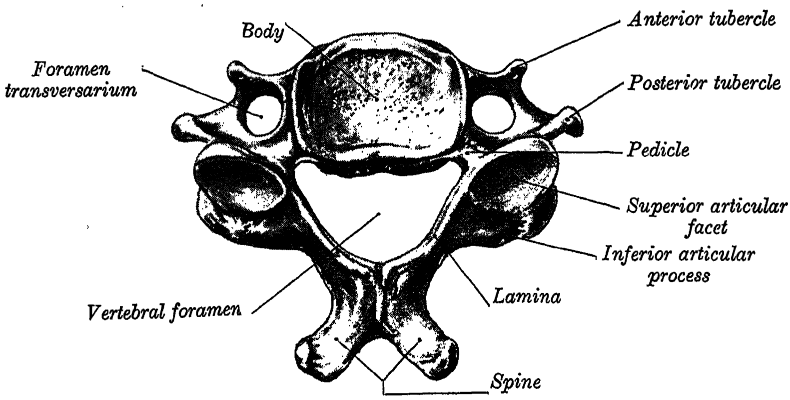
The cervical vertebræ (figs. 264, 270), seven in number, are the smallest of the movable vertebræ and can be identified easily owing to the peculiarity of their transverse processes, each of which is perforated by a foramen. The first, second and seventh cervical vertebræ present special distinguishing features, but the remaining four conform to a common type.

A typical cervical vertebra.—General features.—The body is small and is broader from side to side than from before backwards. The *vertebral foramen* is large in proportion to the size of the body and it is triangular in outline. These two features are accounted for, in part, by the direction of the *pedicles*, which project laterally as well as backwards (fig. 264). The superior and inferior vertebral notches are almost equal, for the pedicle is attached to the body nearly midway between its upper and lower borders. The *laminæ* are relatively long and narrow, and are thinner above than below. The *spine* (*spinous process*) is short and bifid and its terminal tubercles are often unequal in size. The *superior* and *inferior articular processes* form an *articular pillar*, which projects laterally at the unction of the pedicle and lamina. The *transverse process* is pierced by the *foramen transversarium* (fig. 264). It consists of an anterior and a posterior root, connected to each other on the lateral side of the foramen transversarium by a bar of bone, often termed the *costotransverse bar.* The anterior root and the costotransverse bar are homo-

logous with the rib in the thoracic region; the posterior root is the homologue of the thoracic transverse process.

Particular features.—The *anterior surface of the body* is convex from side to side, and its upper and lower borders give attachment to the fibres of the anterior longitudinal ligament. On each side of the ligament a slight depression gives attachment to fibres of the vertical portion of the longus cervicis (longus colli) muscle. The *posterior surface* is flattened and presents near its centre two or more vascular foramina, which transmit the basivertebral veins. Its upper and lower borders give attachment to the posterior longitudinal ligament. The *superior surface* is concave transversely and has an upwardly projecting lip on each side

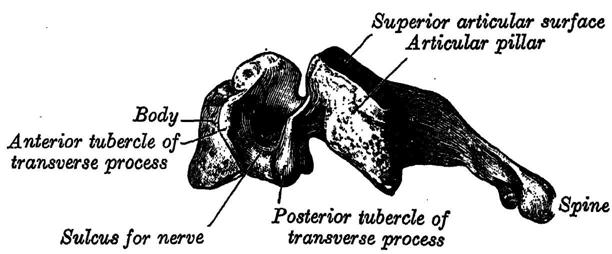
FIG. 264.—A typical cervical vertebra. Superior aspect.



(fig. 270); its anterior border may be slightly bevelled. The inferior surface is saddle-shaped, being convex from side to side and concave from before backwards. A small synovial joint is present on each side between the bevelled lateral border and the projecting lip of the upper surface of the vertebra below. The anterior border of the lower surface projects downwards and hides the intervertebral disc. The upper borders of the laminæ and the lower part of their anterior surfaces give attachment to the ligamenta flava. The spines give attachment to the ligamentum nuchæ and to a number of the deep muscles of the back of the neck, viz. semispinalis thoracis, multifidus, interspinales, spinalis cervicis and semispinalis cervicis.

The articular pillars of the third and fourth cervical vertebræ are grooved on their lateral aspects by the posterior primary rami of the third and fourth cervical nerves, which pass

FIG. 265.—A typical cervical vertebra. Left lateral aspect.



backwards across them.* The superior articular facets are flat and oval in outline; they are directed backwards and upwards. The inferior articular facets, similar in shape, are directed forwards and downwards. The foramen transversarium transmits the vertebral artery and veins and a plexus of sympathetic nerve fibres. The anterior root of the transverse process ends in a rough tubercle, which gives attachment to the scalenus anterior, the longus capitis and the oblique portions of the longus cervicis (longus colli) muscles. The anterior tubercle of the transverse process of the sixth cervical vertebra is enlarged and lies posterior to the common carotid artery, which can be compressed against it. It is therefore termed the *carotid tubercle*. The *costotransverse bar* is oblique in the third cervical vertebra, passing downwards, backwards and laterally; in the fourth also it is oblique, but it is slightly grooved by the emerging anterior primary ramus of the fourth cervical nerve. In the fifth the groove is deeper, and in the sixth it is conspicuously wide and

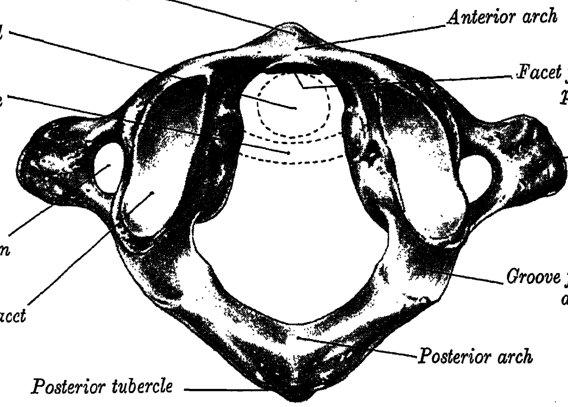
* F. Wood Jones, *Journal of Anatomy and Physiology*, vol. xlvi., 1911.

shallow. The posterior root of the transverse process terminates laterally in a rounded tubercle, which lies lateral to the anterior tubercle and at a lower level in all except the sixth, in which the two tubercles lie approximately on the same plane.

The posterior tubercles give attachment to a number of muscles, including levator scapulæ, scalenus medius (which extends forwards on to the costotransverse bar), scalenus posterior, splenius cervicis, longissimus cervicis and costocervicalis (iliocostalis cervicis).

The first cervical vertebra.—General features: **The first cervical vertebra** (fig. 266) is named the **Atlas,** because it supports the globe of the head. It differs from all the other vertebræ in having no body, and this is due to the fact that the centrum (p. 225) of the atlas has fused with the centrum of the second cervical vertebra. In addition, it has no spine. The atlas consists of two bulky *lateral masses,* connected to each other in front by a short *anterior arch,* and behind by a long, curved, *posterior arch.* It therefore forms a ring of bone. When the atlas and the second cervical vertebra are articulated together, an upward projection from the latter, which is termed the odontoid process and is the centrum of the atlas, comes into position behind the anterior arch, and the resemblance to a vertebra is restored (fig. 266).

FIG. 266.—The first cervical vertebra, or atlas. Superior aspect.



The *anterior arch* is slightly curved from side to side, with a forward convexity which is accentuated by the presence of a roughened, *anterior tubercle.* Its posterior surface is marked by a median, oval or circular facet, which articulates with the front of the odontoid process (dens). The *lateral mass* is set obliquely, and its long axis runs forwards and medially. Its upper surface forms an elongated, concave facet for articulation with the prominent condyle of the occipital bone of the skull. The inferior surface bears a nearly circular facet, flattened or gently concave, for articulation with the superior facets of the second cervical vertebra. The *posterior arch* forms about two-fifths of the ring. Its upper surface shows a wide groove immediately behind the lateral mass, and its spine is represented by a small, rough *posterior tubercle.* The *transverse process* is unusually long (fig. 270) and, as a result, the width of the atlas, measured from tip to tip of its transverse processes, greatly exceeds that of any other cervical vertebra, except the seventh. The length and strength of these transverse processes enables them to function as adequate levers for the rotatory movements of the head, which are effected by the rotation of the skull and the atlas around the pivot provided by the odontoid process of the second cervical vertebra.

Particular features.—The *anterior tubercle* gives attachment to the anterior longitudinal ligament in the median plane: its lateral aspect provides insertion for the upper oblique portion of the longus cervicis (longus colli) muscle. The upper and lower borders of the *anterior arch* give attachment respectively to the anterior atlanto-occipital membrane and the lateral fibres of the anterior longitudinal ligament (anterior atlanto-axial membrane). The superior articular facet of the *lateral mass* is directed upwards and medially and is admirably adapted to the nodding movements of the head, which occur at the atlanto-occipital joints. It is usually constricted near its middle and may be subdivided into two

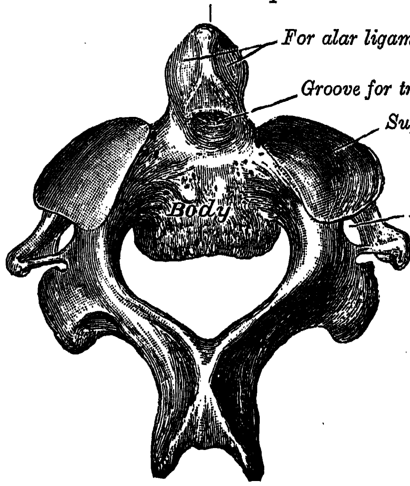
separate areas. Its margins give attachment to the articular capsule of the atlanto-occipital joint. The inferior articular facet is directed downwards, medially and slightly backwards; its margins give attachment to the articular capsule of the atlanto-axial joint. The medial aspect of the lateral mass presents a small roughened tubercle for the attachment of the transverse ligament of the atlas (fig. 512), which passes behind the odontoid process (dens) and helps to retain it in place. This ligament divides the ring of the atlas into an anterior, smaller part, which contains the odontoid process (fig. 266), and a posterior, larger part, which transmits the spinal cord and its membranes. The anterior aspect of the lateral mass gives origin to the rectus capitis anterior muscle.

The *posterior tubercle* gives attachment in the median plane to the ligamentum nuchæ, and, on each side, to the rectus capitis posterior minor. Its small size prevents it from interfering with the nodding movements of the head. The upper surface of the *posterior arch* is grooved anteriorly, where it is overhung on each side by the lateral mass. The groove transmits the vertebral artery, which winds backwards and medially round the posterior aspect of the lateral mass (fig. 514). Occasionally the groove for the vertebral artery is converted into a foramen by a bony spicule which arches backwards from the posterior part of the upper surface of the lateral mass. The first cervical nerve, as it emerges from the vertebral canal, intervenes between the vertebral artery and its groove (fig. 514). Behind the groove, on each side, the upper border of the posterior arch gives attachment to the posterior atlanto-occipital membrane; its lower border gives attachment to the highest pair of ligamenta flava.

The length of the *transverse process* and its functional significance have already been considered. Its down-turned extremity, which shows no differentiation into anterior and posterior tubercles, may be felt through the skin between the tip of the mastoid process and the angle of the mandible. Its recognition is not easy, for it lies deeply under cover of the parotid gland. Numerous muscles are attached to the process. The rectus capitis lateralis, anteriorly, and the superior oblique muscle of the head, posteriorly, arise from its upper surface: the levator scapulæ takes origin from its lateral margin and lower border, concealing the uppermost slip of insertion of the splenius cervicis and itself often hidden by the origin of the scalenus medius. A small, often imperceptible, tubercle may be present on the anterior surface of the lateral mass; it represents the anterior tubercle of the typical transverse process, so that the transverse process of the atlas corresponds to the posterior root and the costotransverse bar of the other cervical vertebræ. The anterior primary ramus of the first cervical nerve runs forwards on the lateral surface of the lateral mass and then turns downwards across the anterior surface of the transverse process. As it does so it is covered by the internal jugular vein, which is crossed in this situation by the accessory nerve and the occipital artery.

The **second cervical vertebra**.—General features: The second cervical vertebra, which is named the **Axis** (figs. 267, 268), provides the pivot upon which

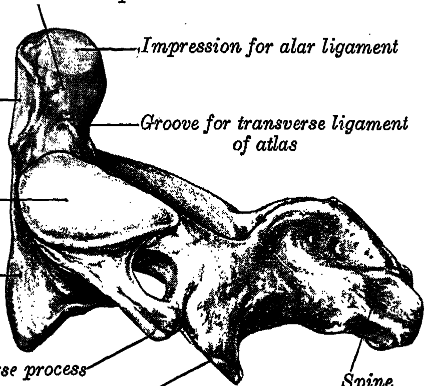
FIG. 267.—The second cervical vertebra, or axis. Posterosuperior aspect.



the atlas, and with it the skull, rotate. It can be distinguished easily from the other vertebræ by means of the strong, toothlike process, named the *odontoid process*

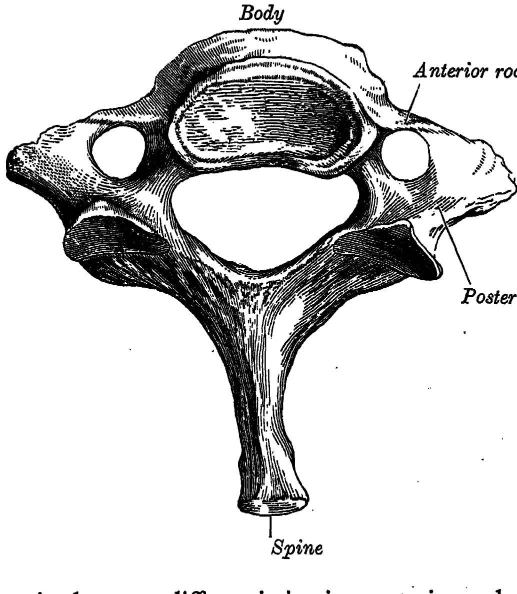
(dens), which projects upwards from the *body*. The process bears on its anterior surface a small oval facet for articulation with the facet on the posterior surface of the anterior arch of the atlas, and posteriorly it is grooved slightly by a ligament which helps to retain it in position (fig. 267). On each side a large, oval or circular facet is borne on the lateral part of the upper surface of the body and the

FIG. 268.—The second cervical vertebra, or axis. Left lateral aspect.



adjoining part of the pedicle for articulation with the inferior facet of the lateral mass of the atlas. The *laminæ* are thick and strong and the vertebral foramen is large and roomy. The *spine* is large and very strong, for it has to provide attachments not only for muscles which extend the neck but also for muscles which retract the head and rotate it from side to side. The *transverse process*, on the other hand, is very

FIG. 269.—The seventh cervical vertebra. Superior aspect.

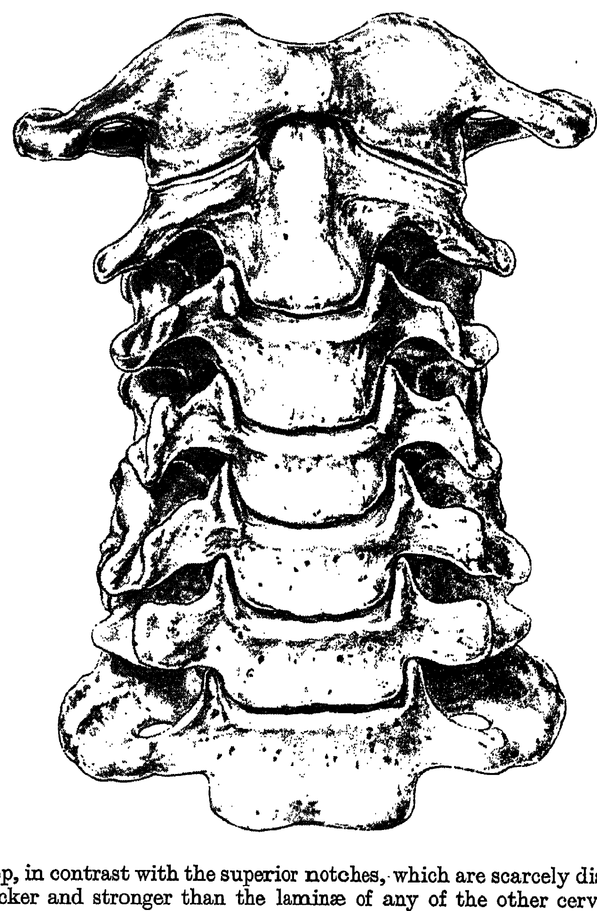


small and its blunt tip shows no differentiation into anterior and posterior tubercles. The foramen transversarium is directed upwards and laterally. The *inferior articular facets* look downwards and forwards, as they do in the typical cervical vertebræ.

Particular features.—The *odontoid process* is conical in shape and about 1·5 cm. long; it is constricted below, where it lies in contact posteriorly with the transverse ligament of

the atlas. A bursa is usually interposed between the bone and the ligament. The apex is pointed and gives attachment to the apical ligament (p. 444). Below the apex the sides of the process are flattened, where the alar ligaments are attached (fig. 267). In structure the odontoid process is composed of more compact bone than the body. The upper surface of the *body* is obscured by the odontoid process and the superior articular facets. Its anterior surface presents a hollowed out impression on each side of the median plane for the insertion of vertical fibres of the longus cervicis (longus colli) muscle. The lower border gives attachment to the anterior longitudinal ligament, and its downward projection is a characteristic feature of the axis. Posteriorly the lower border of the body gives attachment to the posterior longitudinal ligament and to the membrana tectoria, which represents its upward continuation to the occipital bone (p. 444). The *pedicles* are stout and the inferior vertebral

FIG. 270.—The cervical vertebræ. Anterior aspect.



notches are deep, in contrast with the superior notches, which are scarcely discernible. The *laminæ* are thicker and stronger than the laminæ of any of the other cervical vertebræ; they provide attachment for the ligamenta flava. The coarse, strong *spine* gives origin to the inferior oblique muscle, which arises from a rough impression on its lateral aspect, and also to the rectus capitis posterior major, which arises from its posterior border. The wide gap at its extremity gives attachment to the ligamentum nuchæ. In addition it receives the insertions of portions of the semispinalis cervicis, spinalis cervicis, interspinalis and multifidus. The *foramen transversarium* is directed upwards and laterally as, owing to the difference in length between the transverse process of the axis and that of the atlas, the vertebral artery must deviate in a lateral direction after leaving the axis. The *transverse process* is small, and its anterior tubercle is situated at or near the point where the anterior part of the process reaches the body; in this respect it resembles the anterior tubercle of the transverse process of the atlas. Its extremity gives origin to the levator scapulæ and, more anteriorly, to the scalenus medius; more posteriorly, it gives insertion to the splenius cervicis. Intertransverse muscles (p. 550) also gain attachment to its upper and lower surfaces.

The seventh cervical vertebra.—General features: The seventh cervical vertebra (fig. 269) is named the *vertebra prominens* because of its long spine, the tip of which can be felt through the skin at the lower end of the nuchal

furrow. This process is thick and nearly horizontal in direction; it is not bifurcated but ends in a tubercle. The *transverse processes* are of considerable size and their posterior parts are large and prominent. The anterior parts are usually slender, but they may form separate bones, which are then known as *cervical ribs*. The *foramen transversarium* is relatively small; it is sometimes double, or it may be entirely absent.

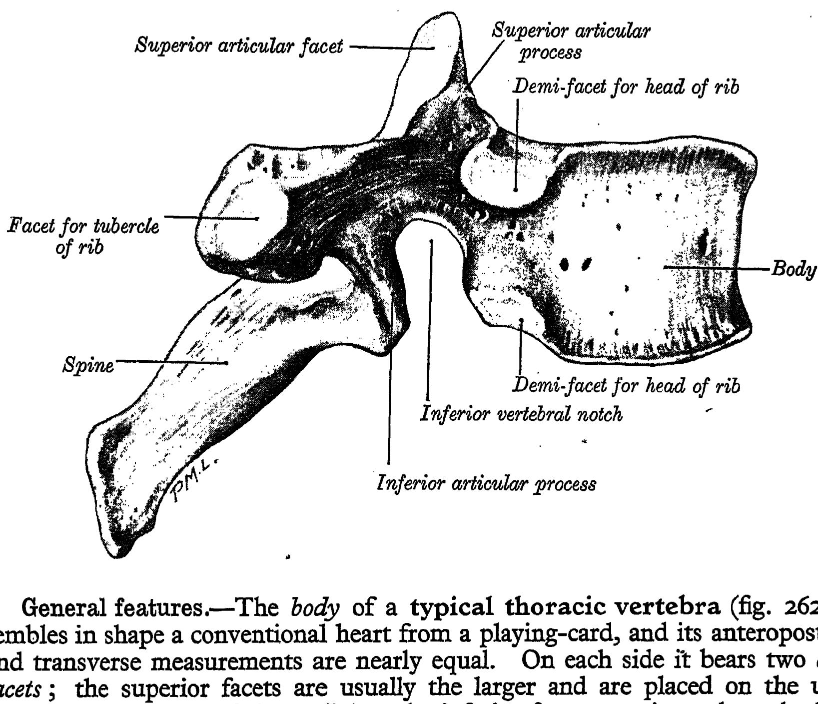
Particular features.—The tip of the spine gives attachment to the lower end of the ligamentum nuchæ, as well as to a number of muscles. These include the trapezius, rhomboideus minor, serratus posterior superior, splenius cervicis, semispinalis thoracis, spinalis cervicis, interspinales and multifidus. The *foramen transversarium* is traversed by an accessory vertebral vein or veins: it is traversed by the vertebral artery only on very rare occasions. The costotransverse bar of the *transverse process*, which shows a shallow groove for the anterior primary ramus of C. 7, is often partly deficient. The prominent posterior tubercle gives origin to the scalenus minimus, when it is present, and to the aponeurotic layer of fascia which covers the cervical dome of the pleura [suprapleural membrane]. Its lower border gives origin to the highest of the levatores costarum muscles.

THE THORACIC VERTEBRÆ [VERTEBRÆ THORACALES]

The **thoracic vertebræ** (figs. 262, 271, 272), twelve in number, show a gradual increase in size from above downwards. All are distinguished by the presence of facets on the sides of the bodies, and all but the last two (sometimes three) by facets on the transverse processes; the former articulate with the heads of the ribs and the latter with the tubercles of the ribs.

The first, ninth, tenth, eleventh and twelfth thoracic vertebræ present certain peculiarities and must be considered separately. The others, although showing individual differences of a minor degree, conform to a common type.

FIG. 271.—A typical thoracic vertebra. Viewed from the right side.



General features.—The *body* of a **typical thoracic vertebra** (fig. 262) resembles in shape a conventional heart from a playing-card, and its anteroposterior and transverse measurements are nearly equal. On each side it bears two *costal facets*; the superior facets are usually the larger and are placed on the upper border near the root of the pedicle; the inferior facets are situated on the lower border of the body just in front of the inferior vertebral notch. The *vertebral foramen* is relatively small, and its circular outline may be associated with the fact that the *pedicles* show no lateral deviation as they pass backwards from the body. This accounts also for the shortness of the *laminæ*, which are broad and thick and overlap each other from above. The *spine* is long and is directed downwards and

backwards. The *superior articular processes* are thin plates of bone which project upwards at the junction of the laminæ and pedicles; their articular facets are almost flat and are directed backwards and a little laterally and upwards. The *inferior articular processes* are fused to the lateral ends of the laminæ; their articular facets are directed forwards and slightly downwards and medially. The *transverse process* is a substantial, club-shaped projection which springs from the vertebral arch at the junction of the lamina and pedicle. It is directed laterally and backwards and bears on its anterior aspect, near its extremity, a facet for articulation with the tubercle of the numerically corresponding rib.

The **first thoracic vertebra** is distinguished by the character of the upper facets on the sides of the body, which are circular in outline, as each articulates with the whole of the head of the first rib. The lower facets are small and semilunar in shape. The spine is thick, long and horizontal; it can be identified easily in the living subject, for it forms a visible projection below the spine of the vertebra prominens.

The **ninth thoracic vertebra** may possess all the features of a typical thoracic vertebra, but it often fails to articulate with the head of the tenth rib, and the lower facets on the body are then absent (fig. 272).

The **tenth thoracic vertebra** articulates with the head of the tenth rib only. The facet is placed at the upper border of the body and encroaches on the pedicle; it is usually incomplete but, when the tenth rib fails to articulate with the ninth thoracic vertebra, it is complete and circular in outline. The transverse process may, or may not, bear an articular facet for the tubercle of the tenth rib.

The **eleventh thoracic vertebra** articulates with the head of the eleventh rib only. The circular facet is placed close to the upper border of the body and extends backwards on to the lateral aspect of the pedicle. The transverse process is small but can be gripped between the finger and thumb; it is not marked by an articular facet.

The **twelfth thoracic vertebra** articulates with the head of the twelfth rib only. The facet, roughly circular in outline, lies below the upper border of the body and extends over the lateral aspect of the pedicle. The body is large and approximates closely to the lumbar type. The transverse process is small and insignificant and is not marked by an articular facet; it presents superior, lateral and inferior tubercles. The inferior articular processes are turned laterally and the articular facets are convex from side to side, like those of a lumbar vertebra.

Particular features of the thoracic vertebræ.—The bodies of the upper thoracic vertebræ show a gradual transition from the cervical to the thoracic type, while the bodies of the lower thoracic vertebræ show a similar transition from the thoracic to the lumbar type. The body of T. 1 is cervical in form, and its transverse is nearly twice as great as its anteroposterior measurement. The body of T. 2 retains the cervical type, but its breadth is less and the disproportion between its two measurements is diminished. The body of T. 3 is actually the smallest of the thoracic bodies, but its anterior aspect, instead of being flattened like the bodies of T. 1 and T. 2, is rounded off and is convex forwards from side to side. From this point the bodies gradually increase in size and, owing to an increase in the anteroposterior measurement, that of T. 4 is typically heart-shaped. The bodies of T. 5 to T. 8 show a gradual increase in the anteroposterior measurement while the transverse measurement shows little alteration. These four vertebræ, when seen on transverse section, are asymmetrical, for the left side of each body shows a flattening produced by the pressure of the descending thoracic aorta. The remaining vertebræ increase in size more rapidly, the increase affecting all the measurements of the body, so that T. 12 approximates closely to the shape of a typical lumbar vertebra.

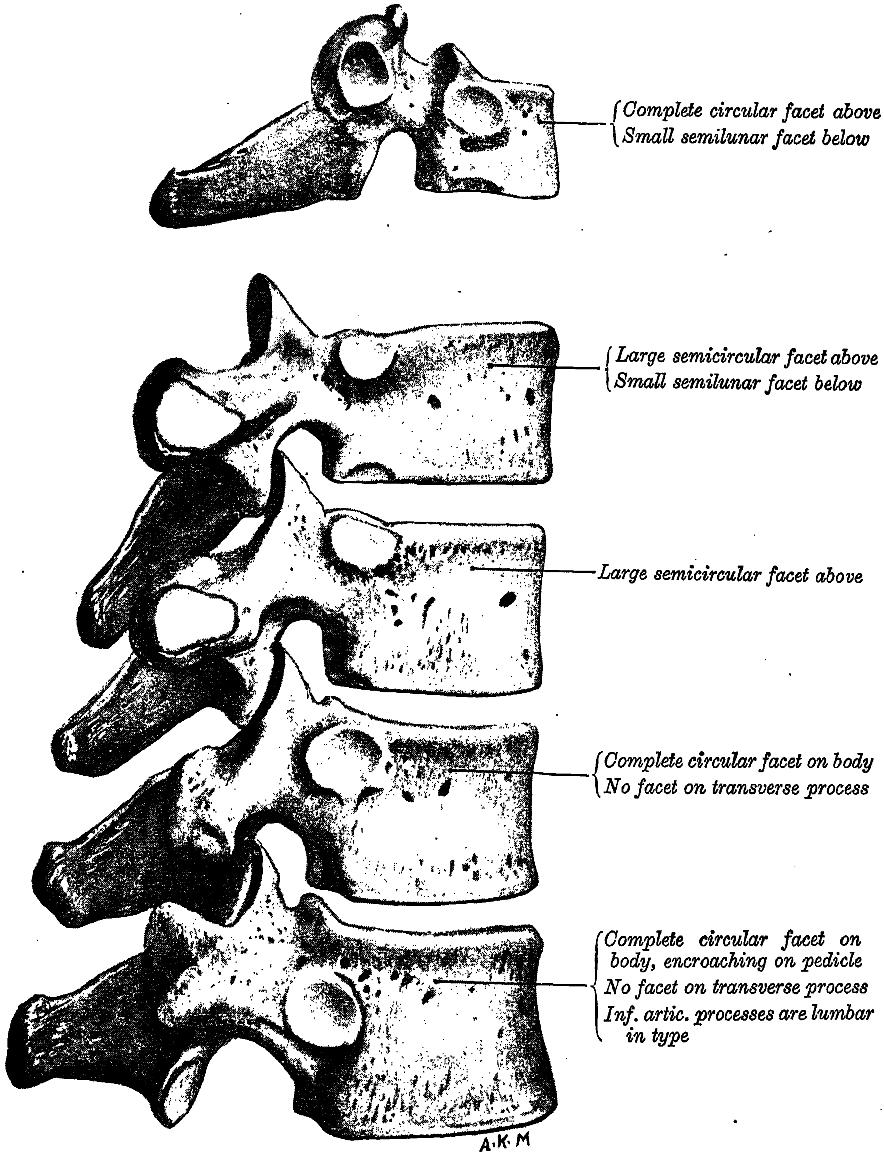
The upper and lower borders of the bodies in front and behind give attachment to the anterior and posterior longitudinal ligaments, respectively; and the margins of the costal facets give attachment to the capsular and radiate ligaments of the joints of the heads of the ribs. The longus cervicis (longus colli) muscle arises from the bodies of the first three thoracic vertebræ, lateral to the anterior longitudinal ligament. The psoas major and minor muscles arise from the lateral aspect of the twelfth thoracic vertebra near its lower border.

The *pedicles* increase in thickness from above downwards. The *superior vertebral notch* is scarcely recognisable except in the first thoracic vertebra, but the *inferior notch* is deep and conspicuous. The upper borders of the *laminæ* and the lower parts of their anterior surfaces serve for the attachment of the ligamenta flava; their dorsal aspects give insertion to the rotatores muscles.

The *transverse processes* gradually diminish in length from above downwards. In the upper six (sometimes five) the costal facets are concave and face forwards and laterally;

in the others the facets are flattened and face upwards, laterally, and slightly forwards. The tuberculated extremity of the process gives attachment to the lateral costotransverse ligament (ligament of the tubercle of the rib): its lower border, to the superior (anterior) costotransverse ligament: its anterior surface, medial to the facet, to the inferior costotransverse ligament (ligament of the neck of the rib): and its base to the posterior costotransverse ligament. In addition, the upper and lower borders of the transverse process

FIG. 272.—The first, ninth, tenth, eleventh and twelfth thoracic vertebræ. Right lateral aspect.



provide attachment for intertransverse muscles or their fibrous vestiges, and the posterior surface for the deep muscles of the back—the levator costæ arising from the dorsal aspect of the tuberculated extremity under cover of the longer muscles.

The *spines* overlap from the fifth to the eighth, which are the longest and most nearly vertical of the thoracic spines. Above and below they are less oblique in direction.* They

* In quadrupeds the majority of the spines of the thoracic vertebræ project dorsally and caudally, while those in the lumbar region are directed dorsally and headwards. The change in inclination is effected in one of the lower thoracic vertebræ, the spine of which points almost straight dorsally. This vertebra is known as the *anticlinal*, and in man its representative is the eleventh thoracic.

give attachment to the supraspinous and interspinous ligaments, and to the trapezius, rhomboideus major and minor, latissimus dorsi, the serratus posterior superior and inferior, and many of the deep muscles of the back.

The **first thoracic vertebra** resembles a cervical vertebra in the shape of its body. In addition, the posterolateral parts of its upper border are raised, as they are in the cervical region, and this projection forms the anterior border of the superior vertebral notch, *which is a distinctive feature of this vertebra.* The upper facet on the side of the body is not always complete, as the head of the first rib often articulates with the intervertebral disc between the seventh cervical and the first thoracic vertebræ. Immediately below the facet there is frequently a small, deep depression in the bone.

In the **eleventh** and **twelfth thoracic vertebræ** the spines are characteristically triangular, with blunted apices. In each case, the lower border of the spine is horizontal, or nearly so, and the upper border is oblique. In the region of the transverse process of the twelfth thoracic vertebra three little tubercles can be distinguished. Of these the *superior* is the largest and juts upwards. It corresponds to the mamillary process of a lumbar vertebra, but it is not so closely connected with the superior articular process. The *lateral tubercle* is small and corresponds to the true transverse process. The *inferior tubercle,* directed downwards, corresponds to the accessory process of a lumbar vertebra.

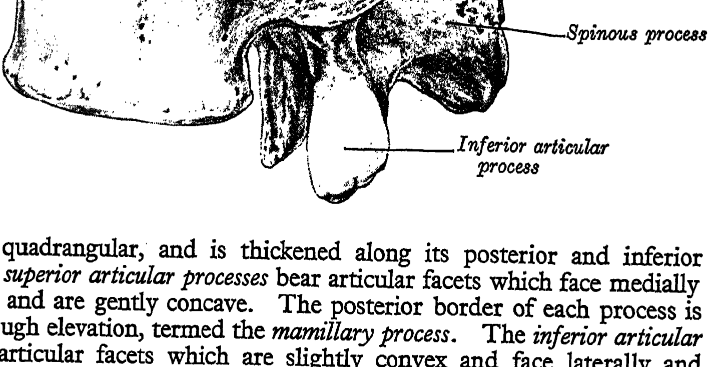
In distinguishing between these two vertebræ the student should be guided by (1) the character of the inferior articular processes; (2) the size and character of the transverse process; and (3) the distance between the costal facet and the upper border of the vertebra (p. 214).

THE LUMBAR VERTEBRÆ [VERTEBRÆ LUMBALES]

General features.—The **lumbar vertebræ** (figs. 273–275), five in number, can be distinguished from the other vertebræ by their great size and by the absence of costal facets on the sides of the bodies.

The *body* is large, wider from side to side than from before backwards, and a little deeper in front than behind. The *vertebral foramen* is triangular in shape, larger than in the thoracic region but smaller than in the cervical region. The shape is accounted for by the shortness of the pedicles and the direction of the laminæ, which pass backwards and medially. The *spine* projects almost horizontally

FIG. 273.—A lumbar vertebra. Left lateral aspect.



backwards, is quadrangular, and is thickened along its posterior and inferior borders. The *superior articular processes* bear articular facets which face medially and backwards and are gently concave. The posterior border of each process is marked by a rough elevation, termed the *mamillary process.* The *inferior articular processes* bear articular facets which are slightly convex and face laterally and forwards. The *transverse processes* are thin and elongated, with the exception of those of the fifth lumbar vertebra, which are strong and substantial. A small, rough elevation marks the postero-inferior aspect of the root of each transverse process and is termed the *accessory process.*

The **fifth lumbar vertebra** (fig. 275) can be distinguished by the fact that its strong *transverse process* is connected to the *whole of the lateral surface of the pedicle*

and encroaches on the side of the body. In addition, its body is usually deeper in front than behind, a condition which is associated with the prominence of the sacrovertebral angle.

FIG. 274.—A lumbar vertebra. Posterosuperior aspect.

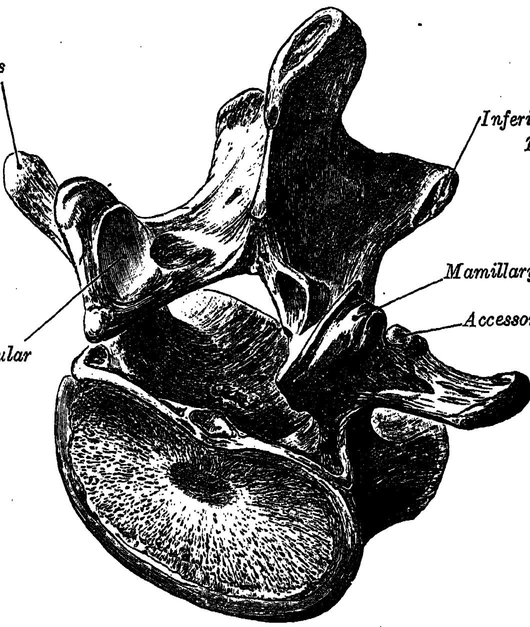


FIG. 275.—The fifth lumbar vertebra. Superior aspect.

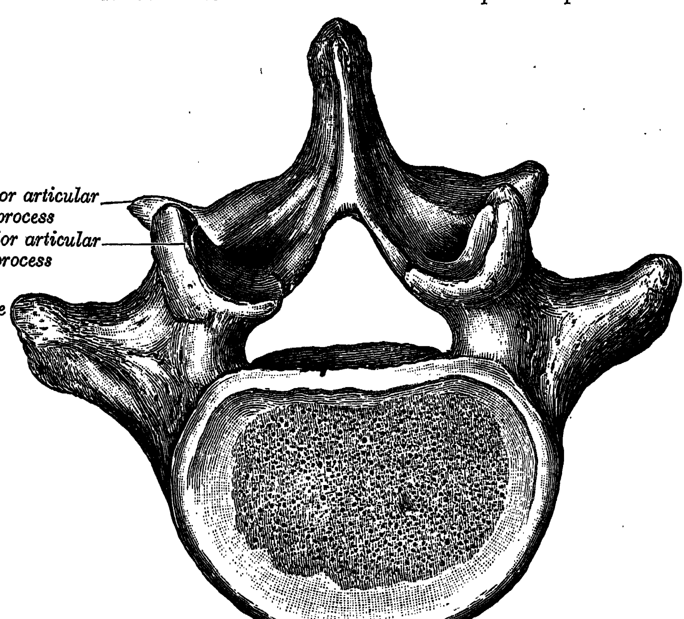


Particular features.—The upper and lower borders of the *bodies* in front and behind give attachment to the anterior and posterior longitudinal ligaments. Lateral to the anterior longitudinal ligament, the bodies of the upper lumbar vertebræ (three on the right side; two on the left) give origin to the crura of the diaphragm. Behind the line of the crus the psoas major arises from the bodies of all the lumbar vertebræ. This muscle throws tendinous arches across the sides of the bodies to protect the lumbar vessels. The *vertebral foramen* of the first lumbar vertebra contains the lower part of the spinal cord—the conus medullaris;

the lower foramina contain the cauda equina and the spinal meninges. The *pedicle* is strong, and springs from the posterolateral aspect of the body just below its upper border. The *superior vertebral notch,* though shallow, is easily recognisable : the *inferior notch* is of considerable depth. The *laminæ* are broad, short and strong, but they do not overlap one another to the same extent as they do in the thoracic region. They give attachment to the ligamenta flava. The *spines* provide attachment for the posterior lamella of the lumbar fascia, the sacrospinalis, the spinalis thoracis, the multifidus, the interspinal muscles and ligaments and the supraspinous ligaments. The spine of the fifth lumbar vertebra is the least substantial and its extremity is more or less rounded and down-turned. The *superior articular processes* are wider apart than the *inferior* in the upper lumbar region, but the difference is very slight in the fourth, and in the fifth the two measurements are approximately equal. The articular facets are so shaped that, while they permit of flexion and extension, they prevent rotation of the lumbar vertebræ. The *transverse processes,* with the exception of the fifth, are not so strongly built as the other parts of the lumbar vertebræ. They increase in length from the first to the third—which is the longest of all the transverse processes—and then become shorter. A faint, vertical ridge marks the anterior surface of the transverse process nearer the tip than the root. It gives attachment to the anterior layer of the lumbar fascia and separates the surface into a medial area for the attachment of the psoas major, and a lateral area for the quadratus lumborum. The tip of the process gives attachment to the middle layer of the lumbar fascia, but, in addition, the tip of the first gives attachment to the medial and lateral arcuate ligaments (lumbocostal arches) and the tip of the fifth to the iliolumbar ligament. The posterior surfaces of the transverse processes are covered by the deep muscles of the back and give origin to fibres of the longissimus thoracis (longissimus dorsi) muscle. The upper and lower borders of the process give attachment to lateral intertransverse muscles. The *mamillary process* is homologous with the superior tubercle in the twelfth thoracic vertebra. It gives attachment to the multifidus and to the medial intertransverse muscle. The *accessory process* * varies in prominence and may be difficult to identify. It gives attachment to the medial intertransverse muscle. The *costal element* is incorporated in the transverse process (fig. 113).

THE SACRUM [OS SACRUM]

General features.—The **sacrum** (figs. 276–280) is a large bone, triangular in shape, formed by the fusion of the five sacral vertebræ. It is situated at the upper and posterior part of the pelvic cavity, where it is inserted like a wedge between the two hip-bones. Its narrow, blunted *apex* is at the inferior end of the bone and articulates with the coccyx. At the opposite end the wide *base* articulates with the fifth lumbar vertebra, with which it forms the *sacrovertebral angle.* The bone is placed very obliquely and is curved longitudinally so that its dorsal surface is convex and its ventral surface is concave (fig. 278). This ventral concavity serves to increase the capacity of the true pelvis. In addition to a base and an apex the sacrum possesses *dorsal, pelvic,* and *lateral surfaces* and encloses a bony *canal.*

In the child the individual sacral vertebræ are connected by cartilage and can be separated by maceration. The adult bone shows many signs of its vertebral constitution, especially on its basal aspect.

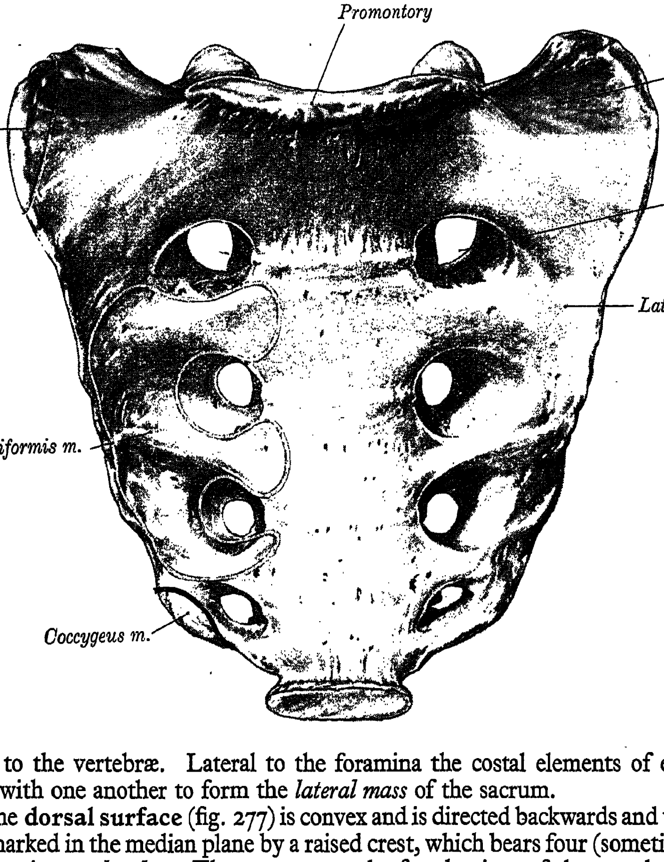
The **base** (fig. 279) is formed by the upper surface of the *first sacral vertebra* and presents all the features of a typical vertebra in a slightly modified form. The *body* is large and much wider from side to side than from before backwards. Its anterior projecting edge is named the *sacral promontory.* The vertebral foramen is triangular, and its shape is explained by the fact that the *pedicles* are short, widely separated, and face backwards and laterally. The *laminæ* are very oblique and incline downwards, medially and backwards. Where they meet, the *spine* is represented by a spinous tubercle. The *superior articular processes* project upwards and bear concave articular facets which face medially and backwards to articulate with the inferior articular processes of the fifth lumbar vertebræ. The posterior part of each process projects backwards, and its lateral aspect bears a roughened area which corresponds to the mamillary process of a lumbar vertebra. The region of the *transverse process* shows important modifications. A broad, sloping mass of bone projects from the lateral side of the body, pedicle and superior articular process;

* The mamillary and accessory processes " are merely muscular processes which, represented and conjoined in the thoracic region, become separated in the lumbar region by the passage of the internal (medial) branch of the posterior division (posterior primary ramus) of the lower thoracic and lumbar nerves between them." (F. Wood Jones, *Journal of Anatomy and Physiology,* vol. xlvii., p. 118.)

a feature which is not found in any of the other vertebræ, although it is foreshadowed in the fifth lumbar vertebra. It is formed by the transverse process and the costal element fused to each other and to the rest of the vertebra, and forms the upper surface of the *lateral mass* of the sacrum.

The **pelvic surface** of the sacrum is concave and is directed downwards and forwards. It is marked by four pairs of *anterior sacral foramina*, which communicate through the intervertebral foramina with the sacral canal. They transmit the anterior primary rami of the sacral nerves. The large area which lies between the foramina of the right and left sides is formed by the flattened anterior surfaces of the bodies of the sacral vertebræ, and the lines of fusion of contiguous vertebræ are clearly visible as four raised *transverse ridges*. The bars of bone which separate the foramina from one another on each side represent the *costal elements*, which are

FIG. 276.—The sacrum. Pelvic surface.



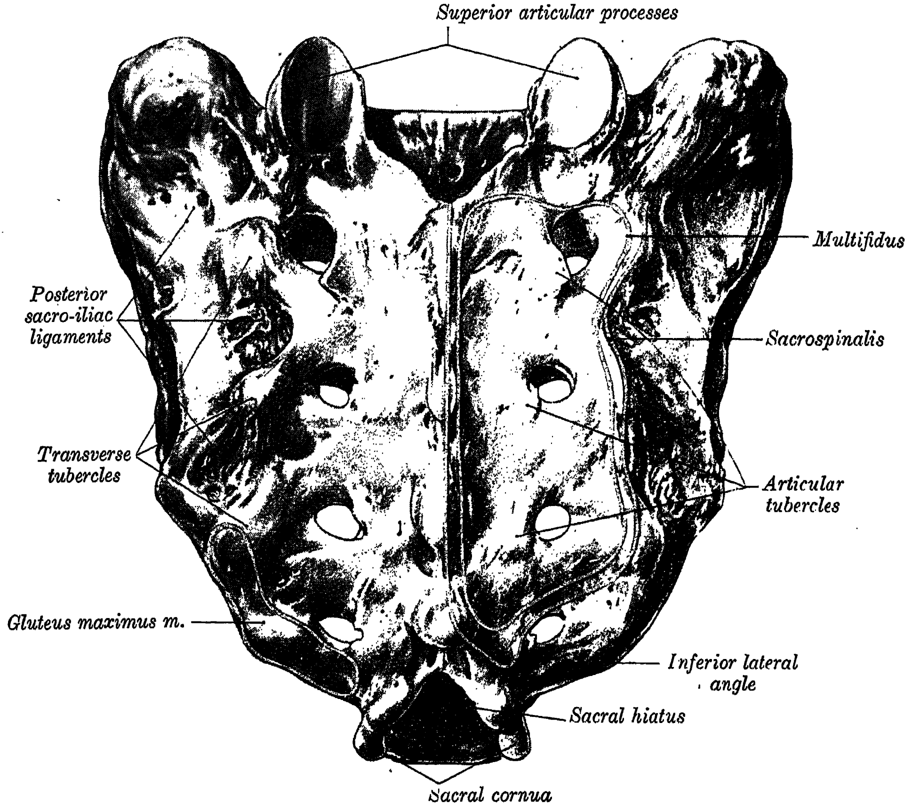
fused to the vertebræ. Lateral to the foramina the costal elements of each side unite with one another to form the *lateral mass* of the sacrum.

The **dorsal surface** (fig. 277) is convex and is directed backwards and upwards. It is marked in the median plane by a raised crest, which bears four (sometimes only three) *spinous tubercles*. These represent the fused spines of the sacral vertebræ. Below the fourth spinous tubercle there is a ∩-shaped gap in the posterior wall of the sacral canal, termed the *sacral hiatus*. This gap is produced by the failure of the laminæ of the fifth sacral vertebræ to meet in the median plane, and, as a result, the posterior aspect of the body of that vertebra is exposed on the dorsal surface of the sacrum. Lateral to the median crest, the posterior surface is formed by the fused *laminæ*. Lateral to this area the dorsal surface of the sacrum presents on each side four *posterior sacral foramina*. Like the anterior foramina they communicate with the sacral canal through the intervertebral foramina; and each transmits the posterior primary ramus of a sacral nerve. Medial to the foramina, and in line with the superior articular process of the first sacral vertebra, the bone is marked on each side by a row of four small tubercles, which represent contiguous articular processes fused together. The inferior articular processes of the fifth sacral vertebra are free and project downwards at the sides of the sacral hiatus. They are termed the *sacral cornua* and are connected to the cornua of the coccyx by ligaments, termed

the intercornual ligaments. The roughened area to the lateral side of the posterior sacral foramina is formed by the fused transverse processes and presents a row of *transverse tubercles*.

The **lateral surface** (fig. 278) of the sacrum is formed by the fused transverse processes and costal elements. It is wide above but rapidly diminishes in breadth in its lower part. The broad, upper part bears an ear-shaped surface, termed the *auricular surface*, for articulation with the ilium, and the area behind it is rough and deeply pitted for the attachment of ligaments. In order to ensure the stability of the body in the erect posture, the sacro-iliac joint, through which one half of the weight of the trunk is transmitted to the lower limb, must provide a good bearing surface. This is obtained by the fusion of the sacral vertebræ and by the persistence of substantial portions of the costal elements. The auricular surface is borne by the costal elements and is shaped like the inverted letter L. The horizontal limb

FIG. 277.—The sacrum. Dorsal surface.



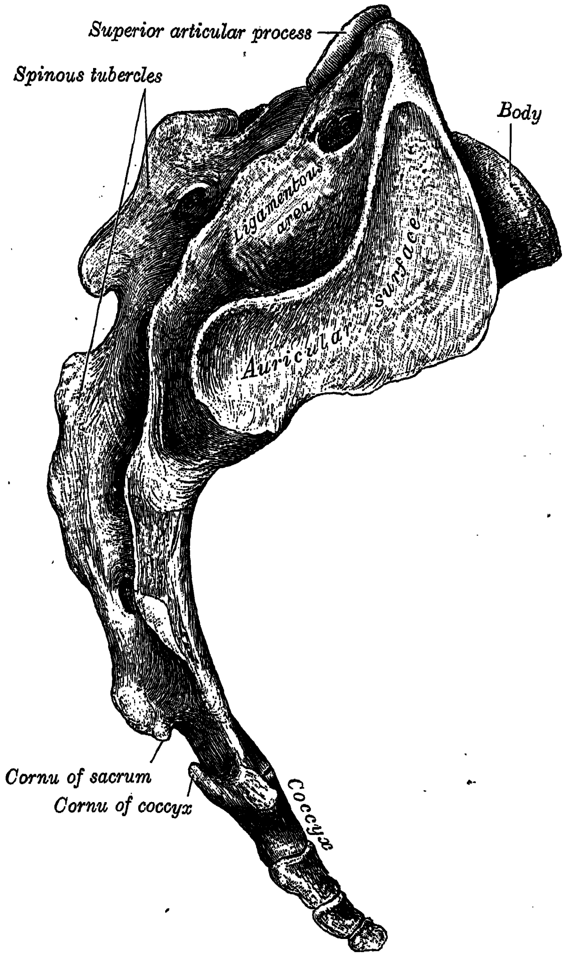
is the shorter and is restricted to the first sacral vertebra: the vertical limb extends downwards to the lower limit of the second or to the middle of the third sacral vertebra. The lower part of the lateral surface takes no part in the transmission of the weight of the body and is consequently reduced in breadth. At its lower end it bends or curves medially to reach the side of the body of the fifth sacral vertebra. The point at which the change of direction occurs is termed the *inferior lateral angle*. Below the angle the lateral surface forms a thin border.

The **apex** of the sacrum is formed by the inferior surface of the body of the fifth sacral vertebra and bears an oval facet for articulation with the coccyx.

The **sacral canal** (fig. 280) is formed by the vertebral foramina of the sacral vertebræ and is triangular on transverse section. Its upper opening, seen on the basal surface, appears to be set obliquely but, owing to the inclination of the sacrum, it is directed upwards in the living subject. The lateral wall of the canal presents four intervertebral foramina, through which the canal is connected with both the anterior and the posterior sacral foramina. The lower opening is the *sacral hiatus*.

Particular features.—The anterior and posterior parts of the *body of the first sacral vertebra* give attachment to the lowest fibres of the anterior and posterior longitudinal ligaments respectively. The upper borders of the *laminæ* of the first sacral vertebra give attachment to the lowest pair of ligamenta flava. The *upper surface of the lateral mass* is smooth and slightly concave in its medial part but is irregularly roughened in its lateral part. It is covered almost entirely by the psoas major muscle. The smooth area is marked by an oblique, shallow groove which lodges the lumbosacral trunk. The rough area gives attachment to the lumbosacral ligament, which lies on the lateral side of the fifth lumbar nerve, and to the anterior ligament of the sacroiliac joint. The anterolateral part of the area gives origin to a portion of the iliacus muscle.

Fig. 278.—The sacrum and coccyx. Right lateral aspect.



The *pelvic surface* of the sacrum gives origin on each side to the piriformis muscle. This muscle arises from the anterior surface of the lateral mass opposite the second, third and fourth sacral vertebræ and from the anterior surfaces of the bars of bone which separate the anterior foramina. On emerging from the anterior sacral foramina the anterior primary rami of the first three sacral nerves pass at once on to the anterior surface of the muscle. Along the medial margins of the foramina, on each side, the sympathetic trunk descends in contact with the bone, and in the median plane the median sacral vessels form an intimate relation. Lateral to the foramina the lateral sacral vessels bear a variable relation to the bone. The anterior surfaces of the bodies of the first and second and part of the third sacral vertebra are covered with parietal peritoneum and crossed obliquely, to the left of the median plane, by the root of the pelvic mesocolon. The rectum lies in contact with the anterior surfaces of the bodies of the third, fourth and fifth sacral vertebræ, but the bifurcation of the superior rectal artery into right and left branches intervenes between it and the third sacral vertebra.

The *dorsal surface* of the sacrum is rough and irregular. The sacrospinalis arises by an elongated U-shaped origin from the spinous and transverse tubercles, and covers the multi-

fidus, which arises from the intervening area. The posterior primary rami of the upper three sacral nerves pierce these muscles after they emerge from the posterior sacral foramina. It not infrequently happens that the laminæ of the fourth sacral vertebra fail to meet in the median plane behind. The sacral hiatus is then elongated considerably.

Fig. 279.—The base of the sacrum.

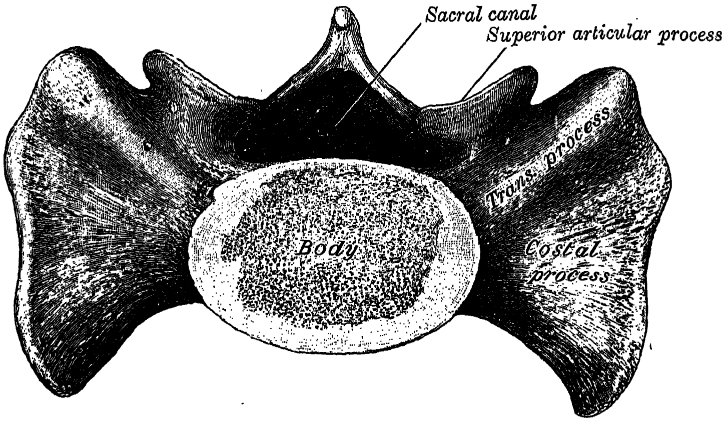


Fig. 280.—A median sagittal section through the sacrum.

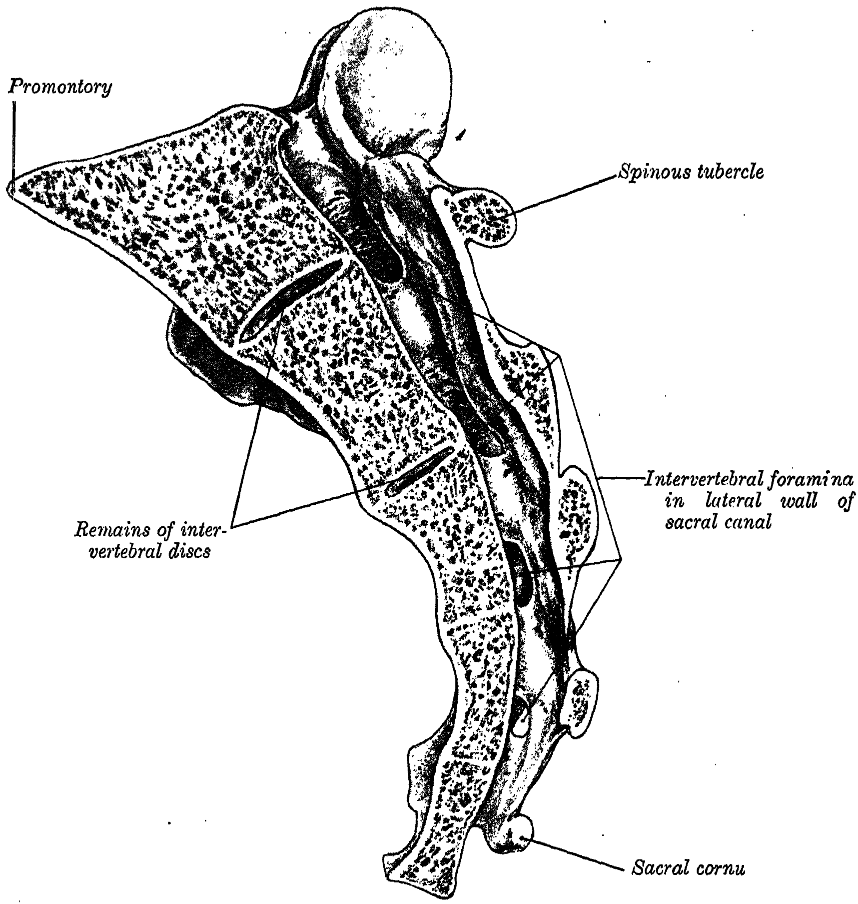

The *auricular surface* is covered with hyaline cartilage in the recent state and is formed entirely by the costal elements. The rough area behind it shows two well-marked depressions and gives attachment to the strong interosseous sacro-iliac ligaments. Below the auricular surface the lateral aspect of the sacrum gives attachment to the gluteus maximus,

the sacrotuberous and sacrospinous ligaments and the coccygeus muscle, the structures being enumerated from behind forwards.

The *sacral canal* contains the cauda equina (including the filum terminale) and the spinal meninges. Opposite the middle of the sacrum the subarachnoid and subdural spaces become closed, and the lower sacral nerve roots and the filum terminale pierce the arachnoid and dura mater at that level. The filum terminale emerges below at the sacral hiatus and passes downwards across the posterior surface of the fifth sacral vertebra and the sacrococcygeal joint to reach the coccyx. The fifth sacral nerve also emerges through the sacral hiatus close to the medial side of the sacral cornu and grooves the lateral part of the body of the fifth sacral vertebra.

Differences in the sacrum of the male and female.—In the female the sacrum is shorter and wider than in the male, reflecting the necessity for a wider and a shallower pelvic cavity. The upper part of the bone is flattened, and the lower part curved abruptly forwards, whereas in the male the curvature is more evenly distributed over the whole length of the bone. It should be remembered, however, that the curvature of the bone may vary considerably in different specimens of the same sex. In the female the pelvic surface of the bone faces downwards more than in the male; this increases the size of the pelvic cavity and renders the sacrovertebral angle more prominent. In the female the auricular surface for articulation with the ilium is shorter than that in the male, extending along the sides of the first and second sacral vertebræ only; in the male it is continued down to the middle or lower limit of the third vertebra. No difficulty will be experienced in distinguishing a typical male or a typical female sacrum, but, as the sexual characters are not always pronounced, there are many cases in which it is by no means easy to determine the sex. When any difficulty is experienced in determining the sex of a sacrum, greatest stress should always be laid on the relationship between the length and the breadth of the bone.

Structure.—The sacrum consists of spongy substance enveloped by a thin layer of compact bone.

Variations—Either the fifth lumbar vertebra or, more commonly, the first coccygeal vertebra may become incorporated in the sacrum, which then has six vertebræ. The inclusion of the fifth lumbar vertebra is usually incomplete and it may be limited to one or other side. In the most minor degree of the abnormality the transverse process of the fifth lumbar vertebra is unusually large, and articulates with the sacrum at the posterolateral part of the upper surface of its lateral mass. Reduction of the number of the constituents of the sacrum is less common. The transverse process of the first sacral segment may not be joined to the rest of the lateral mass on one or both sides, and a considerable part of the posterior wall of the sacral canal may be wanting, in consequence of the imperfect development of the laminæ and spines.

THE COCCYX [OS COCCYGIS]

General features.—The **coccyx** (figs. 281, 282) is a small bone, triangular in shape, which consists usually of four rudimentary vertebræ fused together, but the number may be increased to five or reduced to three. Not infrequently, the first coccygeal vertebra exists as a separate piece. The bone is directed downwards and forwards from the apex of the sacrum, so that its pelvic surface faces upwards and forwards and its dorsal surface downwards and backwards.

The *base* of the coccyx, formed by the upper surface of the body of the *first coccygeal vertebra*, presents an oval, articular facet for articulation with the apex of the sacrum. Posterolateral to the facet, two processes, named the *coccygeal cornua*, project upwards to articulate with the sacral cornua; they are the homologues of the pedicles and superior articular processes of the movable vertebræ. A rudimentary *transverse process* projects laterally and slightly upwards from each side of the body of the first coccygeal vertebra and may ascend to articulate or fuse with the inferior lateral angle of the sacrum. In that event five pairs of foramina are found in the sacrum.

The *second, third* and *fourth coccygeal vertebræ* diminish successively in size and are usually fused with one another. They are mere nodules of bone, which represent the rudimentary bodies of the vertebræ, although the second may show traces of transverse processes and pedicles.

Particular features.—The lateral parts of the *anterior surface*, including the rudimentary transverse process, give insertion to the levatores ani and the coccygei. The anterior sacrococcygeal ligament is attached to the front of the body of the first, and may extend downwards to reach the second, coccygeal vertebra (fig. 540). The *cornua* give attachment to the intercornual ligaments. The interval between the body of the fifth sacral vertebra and the articulating sacral and coccygeal cornua on each side represents the intervertebral foramen between the fifth sacral and the first coccygeal vertebra, and transmits the fifth sacral nerve. The posterior primary ramus of that nerve descends behind the rudimentary *transverse process*, but its anterior primary ramus passes forwards through a foramen placed between the transverse process and the sacrum and bounded laterally by the lateral sacrococcygeal ligament, which connects the process to the inferior lateral angle of the sacrum. The *posterior aspect* of the coccyx gives origin, on each side, to the gluteus maximus muscle and, at its tip, to the sphincter ani externus. The median area gives attachment to the deep and superficial posterior sacrococcygeal ligaments. The latter extends downwards from the margins of the sacral hiatus and may close the lower end of the sacral canal. The filum terminale, which is situated between the two ligaments, blends with them on the posterior surface of the first coccygeal vertebra.

FIG. 281.—The coccyx. Anterior aspect.

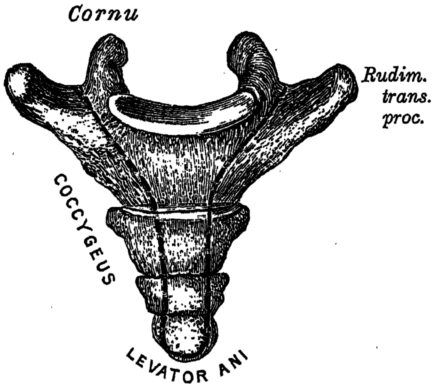

FIG. 282.—The coccyx. Posterior aspect.

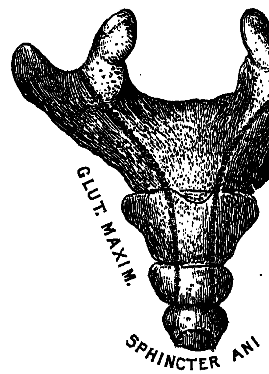

The ossification of the vertebral column.—Each typical vertebra is ossified from three primary centres (fig. 283), two for the vertebral arch, and one for the body.* Ossification of the vertebral arches begins in the upper cervical vertebræ about the seventh or eighth week of intrauterine life, and gradually extends down the column. The centres first appear in the situations where the transverse processes afterwards project, and spread backwards to the laminæ, forwards into the pedicles and laterally into the transverse processes. Ossification of the bodies begins in the lower thoracic vertebræ about the eighth week of intrauterine life, and subsequently extends upwards and downwards along the column. The centre for the body constitutes the *centrum*, which does not correspond to the whole of the body of the adult vertebra, for the posterolateral portions of the body are ossified from the centres for the vertebral arch. During the first few years of life the centrum is connected to each half of the vertebral arch by a primary cartilaginous joint, termed the *neurocentral joint*. In the thoracic region the costal facets on the bodies lie behind the neurocentral joints. At birth a vertebra consists of three pieces, viz., the centrum and the halves of the vertebral arch. During the first year the halves of the arch unite behind, union taking place first in the lumbar region and then extending upwards through the thoracic and cervical regions. In the upper cervical vertebræ the centra unite with the arches about the third year, but in the lower lumbar vertebræ union is not completed until the sixth year. Until puberty the upper and under surfaces of the bodies and the ends of the transverse processes and spines are cartilaginous, but about the sixteenth year five secondary centres appear, one for the tip of each transverse process, one for the end of the spine, and two annular epiphyseal discs for the circumferential parts of the upper and lower surfaces of the body (figs. 284, 285). The costal articular facets arise as extensions of the annular epiphyseal discs (Dixon).† These secondary centres fuse with the rest of the bone about the age of twenty-five years. In the bifid spines of the cervical vertebræ there are two secondary centres.

Exceptions to this mode of ossification occur in the first, second, and seventh cervical vertebræ, and in the lumbar vertebræ.

* The body is occasionally ossified from two lateral centres which sometimes fail to unite. The suppression of one of these centres leads to the formation of a wedge-shaped vertebra, and is a well-recognised cause of lateral curvature of the vertebral column. The condition is frequently multiple.

† A. Francis Dixon, *Journal of Anatomy*, vol. lv., October 1920.

The **atlas**, or first cervical vertebra, is usually ossified from three centres (fig. 286). One appears in each lateral mass about the seventh week of intrauterine life, and gradually extends into the posterior arch, where the two unite between the third and fourth years, either directly or through the medium of a separate centre. At birth, the anterior arch consists of fibrocartilage; in this a separate centre appears about the end of the first year, and unites with the lateral masses between the sixth and eighth years—the lines of union extending across the anterior portions of the superior articular facets. Occasionally the anterior arch is formed by the forward extension and ultimate union of the centres for the lateral masses; sometimes it is ossified from two laterally placed centres.

The **axis**, or second cervical vertebra, is ossified from five primary and two secondary centres (fig. 287). The vertebral arch is ossified from two primary centres, and the centrum from one, as in a typical vertebra; the centres for the arch appear about the seventh or eighth week of intrauterine life, the centre for the centrum about the fourth or fifth month. The odontoid process (dens) represents the centrum of the atlas, and is ossified almost entirely from two laterally-placed centres; these appear about the sixth month of intrauterine life, and join before birth to form a conical mass, deeply cleft above. A wedge-shaped piece of cartilage fills the cleft and forms the summit of the process: in this cartilage a centre appears about the second year and unites with the main mass of the process about the twelfth year. It is regarded as representing the proatlas.* The base of the process is separated from the body of the axis by a cartilaginous disc, the circumference of which ossifies, but the centre remains cartilaginous until advanced age; in this cartilaginous disc rudiments of the lower epiphyseal lamella of the atlas and the upper epiphyseal lamella of the axis may sometimes be found. In addition to these centres there is one for a thin epiphyseal plate on the under surface of the body of the bone; it appears about the time of puberty.

The seventh cervical vertebra.—The costal processes of this vertebra are usually ossified from separate centres, which appear about the sixth month of intrauterine life, and join the body and transverse processes between the fifth and sixth years. As already stated (p. 213), the costal processes may persist as separate pieces, and grow laterally and forwards, to constitute cervical ribs.

Separate ossific centres have also been found in the costal processes of the fourth, fifth, and sixth cervical vertebræ.

The **lumbar vertebræ** (fig. 288) have each two additional centres, one for each mamillary process.

The **sacrum** (figs. 289 to 292).—Each sacral vertebra is ossified from three primary centres, one for the body and two for the vertebral arch. Two epiphyseal plates are ossified for each body, one for the upper and the other for the lower surface.

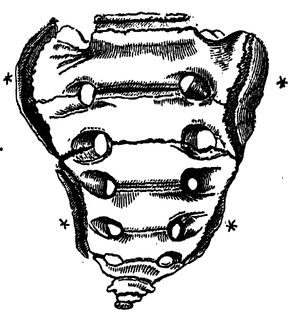

FIG. 292.—The base of the sacrum of a child.

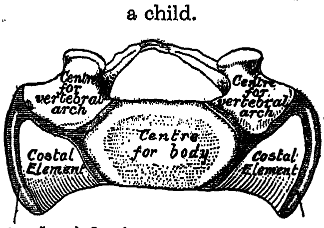

Lateral epiphysis *Lateral epiphysis*

The anterior portions of the lateral masses of the sacrum have six additional (costal) centres, two for each of the first three vertebræ; these appear above and lateral to the anterior sacral foramina (figs. 289, 292).

Two epiphyseal plates are developed on each lateral surface of the sacrum (figs. 291, 292); one for the auricular surface, and another for the thin edge of bone below this surface.

The ends of the spines of the upper three sacral vertebræ are sometimes developed from separate epiphyses, and Fawcett * has pointed out that a number of epiphyses are present in the sacrum at the eighteenth year (fig. 293). These are distributed as follows: One for each of the two mamillary processes of the first sacral vertebra; six on each side, in connexion with the costal processes (two each—an anterior and a posterior—for the first and second, and one each—an anterior—for the third and fourth vertebræ); and eight, four on each side, for the transverse processes, one each for the first, third, fourth and fifth. He is also of opinion (1) that the auricular facets on the lateral surfaces of the sacrum are in the main formed by the development and fusion of the costal epiphyses of the first and second sacral vertebræ, and (2) that the lower part of each lateral surface is formed by the extension and union of the costal epiphyses of the third and fourth, with the epiphyses of the transverse processes of the fourth and fifth sacral vertebræ.

The periods of ossification of the sacrum.—The centres for the bodies of the first, second and third sacral vertebræ appear towards the end of the third month, and those for the bodies of the fourth and fifth vertebræ between the fifth and eighth months of intrauterine life. The centres for the vertebral arches appear about the fifth month, and those for the costal processes of the lateral parts of the bone between the sixth and eighth months of intrauterine life. The first step in the consolidation of the sacrum is the union of these separate parts of the individual vertebræ. The costal element unites with the vertebral arch, before the latter joins the centrum, and this process precedes the union of the laminæ with one another. The fusion of the vertebral arches with the centra is completed at or soon after the eighth year, and traces of the neurocentral joints of the first sacral vertebra can be found after union is complete in the other vertebræ. About the same time or a little later the laminæ fuse with one another, and this process usually begins above and extends in a downward direction, but it is not uncommon to find the laminæ of the fourth sacral vertebræ fused with one another before the process is completed in the first.

The parts of the individual vertebræ are united before puberty. At that time epiphyseal centres develop (1) for the upper and lower surfaces of the bodies, (2) for the spines,

* E. Fawcett, *Anatomischer Anzeiger*, Bd. xxx., 1907.

and (3) for the extremities of the costal and transverse process elements. At the same time the articular processes and the conjoined costal and transverse process elements begin to fuse with one another, from below upwards, but fusion of the individual vertebræ cannot be completed until the upper and lower epiphyses have united with the bodies, a process which is rarely completed before the twenty-first year. Traces of the intervertebral disc between the first and second sacral vertebræ can be found up to, and often after, middle life.

The **coccyx**.—Each segment of the coccyx is ossified from one primary centre. These appear as follows: in the first segment between the first and fourth years; in the second between the fifth and tenth years; in the third between the tenth and fifteenth years; in the fourth between the fourteenth and twentieth years. A secondary centre appears for each coccygeal cornu, and a pair of epiphyseal plates for each of the rudimentary bodies have been described. As age advances, the segments unite with one another, the union between the first and second being frequently delayed until the age of thirty years. At a late period of life, especially in females, the coccyx often fuses with the sacrum.

THE VERTEBRAL COLUMN AS A WHOLE

The **vertebral column** is situated in the median plane, at the posterior part of the trunk. Its average length in the male is about 70 cm.; of this the cervical part measures about 12 cm., the thoracic 28 cm., the lumbar 18 cm., and the sacrum and coccyx about 12 cm. The average length of the female vertebral column is about 60 cm.

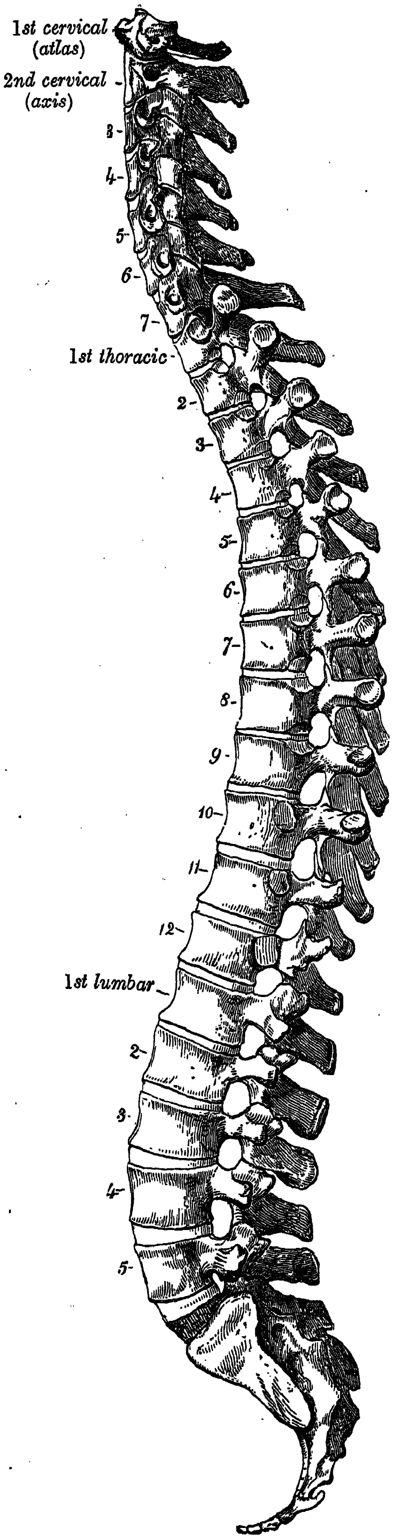
The curves of the vertebral column.—Viewed from the side (fig. 294), the vertebral column presents cervical, thoracic, lumbar, and pelvic curves. The thoracic and pelvic curves are termed primary curves, as they are concave ventrally during fœtal life and retain the same type of curvature after birth. The cervical and lumbar curves are secondary or compensatory; the cervical curve appears late in intra-uterine life and is accentuated when the child is able to hold up its head (at three or four months), and to sit upright (about nine months); the lumbar curve appears at twelve to eighteen months, when the child begins to walk. The *cervical* curve is convex forwards, and is the least marked of the four; it begins at the atlas, and ends at the middle of the second thoracic vertebra. The *thoracic* curve is concave forwards, and reaches from the middle of the second to the middle of the twelfth thoracic vertebra; it is caused by the greater depth of the posterior parts of the vertebral bodies. The *lumbar* curve is convex forwards and is more pronounced in the female than in the male; it reaches from the middle of the last thoracic vertebra to the lumbosacral angle, and the convexity of the lower three segments is greater than that of the upper two; it is caused mainly by the greater depth of the anterior parts of the intervertebral discs, but the shape of the vertebral bodies also helps to produce it. The *pelvic* curve extends from the lumbosacral joint to the apex of the coccyx; its concavity faces downwards and forwards.

In the upper part of the thoracic region of the vertebral column there is sometimes a slight *lateral* curvature, with its convexity directed towards the right side in right-handed persons, and to the opposite side in the left-handed.

The *anterior surface* of the vertebral column.—When viewed from the front, the width of the bodies of the vertebræ is seen to increase from the second cervical to the first thoracic; there is then a slight diminution in the next three vertebræ: below this there is again a gradual and progressive increase in width down to the lumbosacral angle. From this level there is a rapid diminution, to the apex of the coccyx.

The *posterior surface* of the column presents the spines of the vertebræ in the median plane. In the cervical region (with the exception of the second and seventh

FIG. 294.—The vertebral column. Left lateral aspect.



vertebræ) these are short and nearly horizontal, with bifid ends. In the upper part of the thoracic region they are directed obliquely downwards; in the middle part they are long and almost vertical; in the lower part of the thoracic region and in the lumbar region they are nearly horizontal. They are separated by considerable intervals in the cervical and lumbar regions, but are closely approximated in the middle of the thoracic region. Occasionally a spine may deviate from the median plane—a fact to be remembered in practice, as irregularities of this sort are attendant also on fractures or displacements of the vertebral column. At the sides of the spines the *vertebral grooves* lodge the deep muscles of the back. In the cervical and lumbar regions these grooves are shallow and are formed by the laminæ of the vertebræ; in the thoracic region they are deep and wide, and are formed by the laminæ and transverse processes. Lateral to the laminæ are the articular processes, and still more lateral the transverse processes. In the thoracic region the transverse processes lie on a plane considerably behind that of the same processes in the cervical and lumbar regions. In the cervical region the transverse processes are placed in front of the articular processes, lateral to the pedicles, and between the intervertebral foramina. In the thoracic region they are behind the pedicles, intervertebral foramina, and articular processes. In the lumbar region they are in front of the articular processes, but behind the intervertebral foramina. The size of the transverse processes of the atlas has already been emphasised (p. 209), and the breadth from the tip of one transverse process to the tip of the other has been contrasted with the same measurement in the axis. This measurement shows little variation from the second to the sixth cervical vertebra, but in the seventh it shows a substantial increase. In the thoracic region the measurement is greatest in the first and then gradually diminishes, being least in the twelfth, where the transverse process elements are usually reduced to mere vestiges. In the first lumbar vertebra the measurement is greater, in the second it is further increased, while in the third it is greater than it is in any of the other vertebræ. In the fourth and fifth it suffers a slight reduction.

The *lateral surfaces* of the vertebral column are separated from the posterior surface by the articular processes in the

cervical and lumbar regions, and by the transverse processes in the thoracic region. The anterior part of the lateral surface of the column is formed by the sides of the bodies of the vertebræ, marked in the thoracic region by the facets for articulation with the heads of the ribs. The intervertebral foramina are placed behind the bodies and between the pedicles; they are oval in shape, smallest in the cervical and upper part of the thoracic regions, and gradually increasing in size to the last lumbar; they transmit the spinal nerves and vessels.

The *vertebral canal* follows the curves of the column; it is large and triangular in the cervical and lumbar regions, where movement is free, but small and circular in the thoracic region, where motion is more limited.

Applied Anatomy.—Although there is only a very limited amount of movement between any two contiguous vertebræ, there is a considerable range of movement in the vertebral column as a whole. The intervertebral discs act as buffers between the different segments and counteract or neutralize the effect of jars or shocks which may be applied to the column; for example, dropping from a height on to the feet rarely causes concussion of the brain or spinal cord. The security of the column is also increased by the presence of the curves, which enable it to bend without breaking. The vertebræ are so firmly united to one another that violence applied to the column is more likely to produce fracture or dislocation than a tearing of ligaments.

Fractures or fracture dislocations of the vertebral column are the result of (1) forced flexion, e.g. by a violent blow on the back from a large object, and (2) violence transmitted along the long axis of the column, e.g. by falling on to the feet from a height, or by diving on to the head. In the first group the injury commonly occurs at the level of T. 5 or T. 6. In the second group, owing to the normal curvature of the vertebral column, the injury is also a flexion fracture and its site is between T. 9 and L. 2. In either case the upper segment is driven forwards on the lower, and the spinal cord is compressed between the body of the vertebra immediately below, and the arch of the vertebra immediately above the injury. Since the spinal cord does not extend below the level of the upper border of the second lumbar vertebra it follows that partial dislocations, or gunshot wounds, below this level are less serious than those above it.

THE STERNUM

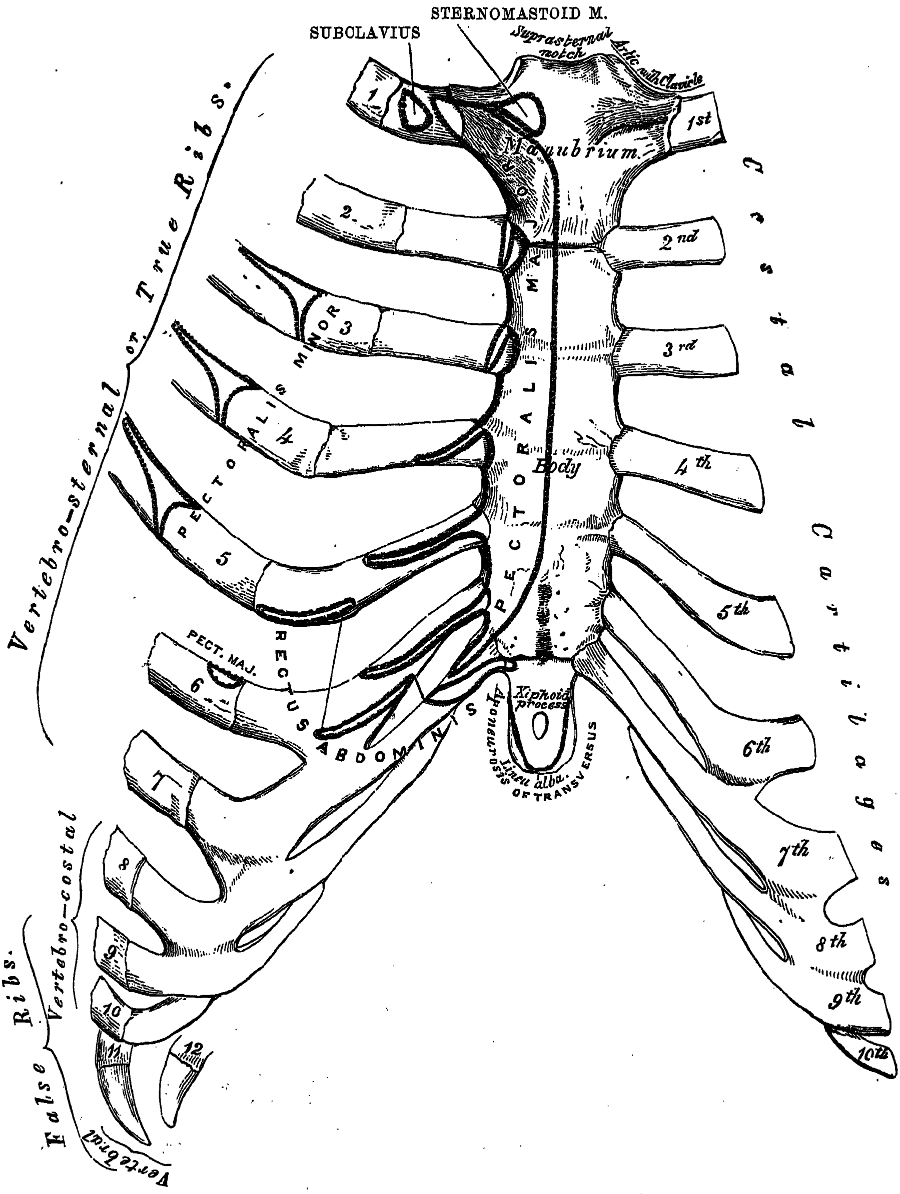
General features.—The **sternum** (figs. 295 to 297) is a long flat bone, forming the median portion of the anterior wall of the thorax. Its average length is 17 cm., and is rather greater in the male than in the female. Its upper end supports the clavicles, and its margins articulate with the cartilages of the first seven pairs of ribs. It consists of three parts, named from above downwards, the *manubrium*, the *body* and the *xiphoid process*; in early life the body consists of four segments. In its natural position the inclination of the bone is oblique from above, downwards and forwards. It is slightly convex in front, and concave behind; it is broad above, narrow at the junction of the manubrium with the body, below which it gradually widens as far as the level of the articulations of the cartilages of the fifth ribs, and then narrows quickly to its lower end.

The **manubrium sterni** is of a somewhat triangular form, broad and thick above, narrow below at its junction with the body. Its *anterior surface* is smooth, convex from side to side and concave from above downwards. Its *posterior surface* is concave and featureless. The *superior border* is thick, and presents at its centre the *suprasternal (jugular) notch*; on each side of this notch there is an oval articular surface, directed upwards, backwards, and laterally, for articulation with the sternal end of the clavicle, and termed the *clavicular notch*. The *inferior border*, oval and rough, is covered in the recent state with a thin layer of cartilage, for articulation with the upper end of the body. The *lateral borders* are each marked above by a depression for the reception of the first costal cartilage, and below by a small articular facet, which, with a similar one on the upper angle of the body, forms a notch for the sternal end of the cartilage of the second rib. Between the depression for the first costal cartilage and the facet for the second, the narrow curved edge slopes from above downwards and medially. The widest part of the sternum is at the level of the first costal cartilages.

The **body** of the sternum is longer, narrower, and thinner than the manubrium, and attains its greatest breadth close to the lower end. Its *anterior surface*, nearly flat, is directed forwards and upwards, and is marked by three ill-defined transverse ridges, which indicate the lines of fusion of four originally separate segments. A

sternal foramen, of varying size and form, is occasionally seen at the junction of the third and fourth pieces of the body (p. 86). The *posterior surface*, slightly concave, is also marked by three transverse lines, less distinct, however, than those on the anterior surface. The *upper end* is oval and articulates with the manubrium at the *sternal angle*, which forms a ridge that can be felt through the skin without difficulty. The *lower end* is narrow, and articulates with the xiphoid process. Each *lateral*

FIG. 295.—The sternum and costal cartilages. Anterior aspect.



border (fig. 297), at its superior angle, has a small notch, which, with a similar one on the manubrium, forms a cavity for the reception of the sternal end of the cartilage of the second rib; below this, four *costal notches* articulate with the sternal ends of the cartilages of the third, fourth, fifth and sixth ribs; the inferior angle has a small facet, which, with a similar one on the xiphoid process, forms a notch for the reception of the cartilage of the seventh rib. These articular depressions are separated by a series of curved edges, which diminish in length from above downwards, and correspond to the anterior ends of the intercostal spaces.

The **xiphoid process** is the smallest piece of the sternum and is thin and elongated. It is cartilaginous in youth, but, at its upper part, more or less ossified in the adult. Above, it articulates with the lower end of the body of the bone, and on the front of each superior angle there is a facet for a part of the cartilage of the seventh rib.

The xiphoid process varies greatly; it may be broad and thin, pointed, bifid, perforated, curved, or deflected to one or other side.

Particular features.—The manubrium lies opposite the third and fourth thoracic vertebræ. Its *anterior surface*, on each side, gives attachment to the sternal origins of the pectoralis major and sternomastoid muscles. Its *posterior surface* gives origin to the sternothyroid muscle, opposite the first costal cartilage; above this level the most medial fibres of the sternohyoid usually arise from the bone (fig. 296). This surface forms the anterior boundary of the superior mediastinum and its lower part is related to the arch of the aorta,

FIG. 296.—The sternum. Posterior aspect.

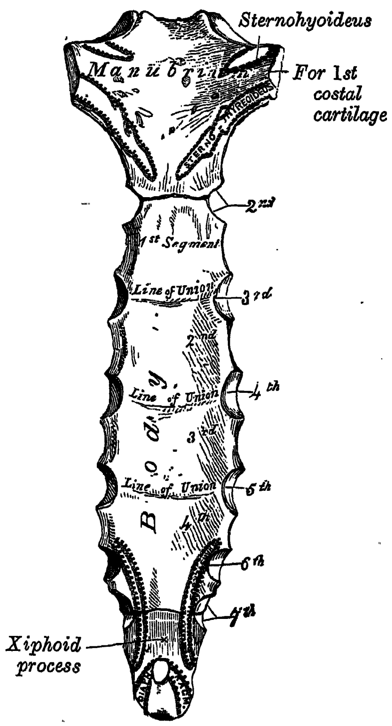


FIG. 297.—The sternum. Lateral aspect.

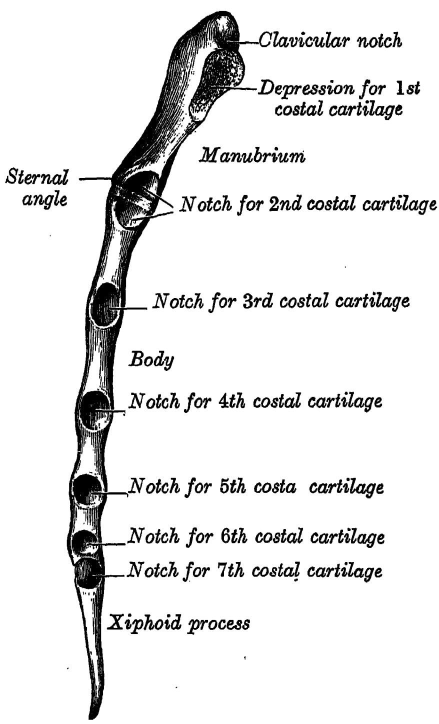

and its upper part to the left innominate vein and the innominate, left common carotid and left subclavian arteries. Its lateral portions are related to the lungs and pleuræ. The *suprasternal notch* gives attachment to some of the fibres of the interclavicular ligament. On the *lateral border* no joint cavity is interposed between the manubrium and the first costal cartilage, and the union is of the nature of a primary cartilaginous joint.

The **body** lies opposite the fifth to the ninth thoracic vertebræ. Its *anterior surface* gives attachment, on each side, to the articular capsules of the sternocostal joints and to the sternal origin of the pectoralis major muscle. Its *posterior surface* gives origin inferiorly to the sternocostalis (transversus thoracis) muscle, and presents numerous important relationships. On the right side of the median plane it is related to the right pleura and the thin, anterior border of the right lung, which intervene between it and the pericardium. To the left of the median plane the upper two pieces are related to the left pleura and lung, but the lower two are directly related to the pericardium. The *borders* give attachment to the anterior intercostal membranes in the intervals between the costal notches. With the exceptions of the first and the sixth the cartilages of the true ribs articulate with the sternum at the lines of junction of its primitive component segments; this is well seen in many of the lower animals, where the parts of the bone remain ununited longer than in man.

The **xiphoid** process lies in the floor of the epigastric fossa. Its *anterior surface* gives insertion to the most medial fibres of the rectus abdominis and to the aponeuroses of the external and internal oblique muscles. Its *lower end* gives attachment to the linea alba,

and its *borders* to the aponeuroses of the internal oblique and transversus abdominis muscles. Its *posterior aspect* gives origin, on each side, to some of the fibres of the diaphragm, and is related to the anterior surface of the liver.

Structure.—The sternum is composed of highly vascular spongy substance covered by a layer of compact bone, which is thickest on the manubrium between the clavicular notches.

Ossification.—At an early stage of development (p. 86) the sternum consists of two cartilaginous *sternal plates*, one on each side of the median plane. Opposite the first eight pairs of ribs these plates fuse in the median plane about the eighth week to form the cartilaginous sternum, which is ossified from six centres: one for the manubrium, four for the body, and one for the xiphoid process (fig. 298).

FIG. 298.—The ossification of the sternum.

A.—Time of Appearance

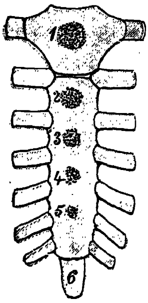

FIG. 299.

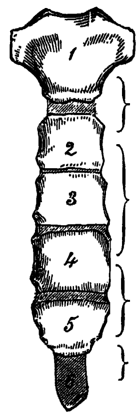
B.—Time of union



These centres appear in the intervals between the costal notches in the following order: in the manubrium and first piece of the body, during the sixth month of intrauterine life; in the second and third pieces of the body, during the seventh month of intrauterine life; in the fourth piece, shortly before birth; and in the xiphoid process, in the third year or much later.* Two small episternal centres sometimes appear, one on each side of the suprasternal notch; they are probably vestiges of the episternal bone of the monotremes and lizards. The manubrium may have two, three, or more centres; when two are present, one is generally situated above the other, the upper being the larger. The first segment of the body seldom has more than one centre; but the second, third, and fourth segments are often ossified from two laterally placed centres.

Union between the centres for the body begins about puberty, and proceeds from below upwards (fig. 299); by the age of twenty-five they are all united. The xiphoid process usually fuses with the body about the age of forty years, but may remain ununited in old age. In advanced life the manubrium is occasionally joined to the body by bone, but when this occurs only the superficial part of the intervening cartilage is converted into bone; the central part remains unossified.

THE RIBS [COSTÆ]

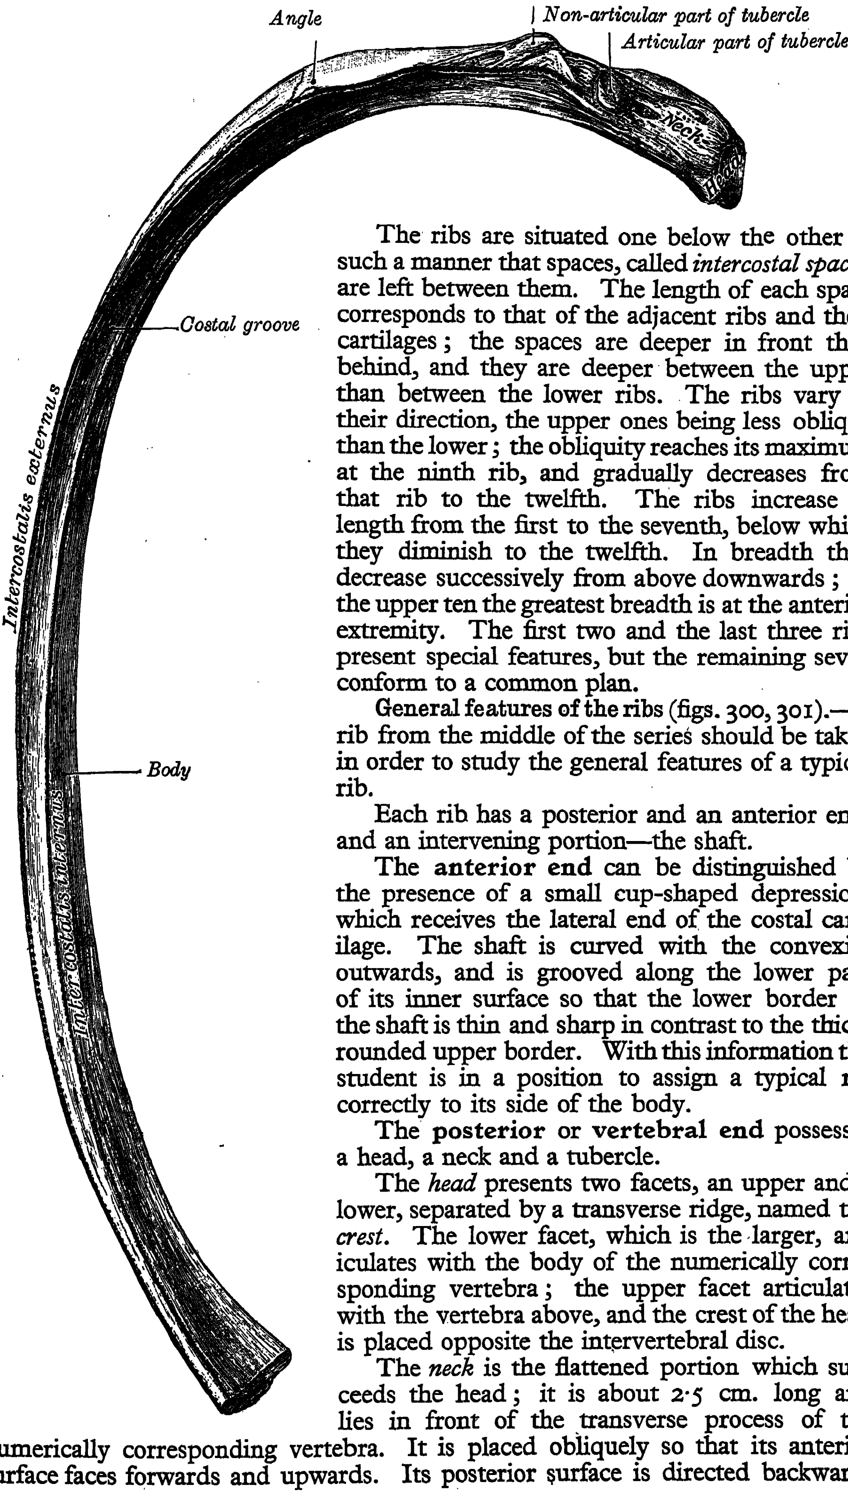
The **ribs** are elastic arches of bone, which are connected behind with the vertebral column, and form a large part of the skeleton of the thorax. They are twelve in number on each side; but this number may be increased by the development of a cervical or a lumbar rib, or may be reduced to eleven. The first seven are connected in front, through the intervention of the costal cartilages, with the sternum (fig. 295); they are called *true* ribs.† The remaining five are *false* ribs; of these

* Paterson (*The Human Sternum*, 1904) found the fourth or lowest centre for the body present only in 26·9 per cent. of cases.

† Sometimes the eighth rib cartilage articulates with the sternum; this condition occurs more frequently on the right side than on the left.

the cartilages of the eighth, ninth and tenth are joined each to the cartilage of the rib immediately above; the eleventh and twelfth are free at their anterior ends and are termed *floating ribs*.

FIG. 300.—A typical rib of the left side. Inferior aspect.



The ribs are situated one below the other in such a manner that spaces, called *intercostal spaces*, are left between them. The length of each space corresponds to that of the adjacent ribs and their cartilages; the spaces are deeper in front than behind, and they are deeper between the upper than between the lower ribs. The ribs vary in their direction, the upper ones being less oblique than the lower; the obliquity reaches its maximum at the ninth rib, and gradually decreases from that rib to the twelfth. The ribs increase in length from the first to the seventh, below which they diminish to the twelfth. In breadth they decrease successively from above downwards; in the upper ten the greatest breadth is at the anterior extremity. The first two and the last three ribs present special features, but the remaining seven conform to a common plan.

General features of the ribs (figs. 300, 301).—A rib from the middle of the series should be taken in order to study the general features of a typical rib.

Each rib has a posterior and an anterior end, and an intervening portion—the shaft.

The **anterior end** can be distinguished by the presence of a small cup-shaped depression, which receives the lateral end of the costal cartilage. The shaft is curved with the convexity outwards, and is grooved along the lower part of its inner surface so that the lower border of the shaft is thin and sharp in contrast to the thick, rounded upper border. With this information the student is in a position to assign a typical rib correctly to its side of the body.

The **posterior or vertebral end** possesses a head, a neck and a tubercle.

The *head* presents two facets, an upper and a lower, separated by a transverse ridge, named the *crest*. The lower facet, which is the larger, articulates with the body of the numerically corresponding vertebra; the upper facet articulates with the vertebra above, and the crest of the head is placed opposite the intervertebral disc.

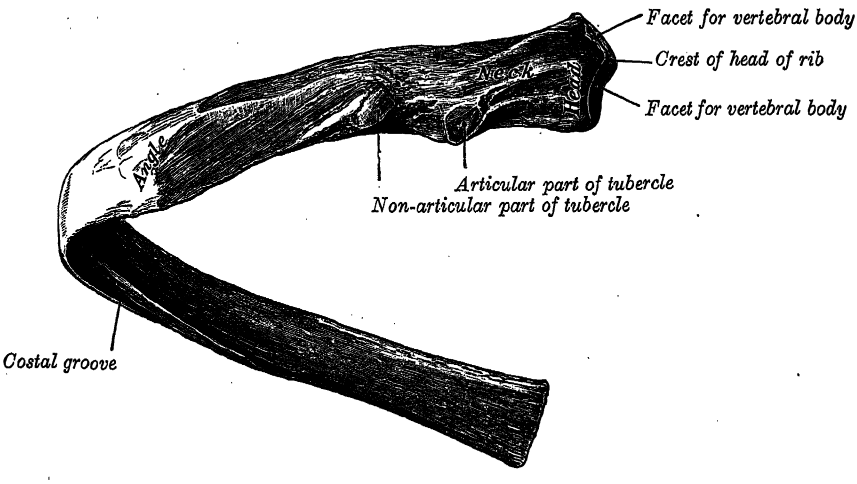
The *neck* is the flattened portion which succeeds the head; it is about 2·5 cm. long and lies in front of the transverse process of the numerically corresponding vertebra. It is placed obliquely so that its anterior surface faces forwards and upwards. Its posterior surface is directed backwards

and downwards, and is roughened and pierced by numerous foramina. Its upper border is sharp and forms the *crest of the neck of the rib*: its lower border is rounded.

The *tubercle* is placed on the outer surface of the posterior part of the rib, at the junction of the neck with the shaft; it is more prominent in the upper than in the lower ribs and is divided into a medial articular and a lateral non-articular portion. The *articular portion* bears a small, oval facet for articulation with the transverse process of the numerically corresponding vertebra; the non-articular portion is rough for ligamentous attachments.

The **shaft** is thin and flattened, with an external and an internal surface, a superior and an inferior border. It is not only curved but is also bent, and the *angle* is situated 5-6 cm. from the tubercle. In addition, the shaft is slightly twisted in its long axis, and this may be demonstrated if the rib is placed with its lower border in contact with a horizontal surface. The part behind the angle inclines medially and upwards, and its outer surface faces downwards and backwards; in front of

FIG. 301.—A typical rib of the left side. Posterior aspect.

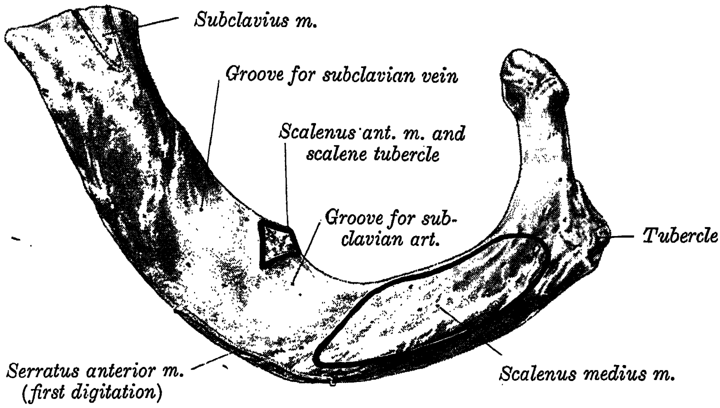


the angle the outer surface faces slightly upwards. The *external surface* is convex and smooth. A short distance from the tubercle it is crossed by a rough line, directed downwards and laterally, which marks the position of the angle. The *internal surface* is smooth and is marked along its lower border by a groove, termed the *costal groove*, which is bounded below by the inferior border of the shaft. The upper border of the groove is continuous behind with the lower border of the neck, but anteriorly it terminates at the junction of the middle and anterior thirds of the shaft; in front of this point, the groove is absent.

The **first rib** (fig. 302) is the most curved and usually the shortest of the ribs; it is broad and flat, its surfaces facing upwards and downwards, and its borders inwards and outwards. It is placed very obliquely in the body—sloping downwards and forwards from its vertebral to its sternal end. The *head* is small and rounded, and bears a single, nearly circular, articular facet, which articulates with the upper part of the side of the body of the first thoracic vertebra. The *neck* is rounded, and is directed upwards, backwards and laterally. The *tubercle*, thick and prominent, is directed upwards and backwards; it bears an oval facet on its medial part for articulation with the transverse process of the first thoracic vertebra. At the tubercle the rib is bent, so that the head of the bone is directed slightly downwards; the angle and the tubercle therefore coincide. The *upper surface* of the shaft is crossed obliquely by two shallow grooves, separated from each other by a slight ridge, which ends at the inner border of the rib in a small projection, termed the *scalene tubercle*. The *under surface* is smooth and has no costal groove. The *outer border* is convex, thick behind, but thin in front. The *inner border* is concave and thin, and marked near its centre by the scalene tubercle. The *anterior end* is larger and thicker than that of any of the other ribs.

The **second rib** (fig. 303) is about twice the length of the first, but has a similar curvature. The non-articular portion of the *tubercle* is often small. The *angle* is slight, and situated close to the tubercle. The *shaft* is not twisted, so that both ends of it touch any plane surface upon which the rib may be laid; but at the tubercle there is an upward convexity, similar to, but smaller than, that found in the

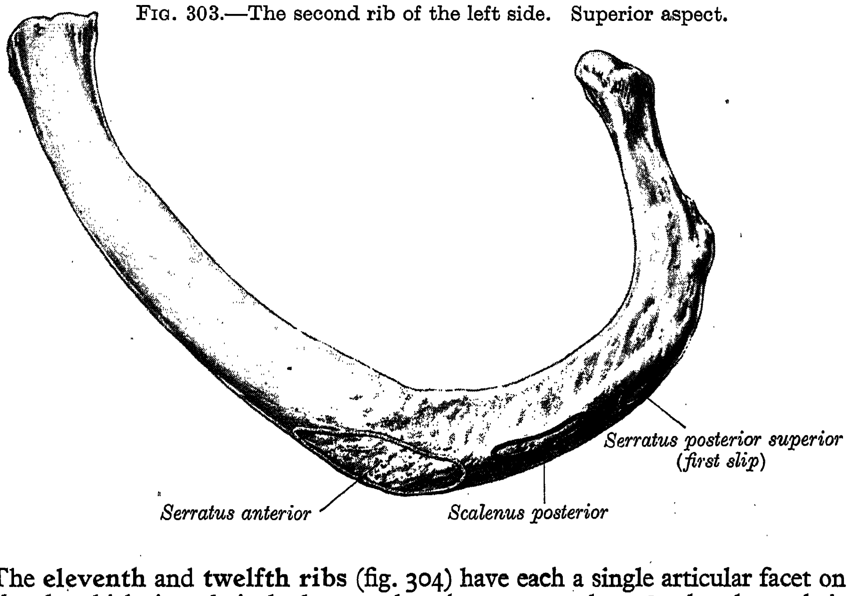
FIG. 302.—The first rib of the left side. Superior aspect.



first rib. The *external surface* of the shaft is convex, and looks upwards and a little outwards; near its middle it is marked by a rough, muscular impression. The *internal surface*, smooth and concave, is directed downwards and a little inwards; on its posterior part there is a short costal groove.

The **tenth rib** has a single articular facet on its head.

FIG. 303.—The second rib of the left side. Superior aspect.

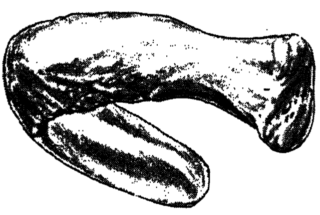


The **eleventh** and **twelfth ribs** (fig. 304) have each a single articular facet on the head, which is relatively large; they have no necks or tubercles; their anterior ends are pointed and tipped with cartilage. The eleventh has a slight angle and a shallow costal groove. The twelfth has neither; it is much shorter than the eleventh, and its vertebral end is directed slightly upwards. The inner surfaces of both ribs look upwards as well as inwards, the upward inclination being more marked in the twelfth. Sometimes the twelfth rib is shorter than the first.

Particular features.—The head *of a typical rib* gives attachment along its anterior border to the radiate ligament, and its crest to the intra-articular ligament. The anterior surface

of the head is related to the costal pleura, and, in the lower ribs, to the sympathetic trunk. The *anterior surface* of the neck is divided into an upper and a lower area by a faint ridge, which affords attachment to the posterior intercostal membrane and is continuous with the inner of the two lips on the superior border of the shaft. The upper area, of varying size and more or less triangular in shape, is separated from the posterior intercostal membrane by some fatty tissue; the lower area is smooth and covered with the costal pleura. The *posterior surface* of the neck gives attachment to the inferior costotransverse ligament (ligamentum colli costæ) and is pierced by numerous vascular foramina. The *crest of the neck* is rough for the attachment of the superior costotransverse (anterior costotransverse) ligament, and it can be traced laterally into the outer lip of the superior border of the shaft. The *inferior border* of the neck is rounded and can be traced laterally into the upper border of the costal groove; it gives attachment to the posterior intercostal membrane. The *articular part of the tubercle* conforms to the shape of the articular facet on the transverse process of the corresponding vertebra. In the upper six ribs it is convex and faces backwards and medially; in the succeeding three or four ribs it is flattened and faces downwards, backwards and slightly medially. The *non-articular part of the tubercle* gives attachment to the lateral costotransverse ligament (ligament of the tubercle of the rib).

FIG. 304.—The twelfth rib of the left side. Viewed from behind.



The ridge which marks the *angle* on the *external surface* of the shaft of a typical rib gives attachment to the upward continuation of the lumbar fascia and the most lateral fibres of the iliocostocervicalis (iliocostalis) muscle. From the second to the tenth ribs the distance between the angle and the tubercle becomes progressively greater. Medial to the angle, the external surface gives attachment to the corresponding levator costæ and is covered by the sacrospinalis muscle. Near the sternal end of this surface an indistinct, oblique line (which marks the anterior angle) separates the origins of the external oblique and the serratus anterior (or latissimus dorsi, in the cases of the ninth and tenth ribs). The *costal groove* on the *internal surface* gives attachment to the internal intercostal muscle, which intervenes between the bone and the intercostal vessels and nerve. At the vertebral end of the bone the groove faces downwards, as its borders lie on the same plane. Near the angle the shaft broadens and the groove passes on to the internal surface. Numerous small nutrient vessels pierce the floor of the groove and traverse the shaft obliquely from before backwards. The upper edge of the groove gives attachment to the intercostalis intimus, which rarely extends on to the anterior fourth of the rib. Posteriorly this edge is continuous with the lower border of the neck. The sharp lower border of the rib gives origin to the external intercostal muscle. Its upper border is marked, posteriorly, by an inner and an outer lip: the inner lip gives attachment to both the intercostalis internus and intimus; the outer lip gives attachment only to the intercostalis externus.

The **first rib** (fig. 302) presents important particular features. The *scalene tubercle* and the adjoining part of the *upper surface* give insertion to the scalenus anterior muscle. The groove in front of the tubercle lodges the subclavian vein, and the irregularly roughened area which intervenes between it and the first costal cartilage gives attachment to the costoclavicular ligament and, more anteriorly, to the subclavius muscle. The groove behind the tubercle is occupied by the subclavian artery and, as a rule, the lower trunk of the brachial plexus.* Behind this groove a rough area which extends as far as the tubercle gives insertion to the scalenus medius. The obliquity of the first rib is responsible for the obliquity of the thoracic inlet and accounts for the appearance of the apex of the lung in the root of the neck.

The *outer border* of the first rib is thin anteriorly but is thicker behind, where it is covered by the scalenus posterior as it descends to the second rib for its insertion. It gives origin to the upper part of the first digitation of the serratus anterior, behind and opposite to the groove for the subclavian artery. The *inner border* gives attachment to the strong fascia which covers the cervical dome of the pleura.

The **second rib** (fig. 303) bears a rough *tubercle for the serratus anterior muscle* on its external surface just behind its midpoint; this tubercle gives origin to the lower part of the first and the whole of the second digitation. The *costal groove* is very poorly marked on the *internal surface* and is restricted to its posterior part. The second intercostal nerve lies between the second rib and the pleura in most of its course. The inner and outer lips of the upper border are distinct and are widely separated behind. Immediately in front of the poorly marked angle the outer lip is roughened to give insertion to the scalenus posterior.

The **twelfth rib** (fig. 304), although short, gives attachment to numerous muscles and ligaments. The lower part of its *anterior surface*, in its medial half to two-thirds, gives

* The intimate relationship of the artery to the first rib is often denied, but it can be demonstrated in most subjects in the dissecting room.

insertion to the quadratus lumborum muscle and its covering fascia. Lateral and superior to these attachments the surface is related to the costodiaphragmatic recess of the pleura. The *lower border* gives attachment to the middle lamella of the lumbar fascia and, at the lateral border of the quadratus lumborum, to the lateral arcuate ligament (lateral lumbocostal arch). The lower border of the neck gives attachment to the lumbocostal ligament, by which it is connected to the transverse process of the first lumbar vertebra. The *external surface* gives attachment to the lowest levator costæ, the longissimus thoracis, and the iliocostalis, in its medial half; more laterally, it gives insertion to the serratus posterior inferior, and origin to the latissimus dorsi and the external oblique muscle of the abdomen.

It should be observed that the lower limit of the pleural sac crosses the anterior aspect of the twelfth rib, approximately at the point where the rib is crossed by the lateral border of the iliocostalis muscle. The lateral extremity of the rib usually lies below the line of pleural reflection and is therefore not covered with pleura.

Structure.—The ribs consist of highly vascular spongy substance, which is enclosed in a thin layer of compact bone, and contains a large proportion of red marrow.

Ossification.—Each rib, with the exception of the first and the last two, is ossified from four centres; a primary centre for the shaft, and three secondary centres, one for the head and one each for the articular and non-articular parts of the tubercle.* The primary centre appears near the angle, towards the end of the second month of intrauterine life, and is seen first in the sixth and seventh ribs. The secondary centres for the head and tubercle appear between the sixteenth and twentieth years, and unite with the shaft about the twenty-fifth year. The first rib has three centres, viz.: a primary one for the shaft, a secondary centre for the head, and one for the tubercle. The eleventh and twelfth ribs, being destitute of tubercles, have each only two centres.

THE COSTAL CARTILAGES

General features.—The **costal cartilages** (fig. 305) are bars of hyaline cartilage which extend forwards from the anterior ends of the ribs and contribute very materially to the elasticity of the walls of the thorax. The first seven pairs are connected with the sternum; the eighth, ninth, and tenth are articulated each with the lower border of the cartilage immediately above; the lower two are pointed, and end in the muscular wall of the abdomen. The costal cartilages vary in their length, breadth and direction. They increase in length from the first to the seventh, and then gradually decrease to the twelfth. They diminish in breadth from the first to the last, like the intervals between them. They are broad at their attachments to the ribs, and taper towards their medial extremities, with the exception of the first and second which are of the same breadth throughout, and the sixth, seventh, and eighth which are enlarged where their margins are in contact. The first cartilage descends a little, the second is horizontal, the third ascends slightly, while the others are angular, continuing the course of the ribs for a short distance, and then inclining upwards to the sternum or preceding cartilage.

Particular features.—Each costal cartilage has two surfaces, two borders, and two ends. The *anterior surface* is convex, and faces forwards and upwards: that of the first gives attachment to the sternoclavicular articular disc, the costoclavicular ligament and the subclavius muscle; those of the first six or seven at their medial ends, to the pectoralis major muscle. The others are covered by, and give partial attachment to, some of the flat muscles of the anterior abdominal wall. The *posterior surface* is concave, and directed backwards and downwards; that of the first gives attachment to the sternothyroid, those of the second to the sixth inclusive to the sternocostalis (transversus thoracis), and the six lower ones to the transversus abdominis and the diaphragm. The *superior border* is concave, and the *inferior* convex; they afford attachment to the internal intercostal muscles and the anterior intercostal membranes. The inferior borders of the sixth, seventh, eighth, and ninth cartilages present heel-like projections at the points of greatest convexity; a similar heel-like projection occurs on the lower border of the fifth right cartilage in 72 per cent. and on the fifth left cartilage in 50 per cent. (Fawcett). On these projections are oblong facets which articulate respectively with facets on slight projections from the superior borders of the sixth, seventh, eighth, ninth, and tenth cartilages. The *lateral end* of each cartilage is continuous with the osseous tissue of the corresponding rib. The *medial end* of the first is con-

* E. Fawcett states that 'in all probability there is usually no epiphysis on the non-articular part of the tuberosity below the sixth or seventh rib' (*Journal of Anatomy and Physiology*, vol. xlv.).

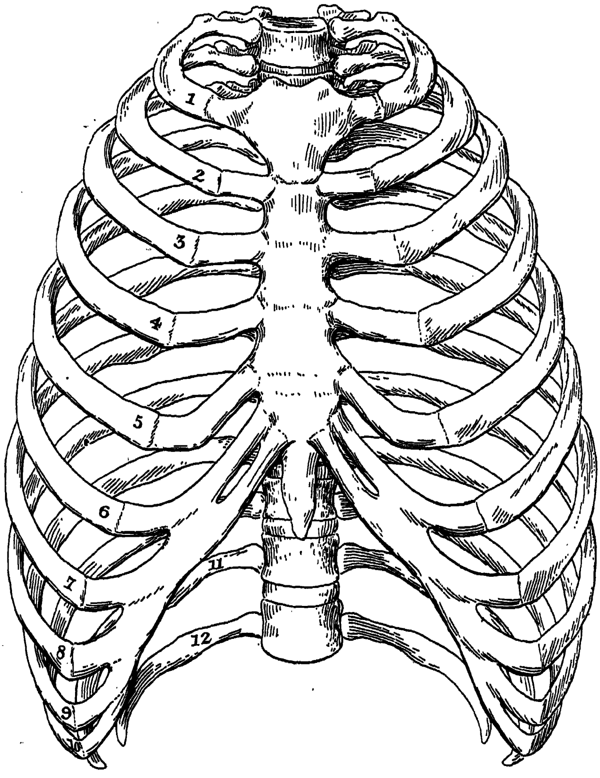
tinuous with the sternum; the medial ends of the six succeeding cartilages are rounded and articulate with the shallow costal notches on the lateral margins of the sternum. The medial ends of the eighth, ninth, and tenth costal cartilages are pointed, and each is connected with the cartilage immediately above. Those of the eleventh and twelfth are pointed and free.

In old age the costal cartilages are prone to undergo superficial ossification.

THE THORAX

The skeleton of the thorax, or chest (fig. 305), is an osseocartilaginous cage which contains and protects the principal organs of respiration and circulation. It is conical in shape, narrow above and broad below, flattened from before backwards, and longer behind than in front. It is reniform on horizontal section on account of the forward projection of the vertebral bodies.

Fig. 305.—The skeleton of the thorax. Anterior aspect.



Boundaries.—*Posteriorly* it is formed by the twelve thoracic vertebræ and the posterior parts of the ribs. At each side of the vertebral column there is a wide and deep groove in consequence of the lateral and backward direction which the ribs follow from their vertebral extremities to their angles. *Anteriorly* it is formed by the sternum, the anterior ends of the ribs and the costal cartilages, and this surface is flattened or slightly convex. *Laterally* it is convex, and is formed by the ribs. The ribs and costal cartilages are separated from each other by the intercostal spaces, eleven in number, which are occupied by the intercostal muscles and membranes.

The *inlet* of the thorax is reniform in shape; its anteroposterior diameter is about 5 cm., its transverse about 10 cm. It slopes downwards and forwards, and is bounded by the first thoracic vertebra behind, the superior border of the manubrium sterni in front, and the first rib on each side. The *outlet* is bounded by the twelfth thoracic vertebra behind, by the twelfth and eleventh ribs at the sides, and in front by the cartilages of the tenth, ninth, eighth, and seventh ribs, which ascend on each side and form an angle, termed the *infrasternal* (*subcostal*)

angle, into the apex of which the xiphoid process projects. The outlet is wider transversely than from before backwards, and slopes obliquely downwards and backwards; it is closed by the diaphragm, which forms the floor of the thorax.

The thorax of the female differs from that of the male as follows: 1. Its capacity is less. 2. The sternum is shorter, and its upper margin is on a level with the lower part of the body of the third thoracic vertebra, whereas in the male it is on a level with the lower part of the body of the second. 3. The upper ribs are more movable and so allow a greater expansion of the upper part of the thorax.

Applied Anatomy.—Fracture of the sternum is by no means common, owing, no doubt, to the elasticity of the ribs and their cartilages, which support it like so many springs.

The ribs are frequently broken, though from their connexions and shape they are able to withstand great force, yielding under pressure and recovering themselves like a spring. The middle ribs are the most liable to fracture. The first, and to a less extent the second, being protected by the clavicle, are rarely fractured; and the eleventh and twelfth on account of their loose and floating condition enjoy a like immunity. The fracture generally occurs from indirect violence from forcible compression of the chest walls, and the bone then gives way at its weakest part, i.e. just in front of the angle. But the ribs may also be broken by direct violence, in which case the bone is driven inwards at the point of impact. Fracture of the ribs is frequently complicated with some injury to the viscera contained within the thorax or upper part of the abdominal cavity; this is most likely to occur in fractures from direct violence.

Cervical ribs derived from the seventh cervical vertebra (page 85) are of not infrequent occurrence, and are important clinically because they may give rise to nervous or vascular symptoms. The cervical rib may be a mere epiphysis articulating only with the transverse process of the vertebra, but more commonly it consists of a definite head, neck and tubercle, with or without a shaft. It extends laterally, or forwards and laterally, into the posterior triangle of the neck, where it may terminate in a free end or may join the first thoracic rib, the first costal cartilage, or the sternum.* It varies much in shape, size, direction, and mobility. If it reaches far enough forwards, its relations are similar to those of the first thoracic rib; part of the brachial plexus and the subclavian artery and vein cross over it, and are apt to suffer compression in so doing. Pressure on the plexus affects the eighth cervical and first thoracic nerves, causing paralysis of the muscles they supply, and neuralgic pains, trophic changes and paræsthesia in the area of skin to which they are distributed: no oculopupillary changes are to be found.

THE SKULL

INTRODUCTORY

The paragraphs which follow are intended primarily for the student who has no previous knowledge of the skull, and may well be omitted by those who are already familiar with its principal features. The detailed description of the skull commences on p. 244.

The skull is the skeleton of the head. It is made up of a large number of bones which, with the exception of the mandible or lower jaw, are so intimately connected to one another that no movement is possible between them. The lines along which the individual bones meet one another are, for the most part, very irregular and are frequently serrated like the edge of a saw (fig. 310). These immovable joints between the bones of the skull are termed *sutures*. They are easily seen in the skulls of young adults, but, as old age approaches, contiguous bones tend to fuse with each other and the suture lines become more or less obliterated.

When the mandible is left out of account the remainder of the skull, strictly speaking, constitutes the cranium, but in this textbook, as well as in many others, the term skull is widely used with the same significance. The upper part of the cranium forms a box to enclose and protect the brain, and is often termed the *calvaria*. The remainder of the skull forms the *facial skeleton*, of which the upper part is immovably fixed to the calvaria and the lower part is the freely movable mandible.

The skull, considered as a whole, is of much greater importance to the student of medicine than the individual bones of which it is made up. Nevertheless, the position of the individual constituents must be determined before the student can be in a position to follow the more detailed description.

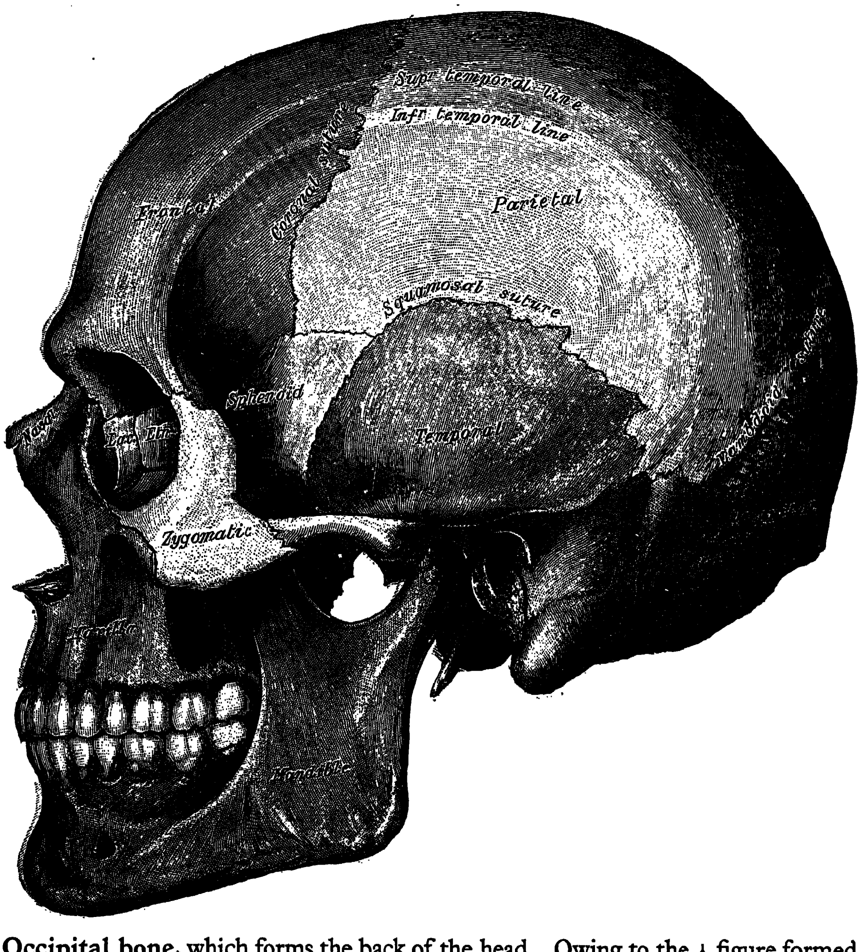
The skull as a whole may be viewed from above (norma verticalis), from below (norma basalis), from behind (norma occipitalis), from in front (norma frontalis)

* W. Thorburn, *The Med. Chronicle*, Manchester, 4th series, xiv. 1907.

and from the side (norma lateralis). The roof of the calvaria, or *skull-cap*, may be removed and the *interior of the skull* may be examined. In the erect attitude the lower margins of the orbital openings and the upper margins of the external auditory meatuses lie on the same horizontal plane, and it is important that the student should bear this in mind when he is examining the various aspects of the skull.

The region of the forehead is formed by the **Frontal bone** (fig. 306), which passes backwards in the vault of the skull as far as the *coronal suture*, where it meets the anterior borders of the right and left **Parietal bones**. These two bones together form the greater part of the top of the head, and they articulate with each other at the serrated *sagittal suture*. Posteriorly they extend backwards to meet the

FIG. 306.—The skull. Lateral aspect. (Norma lateralis.)



Occipital bone, which forms the back of the head. Owing to the λ figure formed by the meeting of the sagittal with the parieto-occipital sutures, the latter are named the *lambdoid suture*. Each parietal bone extends downwards on the side of the vault until it meets the upper limit of the *greater wing* of the **Sphenoid bone** in front, and the *squamous part* of the **Temporal bone** behind. When the skull cap is removed, the section passes through the frontal bone and usually cuts across the lower part of the parietal bone, but it may involve the squamous part of the temporal bone. Posteriorly the section cuts the occipital bone. Consequently, the *skull cap* consists of (1) a large part of the frontal bone, (2) most of the two parietal bones, (3) possibly, small parts of the squamæ of the temporal bones, and (4) a small part of the occipital bone.

When the skull cap is removed, the floor of the calvaria, almost invariably termed the **base of the skull**, is exposed. It shows a natural subdivision into three areas, which are named the anterior, middle and posterior cranial fossæ (fig. 307). The **anterior cranial fossa** forms less than the anterior third of the base and is limited

behind by a sharp edge on each side of the median plane. It is important to observe that the floor of the anterior cranial fossa constitutes the roof of the orbit, on each side, and the roof of the nose, in the median area. On each side of the median plane an *orbital plate* projects backwards from the **Frontal bone** and constitutes most of the roof of the orbit. These two plates are separated by a relatively narrow interval, which is occupied by a perforated strip of bone. This is termed the *cribriform plate* of the **Ethmoid bone**; it forms a large part of the roof of the nose, while the rest of the bone to which it belongs participates in the formation of the side walls of the nose. In the median plane the cribriform plate bears a crestlike elevation, termed the *crista galli*. The most posterior part of the floor of the anterior cranial fossa is formed by the **Sphenoid bone.** In the median area the front of the *body* of the sphenoid meets the cribriform plate of the ethmoid. On each side a narrow *lesser wing* projects laterally from the body of the sphenoid and meets the posterior margin of the orbital plate of the frontal bone. It is the sharp posterior border of the lesser wing of the sphenoid bone which forms the posterior limit of the floor of the anterior cranial fossa on each side of the median plane.

Fig. 307.—The internal surface of the left half of the base of the skull. (Basis cranii interna.)

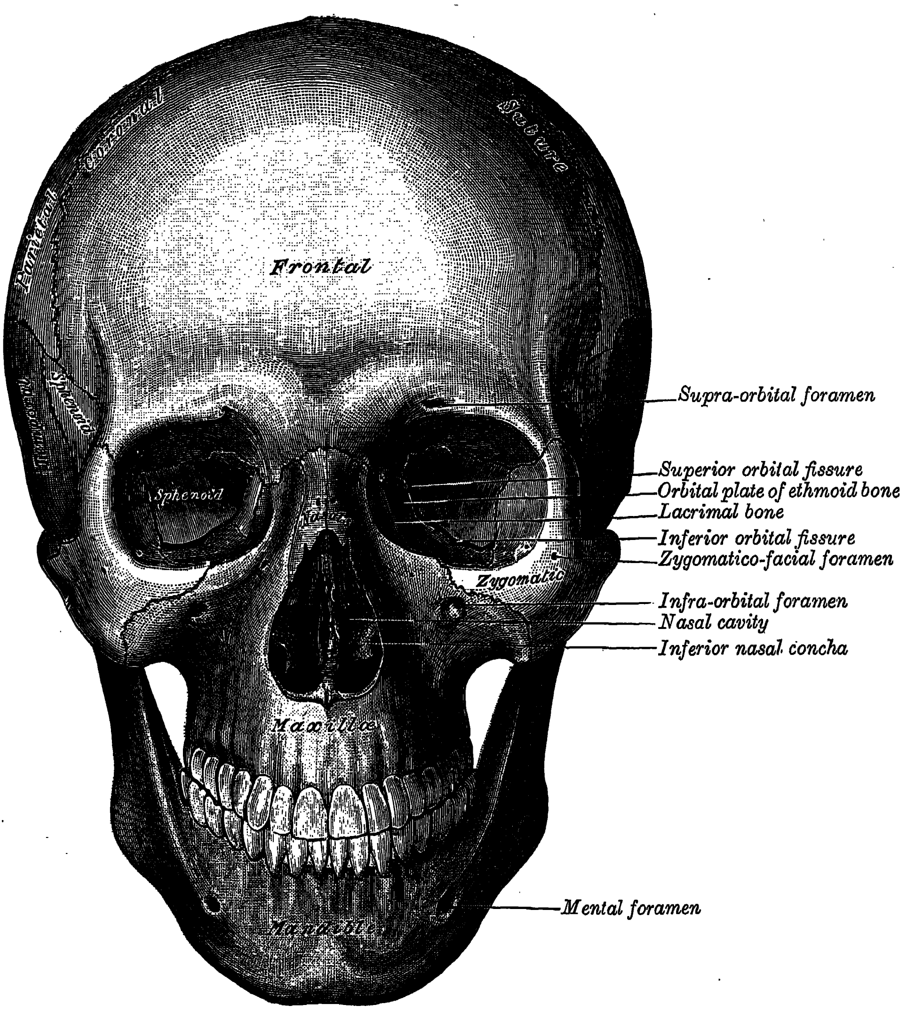
The **middle cranial fossa** (fig. 307), which lies immediately behind the anterior fossa, is of small extent in the median region but is expanded, in a backward and lateral direction, on each side. The narrow median portion of the floor is formed by the *body* of the **Sphenoid,** the upper surface of which is hollowed out to contain the hypophysis cerebri—an important ductless gland. The floor of the lateral part of the fossa is formed by the *greater wing* of the sphenoid in front, and by the *petrous part* of the **Temporal bone** behind. The greater wing extends laterally from the side of the body of the sphenoid and curves upwards in the side of the skull to reach the antero-inferior part of the parietal bone. Behind it the floor of the fossa is formed by the anterior surface of the petrous part of the temporal bone, which is continuous laterally with the squamous part of the same bone.

The **posterior cranial fossa** (fig. 307) is almost circular in outline and occupies roughly two-fifths of the base of the skull. It is formed to a very large extent by the **Occipital bone.** The large opening in its floor, termed the **foramen magnum,** is placed entirely within that bone and allows the brain to become continuous with the spinal cord. The anterior part of the fossa is formed by the *basilar part* of the occipital bone, which is fused in front with the posterior part of the sphenoid bone. On each side the lateral wall of the fossa is formed by the posterior surface of the petrous part of the temporal bone above, and by the *condylar* (lateral) *part* of the occipital bone, below. The *mastoid part*

of the temporal bone, which lies immediately behind the petrous part, helps the *squamous part* of the occipital bone to complete the fossa.

When the skull is viewed from in front (norma frontalis, fig. 308) the **orbits,** which lodge the eyeballs, and the anterior aperture of the **nose,** can easily be identified. The part below the mouth is formed entirely by the *body* of the **Mandible**; the part above the mouth is formed almost entirely by the **Maxillæ,** or upper jaws. These bones form the upper boundary of the mouth, and the lower and lateral boundaries of the anterior nasal aperture. In addition, on each side the

FIG. 308.—The skull. Anterior aspect. (Norma frontalis.)



maxilla forms the medial part of the lower margin of the orbit, which it helps the **Zygomatic bone** to complete, while its frontal process ascends in the medial margin of the orbit to reach the **Frontal bone.** The frontal processes of the two maxillæ are separated from each other by the two **Nasal bones,** which form the upper boundary of the anterior nasal aperture.

When the skull is viewed from the side (norma lateralis, fig. 306) the *ramus* of the **Mandible,** which passes from the posterior end of the body of the bone upwards and slightly backwards to reach the cranium, can be identified without difficulty. The *head* of the mandible, which lies at the upper end of the posterior border of the ramus, is received into the *articular fossa* on the under surface of the squamous part of the temporal bone. The back of the mandibular head is separated

from the ear passage, termed the *external auditory meatus*, by the *tympanic part* of the temporal bone. Above and in front of the meatus the thin *zygomatic process* of the temporal bone passes forwards to meet the zygomatic or cheek bone, and the two form the *zygomatic arch*, which is separated by a wide gap from the rest of the side of the skull. The **Zygomatic bone** is responsible for the prominence of the upper and anterior part of the cheek. It forms the lateral part of the lower margin of the orbital opening, as already stated, and ascends in the lateral margin to meet the **Frontal bone.**

FIG. 309.—The external surface of the left half of the base of the skull. (Norma basalis.) For Key, see fig. 320.

When the mandible is removed (fig. 317) a process of bone can be seen immediately behind the maxilla and above the level of the maxillary teeth. This is the *pterygoid process*, which projects downwards from the **Sphenoid** along the line of union of its greater wing with its body. It consists of a large lateral plate with a smaller, medial plate on its medial side.

The inferior aspect of the cranium (norma basalis, fig. 309) is termed the external aspect of the base of the skull. It should be examined next. Posteriorly the **Occipital bone**, with the foramen magnum, can be located without difficulty. Lateral to the foramen magnum the occipital bone articulates with the *mastoid part* of the **Temporal bone.** Antero-laterally it articulates with the *petrous part*, which extends forwards almost to the root of the *pterygoid process*. In the anterior part of the inferior aspect of the cranium, the **bony palate**, which lies in the roof of the mouth, can be seen within the arch of the teeth of the maxilla. Four bones contribute to its formation, viz., the two **Maxillæ** and the two **Palatine bones.** The anterior three-fourths of the bony palate are formed by the *palatine processes* of the maxillæ, which meet each other in the median plane; the posterior fourth is formed by the *horizontal plates* of the *palatine bones*. The palatine bones are now seen, in part, for the first time; their *perpendicular plates* are still hidden as they ascend, on each side, from the lateral border of the horizontal plate to form the posterior part of the lateral wall of the nose.

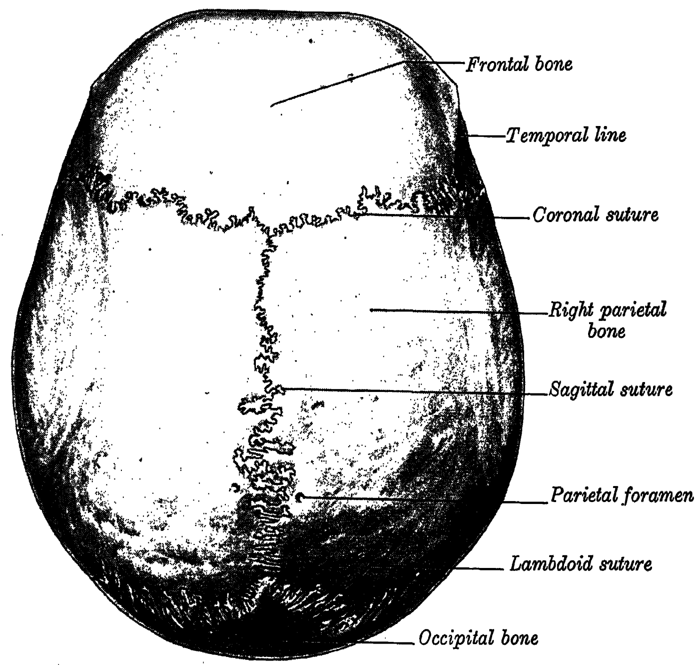
The **Lacrimal bone,** which lies in the anterior part of the medial wall of the orbit, the **Vomer,** which forms a large part of the nasal septum (fig. 328), and the **Inferior Concha,** which lies in the lateral wall of the nose, can be seen only when the orbits and the nose are examined (pp. 247 and 273). With these exceptions all the bones of the skull have now been identified, and the student is in a position to undertake profitably a more detailed study of the skull as a whole.

THE EXTERIOR OF THE SKULL

NORMA VERTICALIS (fig. 310)

The outline of the skull, as seen from above, varies greatly in different specimens. In some the outline is more or less oval: in others it is more nearly circular, but its greatest width is usually nearer to the occipital than to the frontal region. This aspect of the skull is traversed by three sutures. (1) The *coronal suture* is placed between the posterior edge of the frontal bone and the anterior borders of the parietal bones. From the median plane it passes downwards and forwards across the cranial vault. (2) The *sagittal suture* is placed in the median plane between the interlocking upper borders of the two parietal bones. (3) The *lambdoid suture* is placed between the posterior borders of the parietal bones and the superior border of the squamous part of the occipital bone. It runs downwards and forwards across the cranial vault. The meeting-place of the coronal and sagittal sutures is termed

Fig. 310.—The skull, viewed from above.



the *bregma*, and it is the site of a membrane-filled gap in the fœtal skull which is named the *anterior fontanelle* (p. 326). The *lambda* is situated at the junction of the sagittal and lambdoid sutures and is the site of the *posterior fontanelle* (p. 326) in the fœtal skull, which is a similar but smaller gap.

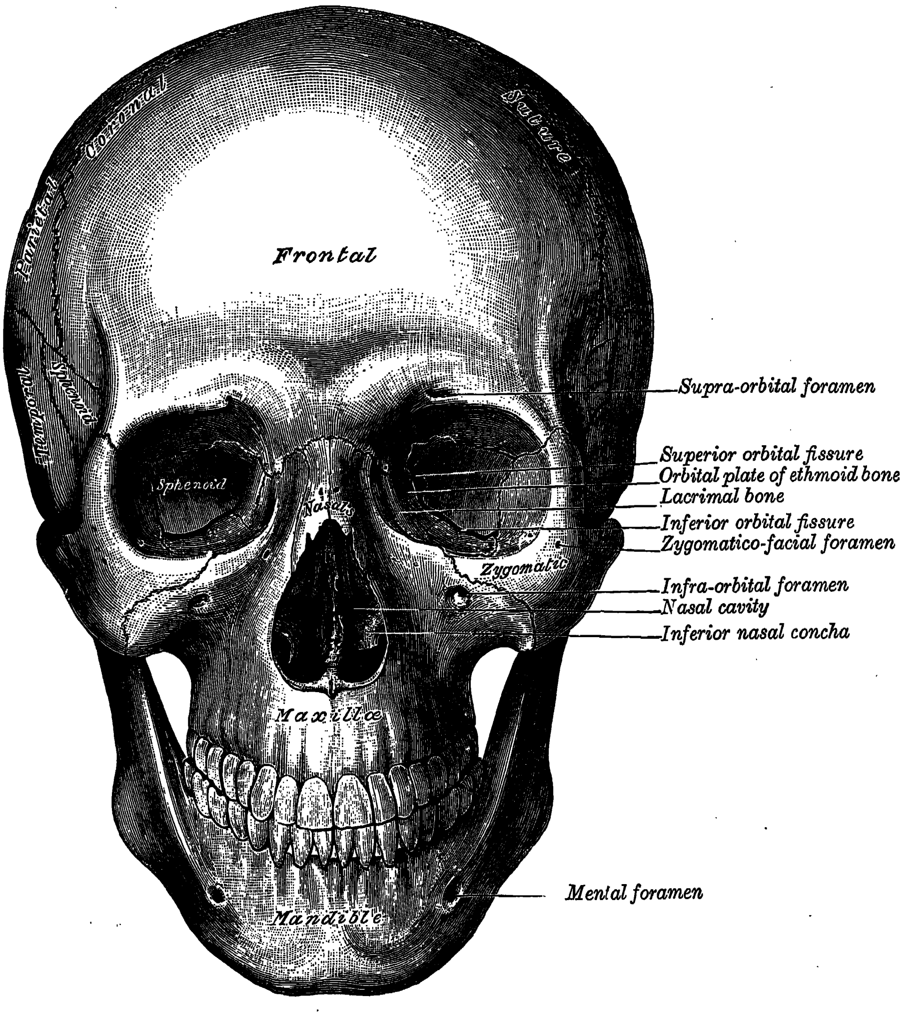
The region of maximum convexity of the parietal bone is termed the *parietal eminence* (tuberosity) and can be identified easily in the living subject. In this situation the norma verticalis passes into the norma lateralis and the norma occipitalis, but there are no sharp lines of demarcation. The *parietal foramen*, which may be absent on one or both sides, pierces the parietal bone near the sagittal suture about 3·5 cm. in front of the lambda. It transmits a small emissary vein from the superior sagittal sinus within the skull, and this vessel constitutes one of the important connexions between the extra- and the intracranial veins. Anteriorly the norma verticalis slopes down into the norma frontalis.

NORMA FRONTALIS (fig. 311)

Viewed from in front the skull exhibits a more or less oval outline, wider above than below. Its upper part is formed by the frontal bone and is smooth and convex. Its lower part is very irregular and is interrupted by the orbits and the anterior bony

aperture of the nose. Immediately above the medial part of each orbit the *superciliary arch* forms a rounded elevation, better marked in the male than in the female skull, and these two arches are connected by a median elevation termed the *glabella*. Below the glabella the skull recedes to the point where the nasal bones meet the frontal, forming the floor of a depression at the root of the nose. The point where the internasal and frontonasal sutures meet is named the *nasion*. Above the superciliary arch on each side there is a slight rounded elevation termed the *frontal*

FIG. 311.—The skull. Anterior aspect. (Norma frontalis.)



eminence. All these are bony landmarks which can be felt without difficulty in the living subject, and the glabella and nasion provide reference points for the surgeon in certain intracranial operations.

The **orbital opening** is more or less quadrangular in shape. Its *supra-orbital margin* is formed entirely by the frontal bone and, at the junction of its sharp lateral two-thirds with its rounded medial third, it presents the supra-orbital notch (or foramen, as the case may be), which transmits the supra-orbital vessels and nerve. The *lateral margin* is formed almost entirely by the frontal process of the zygomatic bone, but it is completed above by the zygomatic process of the frontal bone, and the suture which connects these two bones can be felt in the living subject as a slight depression. The zygomatic bone laterally, and the maxilla medially, share in the formation of the *infra-orbital margin*. Both these margins

are sharp and can be felt easily through the skin. The *medial margin* is not so clear-cut; it is formed above by the frontal bone and below by the lacrimal crest of the frontal process of the maxilla, which is sharp and distinct in its lower half only.

The **anterior bony aperture of the nose** is pear-shaped, wider below than above and bounded by the nasal bones and the maxillæ. The two nasal bones articulate with each other in the median plane and both articulate with the frontal bone above. On each side the nasal bone articulates behind with the frontal process of the maxilla, but its lower border, to which the upper nasal cartilage (fig. 1003) is attached in the fresh specimen, is free and forms the upper boundary of the bony nasal aperture.

The maxillæ take a very large share in the formation of the skeleton of the face, and it is the growth of these bones which is responsible for the elongation of the face that occurs between the ages of 6 and 12. It is only the anterior surface of the maxilla which is visible in the norma frontalis. Medially this surface presents the well-marked *nasal notch*, which forms the lower border and the adjoining part of the lateral border of the anterior bony aperture of the nose. A prominent, sharp projection marks the meeting of the two maxillæ in the lower boundary of the aperture and is termed the *anterior nasal spine*. It can be identified in the lower border of the free part of the nasal septum in the living subject. About 1 cm. below the infra-orbital margin the maxilla is perforated by the *infra-orbital foramen*, which transmits the infra-orbital vessels and nerve; it lies on, or just lateral to, a vertical line passing through the supra-orbital notch. The *alveolar process* of the maxilla, which provides the sockets for the maxillary teeth, can be examined most satisfactorily in the norma basalis (p. 256). The *zygomatic process* of the maxilla is a short but stout projection from the upper and lateral part of the anterior surface of the bone. Its upper surface is oblique and articulates with the zygomatic bone at the zygomaticomaxillary suture. Inferiorly it presents a free lower border, which meets the body of the bone above the first molar tooth, and can be palpated through the skin of the cheek or through the mucous membrane of the vestibule of the mouth. The *frontal* process of the maxilla ascends behind the nasal bone, forming the lower part of the medial margin of the orbital opening, and reaches the frontal bone. It will be examined subsequently, both in the orbit and in the nose.

The *prominence of the cheek* below and lateral to the orbit is produced by the zygomatic bone. It is the convex lateral surface of the bone which can be examined both in the norma frontalis and in the norma lateralis. Its contributions to the margins of the orbital opening and its articulation with the maxilla have already been noted.

The mandible is described on p. 277.

Particular features.—The *glabella* may show the remains of the frontal suture, which in about 9 per cent. of skulls extends upwards to the coronal suture. It indicates that the adult frontal bone is formed by the fusion of right and left halves, which ossify independently of each other. The medial part of the *superciliary arch* gives origin to the corrugator muscle. The nasal part of the frontal bone and the frontal process of the maxilla give origin to the orbital part of the orbicularis oculi muscle. Between these two areas the medial palpebral ligament is attached to the frontal process of the maxilla (fig. 381). The procerus muscle arises from the nasal bone near the median plane. The lower margin of the nasal bone usually presents a small notch, converted into a foramen in the fresh specimen by the lateral cartilage of the nose. It transmits the external nasal nerve. In front of the orbicularis oculi the levator labii superioris alæque nasi (angular head of the quadratus labii superioris) takes origin from the frontal process of the maxilla. More laterally, the levator labii superioris (infra-orbital head of the quadratus labii superioris) arises from the maxilla in the interval between the infra-orbital margin and the foramen of the same name.

The stout root of the canine tooth produces an elevation termed the *canine eminence*, which separates the *canine fossa* on its lateral side from the *incisive fossa* on its medial side. The levator anguli oris (m. caninus) arises from the canine fossa, while the incisive fossa gives origin to the compressor naris muscle (transverse part of the m. nasalis). Below these fossæ the anterior surface of the maxilla gives origin to the depressor septi, the dilator naris (alar part of m. nasalis) and the incisive muscle of the upper lip.

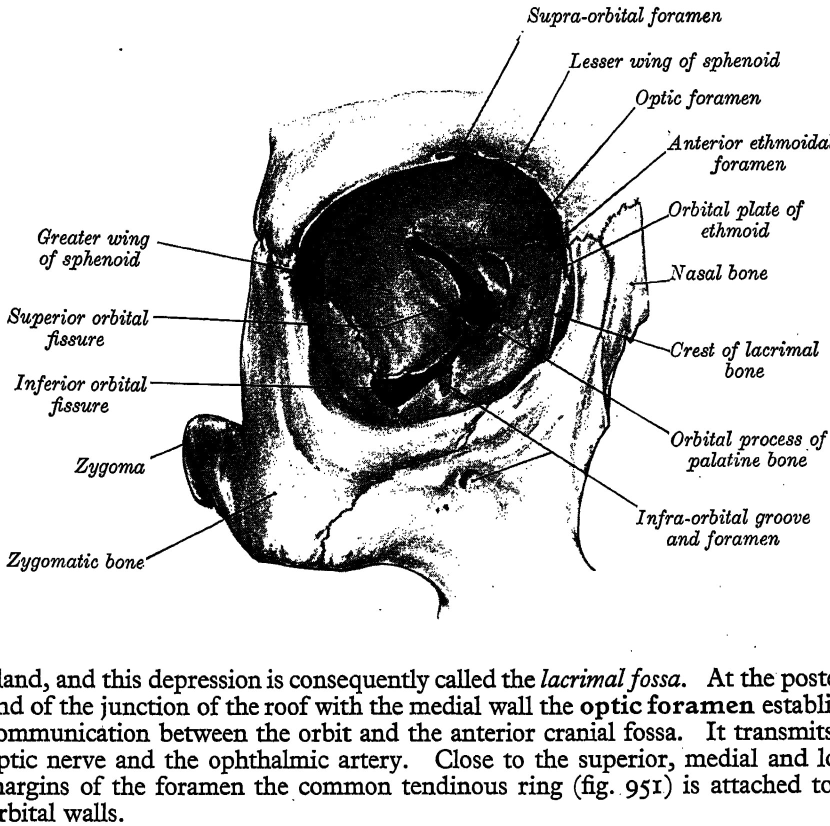
The zygomatic bone is marked opposite the junction of the infra-orbital and lateral margins of the orbit by the small *zygomaticofacial foramen*, which transmits the nerve of the same name and a minute artery. The foramen, which is sometimes duplicated, opens laterally and downwards. Below the foramen the zygomatic bone gives origin to the zygomaticus minor muscle (zygomatic head of the m. quadratus labii superioris), and more laterally to the zygomaticus major muscle (m. zygomaticus).

The Orbit (figs. 312–315)

General features.—The **orbits** are a pair of roomy cavities which contain the eye-balls, their associated muscles, vessels, nerves, etc., and most of the lacrimal apparatus, together with a variable amount of soft fat. The orbital cavity is pyramidal in shape; its base is the orbital opening on the face, and its long axis is directed backwards and medially. Each orbit presents a roof, a floor, medial and lateral walls, a base or orbital opening and an apex.

The **roof** is a thin, gently concave plate of bone which intervenes, throughout most of its extent, between the orbit and the part of the brain in the anterior cranial fossa. In its anteromedial part it is separated into two laminæ by the frontal sinus, which is an air-space in the bone communicating with the nasal cavity. In its anterolateral part it is deeply hollowed out to contain the orbital part of the lacrimal

Fig. 312.—The right orbit, viewed from in front.



gland, and this depression is consequently called the *lacrimal fossa*. At the posterior end of the junction of the roof with the medial wall the **optic foramen** establishes communication between the orbit and the anterior cranial fossa. It transmits the optic nerve and the ophthalmic artery. Close to the superior, medial and lower margins of the foramen the common tendinous ring (fig. 951) is attached to the orbital walls.

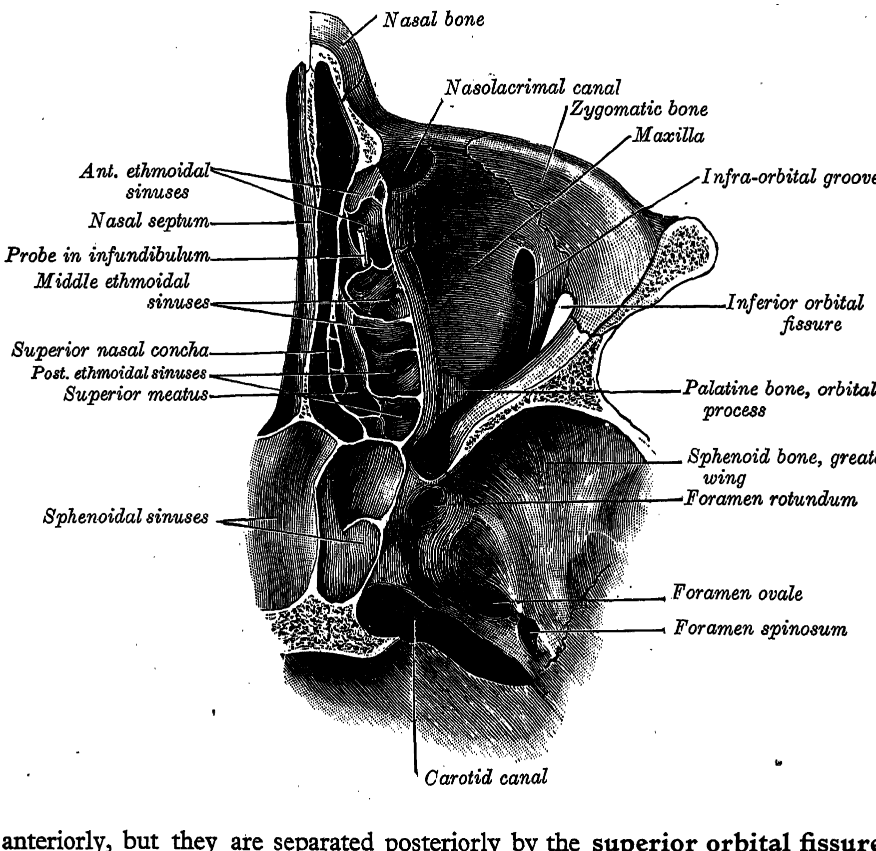
The **medial wall** (fig. 314) is exceedingly thin, except at its most posterior part, and slopes gently downwards and laterally into the floor. Anteriorly, it presents the *lacrimal groove*, which lodges the lacrimal sac. The groove communicates below with the nasal cavity through the *nasolacrimal canal*, which is little more than 1 cm. long and transmits the nasolacrimal duct. The floor of the groove separates the orbital cavity from the nasal cavity, but behind the groove the air-containing ethmoidal sinuses intervene between the two cavities. Posteriorly the medial wall is related to the anterior part of the sphenoidal sinus and forms its lateral wall.

The **floor** of the orbit (fig. 313) is relatively thin and constitutes, in most of its extent, the roof of the maxillary sinus (fig. 314). It is not quite horizontal, but faces upwards and slightly laterally. In front it is directly continuous with the lateral wall, but posteriorly the two walls are separated by the **inferior orbital fissure.** This fissure leads into the orbit from the pterygopalatine fossa posteriorly,

and from the infratemporal fossa anteriorly. The maxillary nerve is the most important structure which it transmits. The lower lip of the fissure is notched by the *infra-orbital groove*, which passes forwards in the floor, sinking into it anteriorly and becoming converted into the *infra-orbital canal*. The anterior opening of the canal forms the infra-orbital foramen. The groove, canal and foramen transmit the infra-orbital nerve, which is the continuation of the maxillary nerve. Through the anterior part of the inferior orbital fissure a vein passes to connect the inferior ophthalmic vein with the veins of the pterygoid plexus in the infratemporal fossa.

The **lateral wall** (fig. 315) is the thickest of the orbital walls, especially behind, where it separates the orbit from the middle cranial fossa. In front it is interposed between the orbit and the temporal fossa. The lateral wall and the roof are continuous

FIG. 313.—A horizontal section through the nasal and orbital cavities. Superior aspect.



anteriorly, but they are separated posteriorly by the **superior orbital fissure.** This important fissure is noticeably widened at its medial end (fig. 312), and its long axis is directed medially, backwards and slightly downwards. It communicates with the middle cranial fossa and transmits the oculomotor, trochlear and abducent nerves and the terminal branches of the ophthalmic nerve, together with the ophthalmic veins. Where the fissure begins to widen its lower border is marked by a bony projection, often sharp in character, which gives attachment to the lateral part of the common tendinous ring for the origin of certain muscles of the eyeball (fig. 951).

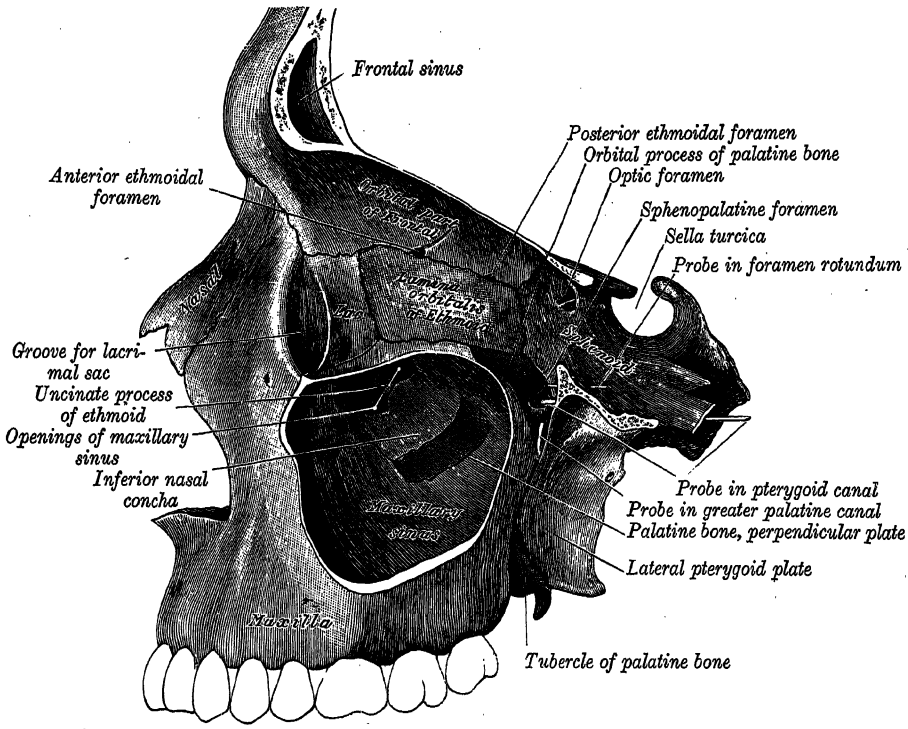
The boundaries of the **orbital opening** have already been described (p. 245). The **apex** of the orbit is at the medial end of the superior orbital fissure.

Particular features.—The roof of the orbit is formed almost entirely by the orbital plate of the frontal bone, but the under surface of the lesser wing of the sphenoid forms its posterior part. The suture between the two bones is almost horizontal. The *optic foramen* lies between the two roots of the lesser wing and is bounded medially by the body of the

sphenoid bone. Near the junction of the roof and the medial wall, and close to the orbital opening, the small *trochlear fossa* (occasionally replaced by a trochlear spine) gives attachment to the fibrous pulley through which the tendon of the superior oblique muscle of the eyeball passes.

The **medial wall** (fig. 314) is limited in front by the lacrimal crest of the frontal process of the maxilla, which gives attachment to the orbicularis oculi muscle and to the lacrimal fascia. Behind this crest the maxilla and the lacrimal bone participate in the formation of the *lacrimal groove*, and the suture between them can be seen in its floor. The upper opening of the *nasolacrimal canal* lies at the lower end of the groove, and its lateral boundary is formed by the tiny *hamulus of the lacrimal bone*, which curves forwards and medially to meet the lower part of the lacrimal crest of the frontal process of the maxilla. The posterior border of the groove is formed for the most part by the *crest of the lacrimal bone*, which gives origin to the lacrimal part of the orbicularis oculi muscle (p. 527) and to the lacrimal fascia,

FIG. 314.—The medial wall of the left orbit.



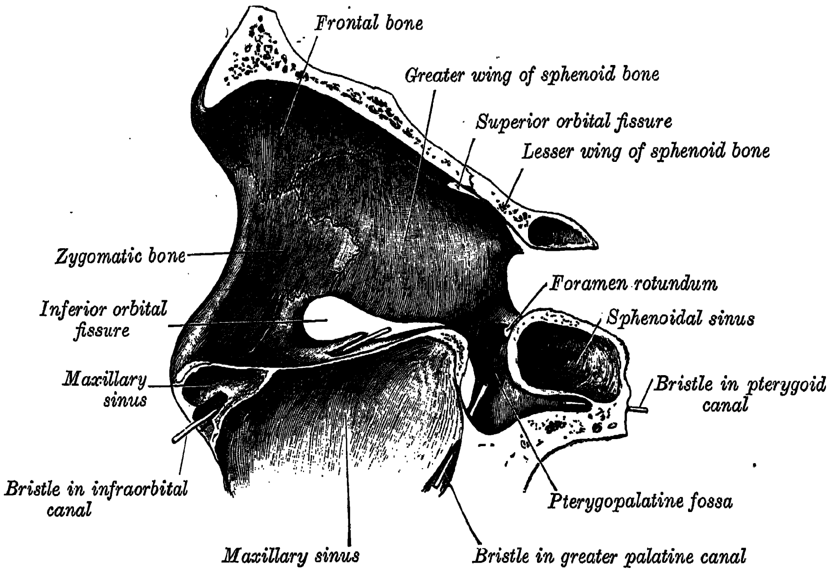
which bridges over the groove. The posterior part of the orbital surface of the lacrimal bone is flattened, and articulates behind, by an almost vertical suture, with the orbital plate of the labyrinth of the ethmoid bone. The frontolacrimal suture and the lacrimomaxillary suture indicate the other limits of the orbital aspect of the lacrimal bone. The *orbital plate of the ethmoid* makes the largest contribution to the medial wall. Almost rectangular in outline, it consists of very thin bone, which forms the lateral walls of the ethmoidal sinuses. Above, it articulates with the medial edge of the orbital plate of the frontal bone, and the line of this suture is interrupted by the *anterior* and *posterior ethmoidal foramina*, which lead into minute bony canals. These canals transmit vessels and nerves of the same names—the posterior ethmoidal nerve, however, is often absent—and lead into the anterior cranial fossa, where they open at the lateral edge of the cribriform plate. Below, the orbital plate articulates with medial edge of the orbital surface of the maxilla and, at its most posterior part, with the orbital process of the palatine bone. Posteriorly the orbital plate of the ethmoid articulates with the body of the sphenoid, which forms the most posterior part of the medial wall of the orbit and is separated from the roof by the optic foramen.

The **floor** of the orbit (fig. 313) is formed for the most part by the orbital surface of the maxilla and, in its anterolateral part, by the zygomatic bone. At its posteromedial corner, where the floor meets the medial wall, a small triangular area is formed by the orbital process of the palatine bone. In addition to the maxillary nerve the *inferior orbital fissure* transmits the infra-orbital vessels, the zygomatic nerve, and a few minute twigs from the sphenopalatine ganglion to the orbital periosteum. The fissure is bounded above by the

greater wing of the splenoid, below by the maxilla and the orbital process of the palatine bone, and laterally by the zygomatic bone or the zygomaticomaxillary suture. In from 35 to 40 per cent. of skulls the maxilla and the sphenoid bone articulate with each other at the anterior end of the fissure and exclude the zygomatic bone from it. In the anteromedial part of the floor, just lateral to the hamulus of the lacrimal bone, a small depression may mark the origin of the inferior oblique muscle from the maxilla.

The lateral wall of the orbit (fig. 315) is formed by the orbital surface of the greater wing of the sphenoid behind, and by the orbital surface of the frontal process of the zygomatic bone in front. These two bones meet at the sphenozygomatic suture. This aspect of the zygomatic bone presents the openings of minute canals for the zygomaticofacial and the zygomaticotemporal nerves. The former lies near the junction of the floor of the orbit

Fig. 315.—The lateral wall of the right orbit.



with its lateral wall; the latter lies at a slightly higher level, and may be close to the sphenozygomatic suture. The *superior orbital fissure* is bounded above by the lesser and below by the greater wing of the sphenoid and medially by the body of that bone. The lacrimal and frontal nerves traverse the narrow, lateral part of the fissure, which transmits also the meningeal branch of the lacrimal artery and the occasional orbital branch of the middle meningeal artery. The trochlear nerve is situated more medially and lies just outside the common tendinous ring. The two divisions of the oculomotor nerve, the nasociliary and the abducent nerves pass within the common tendinous ring, and therefore traverse the wider medial part of the fissure. They may be accompanied by the superior and inferior ophthalmic veins, but the superior ophthalmic veins may accompany the trochlear nerve and the inferior ophthalmic veins may pass through the medial end of the fissure below the common tendinous ring.

NORMA OCCIPITALIS

The outline of the skull, as viewed from behind, is shaped like a broad arch, being convex above and on each side, and flattened below. The *lambdoid suture*, which has already been seen in part, can now be traced through its entire length. The serrations are deep and prominent above and behind, but become much less conspicuous as the suture is traced downwards and forwards. Inferiorly the lambdoid suture meets the *occipitomastoid suture* and the *parietomastoid suture* at the posteroinferior angle of the parietal bone. The posterior portions of the parietal bones, the parietal eminences and foramina, which are visible on the norma occipitalis, have already been viewed from above.

The most outstanding feature of the norma occipitalis is the **external occipital protuberance** (fig. 316) and the ridges which lead away from it. The protuberance is situated in the lower part of the field in the median plane and may be overhanging. It can readily be identified in the living subject, as it lies at the upper end of the median furrow at the back of the neck. The *superior nuchal*

lines are the ridges, often sharp in character, which pass laterally from the protuberance. They form the boundary lines between the scalp and the back of the neck, and the portions of the occipital bone below them, now seen in perspective, will be examined in the norma basalis. The *highest nuchal lines*, when present, are curved bony ridges, which lie about 1 cm. above the superior nuchal lines. Commencing at the upper part of the protuberance they are more arched than the superior nuchal lines.

The mastoid process and the mastoid part of the temporal bone can be seen in the inferolateral part of this aspect of the skull, but they can be examined much more satisfactorily in the norma lateralis.

Particular features.—The *inion* is the name given to the most salient point on the external occipital protuberance in the median plane. The lower part of the protuberance gives attachment to the upper end of the ligamentum nuchæ, and its upper part gives origin to fibres of the trapezius muscle, which arises also from the adjoining part of the *superior nuchal line*. The lateral part of the superior nuchal line (fig. 342) gives insertion to the posterior fibres of the sternomastoid and, under cover of that muscle, to fibres of the splenius capitis. The *highest nuchal line* gives attachment medially to the epicranial aponeurosis (galea aponeurotica) and laterally to the occipital belly of the occipitofrontalis (epicranius) muscle.

NORMA LATERALIS (fig. 316)

When the skull, minus the mandible (which is described on p. 277), is examined from the side, it will be found that the anterior, superior and posterior parts have been described already in the normæ frontalis, verticalis and occipitalis, respectively. The central area, however, presents many important features which have not yet been described. It is limited above by the **temporal line**, which corresponds to the peripheral limit of the origin of the temporalis muscle. This line arches upwards and backwards from the zygomatic process of the frontal bone across the coronal suture to the parietal bone. Salient at first, it can be felt easily through the skin, but as it arches across the parietal bone it is much less distinct and is usually represented by two curved ridges, which enclose between them a smooth and often polished strip of bone. Posteriorly the upper of these two lines fades away, but the lower becomes more prominent as it curves downwards and forwards across the squamous part of the temporal bone, just above its union with the mastoid portion. This part of the line, which is termed the *supramastoid crest*, becomes continuous with the posterior root of the zygomatic process. Throughout the whole of its extent the temporal line marks the periphery of the temporalis muscle and its covering fascia. On the parietal bone the muscle arises from the lower ridge, while the fascia is attached to the upper ridge and the bone below.

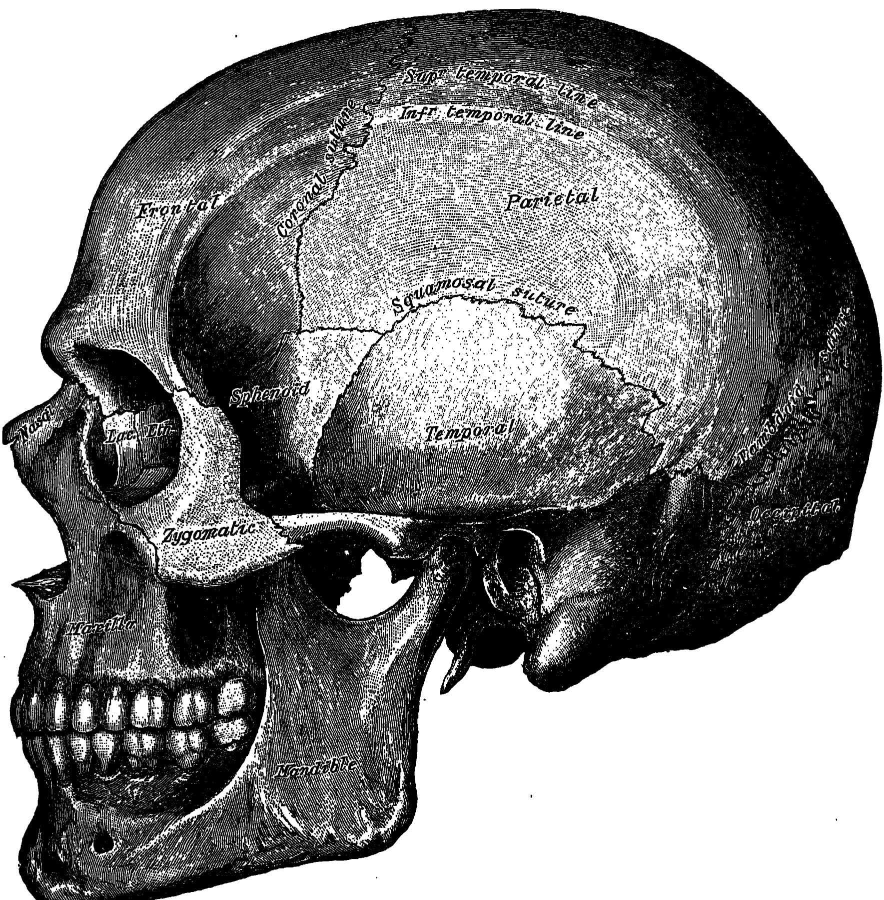
The **temporal fossa** is the region bounded by the zygomatic arch, the temporal line and the frontal process of the zygomatic bone, and its floor gives origin to the temporalis muscle. An irregularly H-shaped arrangement of sutures can be seen in the anterior part of the fossa, the more or less horizontal limb of the H being formed by the suture between the antero-inferior part of the parietal and the upper border of the greater wing of the sphenoid bone. In this situation the frontal, the sphenoid, the parietal and the squamous part of the temporal bone closely adjoin one another (fig. 316), and a small circular area can be outlined so as to include portions of all four. This area is termed the **pterion**, and its centre—which is an important landmark for the surgeon—lies 3·5 cm. behind and 1·5 cm. above the frontozygomatic suture. The anterior wall of the fossa is formed by the posterior aspect of the upper part of the zygomatic bone, the adjoining part of the greater wing of the sphenoid and a small portion of the frontal bone. It is interposed between the fossa and the orbit. Inferiorly the fossa communicates freely with the infratemporal fossa through the gap which separates the zygomatic arch from the rest of the skull. In this situation the tendon and some fleshy fibres of the temporalis descend to reach their insertion into the mandible (p. 280).

The **zygomatic arch**, which is formed by the temporal process of the zygomatic bone and the zygomatic process of the temporal bone, is easily felt through the skin where the cheek and the region of the temple meet each other. Its sharp, upper border is obscured by the attachment of the temporal fascia, and its lower border by the origin of the masseter muscle, which arises also from its deep surface. The

arch stands away from the rest of the skull and is separated from it by a gap which is deeper in front than behind. Anteriorly, the arch is crossed by the zygomatico-temporal suture, which is directed obliquely downwards and backwards.

The *zygomatic process of the temporal bone*, or *zygoma*, widens posteriorly as it approaches the squamous part, and divides into an anterior and a posterior root. The *anterior root* passes medially in front of the *articular fossa* for the head of the mandible and becomes continuous with the smooth *articular eminence*, which forms the anterior boundary of the fossa. The *posterior root* passes backwards, lateral to the fossa, and its upper border becomes continuous with the supramastoid crest of the temporal bone.

FIG. 316.—The skull. Lateral aspect. (Norma lateralis.)

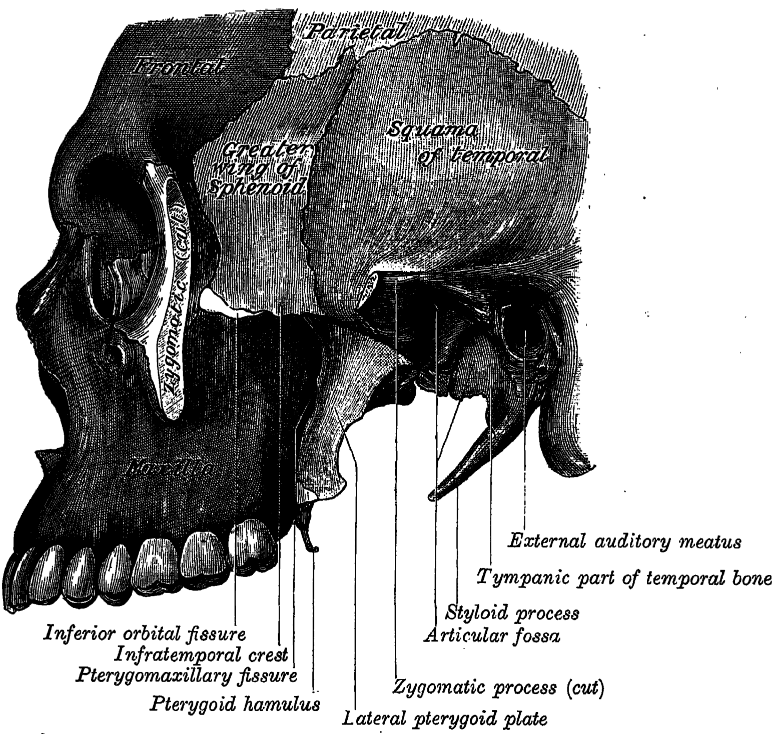


The **external auditory meatus** opens immediately below the posterior part of the posterior root of the zygoma. The margins of the orifice are roughened, especially below and in front, for the attachment of the cartilaginous segment of the meatus. The upper margin and the upper part of the posterior margin are formed by the squamous part of the temporal bone; the anterior margin, the inferior margin and the lower part of the posterior margin are formed by the *tympanic plate*. The squamotympanic suture can be seen without difficulty at the anterosuperior part of the opening, but the suture on the posterior wall is usually obliterated in the adult skull. Below the orifice of the meatus the tympanic plate is drawn downwards, forming a somewhat triangular roughened area. Immediately above and behind the meatus there is frequently a small depression with a bony spicule in its anterior margin (*suprameatal spine*). This lies within the area of the *suprameatal triangle*, which is bounded above by the supramastoid crest, in front by the postero-superior margin of the orifice of the meatus and behind by a vertical line, drawn as a tangent to the curve of the posterior margin of the meatal orifice. This triangle

forms the lateral wall of the tympanic antrum (p. 297), which is an air-space of great importance to the surgeon and is contained in the petrous part of the temporal bone.

Behind the meatus the norma lateralis is formed by the **mastoid portion of the temporal bone.** Above, it is continuous with the squamous portion in front, but, behind, it possesses a free upper border which articulates with the postero-inferior part of the parietal bone at the horizontal *parietomastoid suture.* Its posterior border is free and articulates with the squamous part of the occipital bone at the *occipitomastoid suture.* These two sutures meet each other at the lateral extremity of the lambdoid suture. The **mastoid process** (fig. 316) is a strong, nipple-shaped projection from the lower part of the mastoid portion of the temporal bone. It lies immediately behind the external auditory meatus, but at a lower level, and its anterior part can be felt through the skin under cover of the lobule of the auricle. The *mastoid foramen* pierces the bone above the base of the mastoid

FIG. 317.—The left infratemporal fossa.



process and near or on the occipitomastoid suture; it transmits an important emissary vein from the sigmoid sinus.

The **styloid process** (fig. 316) is a slender, elongated projection which, although attached to the norma basalis, can be examined conveniently at this stage. It lies a short distance in front of the mastoid process but is on a deeper plane, its base being partly ensheathed by the lower margin of the tympanic plate. Directed downwards, forwards and slightly medially, its tip is usually hidden by the posterior margin of the ramus of the mandible, when that bone is in place. From its extremity the stylohyoid ligament passes downwards and forwards to the lesser horn of the hyoid bone (p. 284), which is therefore suspended from the skull.

The **infratemporal fossa** (fig. 317) is an irregularly shaped space which lies behind the posterior surface of the maxilla. It communicates with the temporal fossa through the gap between the zygomatic arch and the side of the skull. Medial to this gap, the roof is formed by the infratemporal surface of the greater wing of the sphenoid, and a small part of the squamous temporal. In this situation the greater wing is pierced by the foramen ovale and the foramen spinosum. The medial wall is formed by the lateral pterygoid plate. These walls are con-

sidered in detail in connexion with the norma basalis (p. 258). Behind, below and on the lateral side the fossa is freely open. The anterior and medial walls meet below but they are separated above by the *pterygomaxillary fissure*, through which the infratemporal fossa communicates with the pterygopalatine fossa. The upper end of the pterygomaxillary fissure is continuous with the posterior end of the *inferior orbital fissure*, which is placed between the upper part of the posterior surface of the maxilla and the greater wing of the sphenoid. This fissure connects the infratemporal fossa with the orbit and transmits the maxillary nerve and an important venous connexion between the inferior ophthalmic vein and the pterygoid venous plexus.

The **pterygopalatine fossa** is a small pyramidal space situated below the apex of the orbit. It communicates with the infratemporal fossa through the pterygomaxillary fissure and with the orbit through the posterior end of the inferior orbital fissure. The foramen rotundum opens on its posterior wall, and the maxillary nerve, which runs forwards and laterally from the foramen across the upper part of the fossa, is the most important of its contents.

Particular features.—The floor of the *temporal fossa* is marked by a few small vascular furrows, of which the most constant are above the external auditory meatus and are produced by the middle temporal vessels. In the anterior wall of the fossa the *zygomaticotemporal foramen* pierces the temporal surface of the zygomatic bone in an upward and backward direction. It transmits the zygomaticotemporal nerve and a minute artery. In addition to the tendon of the temporalis muscle, the deep temporal vessels and nerves traverse the gap between the zygomatic arch and the rest of the skull and ascend into the temporal fossa.

As the anterior root of the zygoma springs from the process, it is marked by a small tubercle, termed the *tubercle of the root of the zygoma*. It gives attachment to fibres of the temporomandibular ligament (fig. 508) and can be felt through the skin immediately in front of the head of the mandible. Behind the articular fossa a small downward projection from the posterior root of the zygoma (sometimes termed the *post-glenoid tubercle*) meets the tympanic plate at the anterosuperior part of the orifice of the external auditory meatus, and its anterior aspect takes a small part in the formation of the articular fossa.

The posterior part of the lateral surface of the *mastoid process* and its rounded apex are roughened by the insertions of the sternomastoid, splenius capitis and longissimus capitis muscles, in that order from before backwards. In front of, and parallel to, this roughened area, the partially obliterated remains of the squamomastoid suture may be visible. From the position of the suture it will be obvious that the floor of the suprameatal triangle, and therefore the lateral wall of the tympanic antrum, is formed by the squamous part of the temporal bone. The tympanomastoid fissure is placed on the anterior aspect of the base of the process. The outer opening of the mastoid canaliculus (p. 263), which transmits the auricular branch of the vagus nerve, is placed between the lips of the fissure.

The *styloid process* is covered on its lateral aspect by the parotid gland and intervenes between that structure and the internal jugular vein. It gives origin to three muscles. The stylohyoid arises by a delicate tendon from its posterior aspect, about midway between the tip and the base; the styloglossus from the tip and the adjacent part of the anterior aspect; and the stylopharyngeus from the medial aspect of the base. The stylomandibular ligament is attached to the lateral aspect of the process in its lower part and the stylohyoid ligament to its tip. Behind the base of the process the facial nerve emerges from the stylomastoid foramen and passes forwards lateral to the process in the substance of the parotid gland.

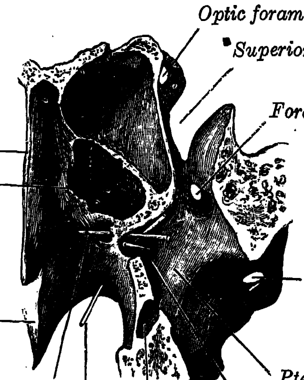
The **infratemporal fossa** (fig. 317) contains the lower part of the temporalis muscle as it passes to be inserted into the coronoid process. The maxillary (internal maxillary) artery and its branches and the pterygoid plexus of veins lie deep to the temporalis in relation to the lower head of the lateral pterygoid muscle. The deepest part of the fossa is occupied by the medial pterygoid muscle, the mandibular nerve and the chorda tympani. The mandibular nerve enters the fossa through the foramen ovale in its roof and breaks up into its terminal branches under cover of the lateral pterygoid muscle. Its branches traverse the fossa and most of them leave it to gain other regions. The chorda tympani enters the fossa on the medial side of the spine of the sphenoid and runs downwards and forwards to join the lingual nerve before it emerges at the lower border of the lateral pterygoid muscle. The maxillary nerve appears at the upper part of the fossa as it passes from the upper end of the pterygomaxillary fissure to the inferior orbital fissure. The *anterior wall* of the fossa is pierced by two or three small foramina which transmit the posterior superior dental (alveolar) vessels and nerves. It is limited below by the alveolar part of the maxilla in the region of the molar teeth, and in this situation a horizontal strip of the bone is closely covered with the mucous membrane of the gum. Immediately above this strip the bone gives origin to the upper fibres of the buccinator muscle, which extends backwards behind the last molar tooth on to the tuberosity of the maxilla. The medial wall of the fossa, formed by the lateral pterygoid plate, is completed below and in front by the tubercle

(pyramidal process) of the palatine bone, which is wedged in between the tuberosity of the maxilla and the lateral pterygoid plate. The superficial head of the medial pterygoid muscle arises from this surface of the palatine tubercle and the adjoining part of the maxillary tuberosity.

The **pterygomaxillary fissure** is a triangular interval formed by the divergence of the maxilla from the pterygoid process of the sphenoid bone. It transmits the terminal part of the maxillary (internal maxillary) artery to the pterygopalatine fossa, and its uppermost part gives passage to the maxillary nerve, which appears for a very short part of its course in the upper part of the infratemporal fossa before it enters the inferior orbital fissure. The **inferior orbital fissure** leads forwards into the orbit. Its lower border is marked by a notch which lodges the maxillary nerve and forms the posterior end of the infra-orbital groove.

The **pterygopalatine fossa** (fig. 318) is bounded above by the inferior surface of the body of the sphenoid and the orbital process of the palatine bone on the medial side, but laterally it communicates with the orbit through the posterior end of the inferior orbital fissure. It is bounded behind by the root of the pterygoid process and the adjoining part of the anterior surface of the greater wing of the sphenoid; medially, by the upper part of the

Fig. 318.—A section showing the posterior wall of the pterygopalatine fossa.



perpendicular plate of the palatine bone with its orbital and sphenoidal processes; in front, by the upper part of the posterior surface of the maxilla. On the lateral side it communicates with the infratemporal fossa through the pterygomaxillary fissure, and inferiorly its anterior and posterior walls come into apposition. The fossa contains the maxillary nerve, the sphenopalatine ganglion and the terminal part of the maxillary (internal maxillary) artery. In addition to the pterygomaxillary and inferior orbital fissures five openings lead to or from the fossa. Of these, three are situated on the posterior wall, viz., the foramen rotundum, the pterygoid canal and the palatinovaginal (pharyngeal) canal, in that order downwards and medially. The *foramen rotundum* transmits the maxillary nerve from the middle cranial fossa; the *pterygoid canal*, the nerve and artery of the same name from the lower part of the anterior wall of the foramen lacerum; and the *palatinovaginal* (pharyngeal) *canal*, which is frequently double (p. 260), the pharyngeal nerve and artery to the roof of the posterior nasal aperture. The fourth foramen is placed on the medial wall and is termed the *sphenopalatine foramen* (fig. 329). It is bounded above by the body of the sphenoid, in front by the orbital process of the palatine bone, behind by the sphenoidal process and below by the upper border of the perpendicular plate. It transmits the long and short sphenopalatine nerves (nasopalatine and posterior superior lateral nasal nerves) and the artery of the same name. The fifth foramen is placed inferiorly at the junction of the anterior and posterior walls, and leads into the *greater palatine canal* (pterygopalatine canal). Bounded anterolaterally by the maxilla, and posteromedially by the perpendicular plate of the palatine bone, this canal transmits the greater and lesser palatine nerves and vessels, which appear at the greater and lesser palatine foramina on the bony plate (p. 256).

NORMA BASALIS (BASIS CRANII EXTERNA), (figs. 319–322)

The external surface of the base of the skull, excluding the mandible, is bounded in front by the incisor teeth of the maxillæ, behind by the superior

nuchal lines of the occipital bone, and laterally by the remaining teeth, the zygomatic arch and its posterior root, and the mastoid process. It is very irregular and, unlike the internal surface, shows no natural subdivision into regions suitable for descriptive purposes. It is, however, useful to divide the area into anterior, middle and posterior parts. The anterior part, which is formed by the hard palate and the alveolar arches is on a lower level than the part behind. The remainder of the surface is divided, in an arbitrary manner, into a middle and a posterior part by a transverse line drawn through the anterior margin of the foramen magnum.

FIG. 319.—The external surface of the left half of the base of the skull. (Norma basalis.)

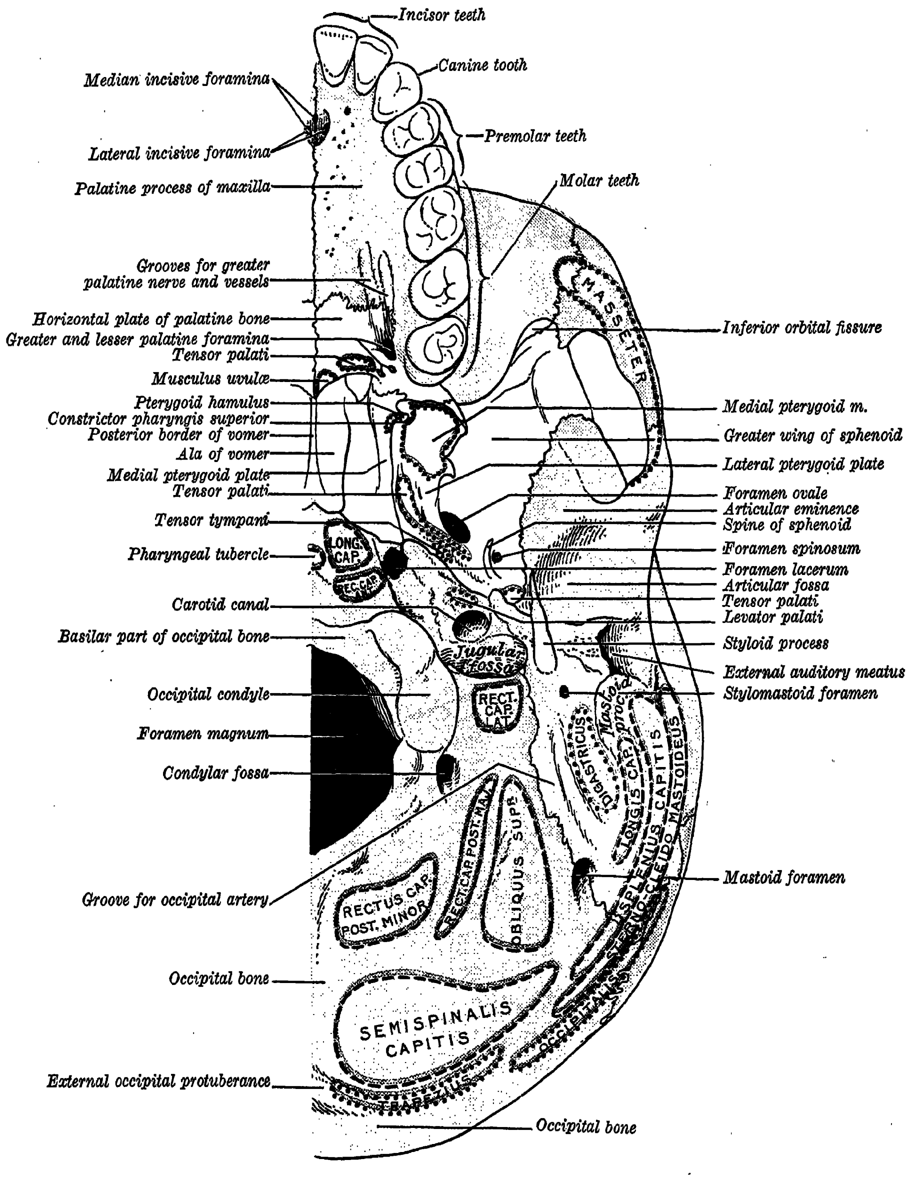
The Anterior Part of the Norma Basalis

The **bony palate** (fig. 321) lies within the arch formed by the teeth of the maxillæ and the alveolar processes. It is formed by the palatine processes of the maxillæ and the horizontal plates of the palatine bones, which are separated from one another by a cruciform suture, made up of the intermaxillary, interpalatine and palatomaxillary sutures. Owing partly to the downward projection of the alveolar arches, the palate is arched both from before backwards and from side to side. The depth and the breadth of the palatine vault are subject to considerable variation but are always greatest in the region of the molar teeth. A deep fossa, termed the *incisive fossa*, lies in the median plane anteriorly. The *lateral incisive foramina*, which lead into the incisive canals, are situated in its lateral walls; the *median incisive foramina*, which are present in some skulls, open on its anterior and posterior walls. The *greater palatine foramen*, which is the lower orifice of the canal of the same name, opens close to the lateral border of the palate immediately behind the palatomaxillary suture. A vascular groove, deep behind and becoming shallower in front, leads forwards away from the foramen. The *lesser palatine foramina*, usually two in number, are situated behind the greater foramen. They pierce the *tubercle* (pyramidal process) *of the palatine bone*, which projects backwards and laterally from the posterolateral corner of the bony palate and becomes wedged into the notch between the lower ends of the two pterygoid plates. The vault of the bony palate is uneven, pierced by numerous small foramina and marked by depressions for the palatine glands. Near the posterior border it presents a slightly curved ridge of variable prominence, termed the *palatine crest*, which commences behind the greater palatine foramen and runs medially. The posterior

border of the bony palate is free and projects backwards in the median plane to form the *posterior nasal spine.*

The *alveolar arch* provides sixteen sockets (alveoli) for the roots of the teeth. These sockets vary in size and depth and are single or subdivided by septa according to the teeth which they contain.

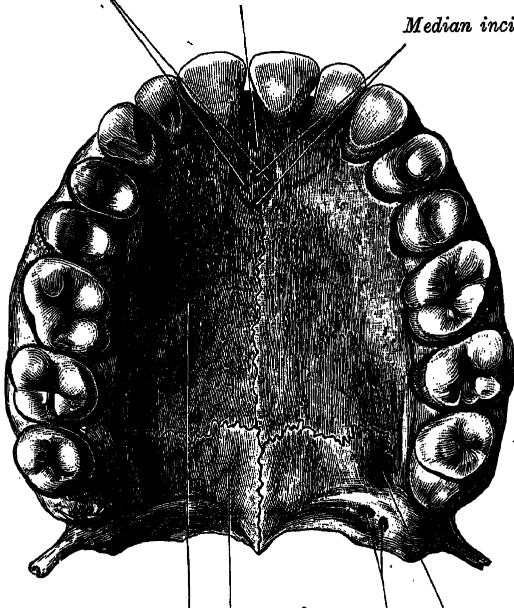
Fig. 320.—Key to fig. 319.



Particular features.—The *lateral incisive foramen* transmits the terminal branches of the greater palatine vessels and the long sphenopalatine (nasopalatine) nerve. When median incisive foramina are present the left sphenopalatine nerve passes through the anterior and the right through the posterior foramen. The lateral incisive foramina are placed in the line of fusion of the os incisivum (premaxilla) with the maxilla proper, and represent a primitive communication between the mouth and the nose. In young skulls the suture line between the os incisivum and the maxilla may be visible, extending from the posterior part of the incisive fossa to the septum between the sockets of the lateral incisor and canine teeth. The *greater palatine foramen* transmits the greater palatine nerve and vessels, and

the vessels groove the lateral part of the palate as they run forwards to the incisive fossa. The *lesser palatine foramina*, usually two, sometimes one and occasionally three in number, perforate the inferior and medial aspects of the tubercle of the palatine bone; they transmit the lesser palatine nerves. The *palatine crest*, which commences on the tubercle and extends on to the horizontal plate of the palatine bone, gives attachment to part of the tendon of the tensor palati muscle. The free posterior border of the bony palate gives attachment to the palatine aponeurosis and the posterior nasal spine to the musculus uvulæ.

Fig. 321.—The bony palate and the alveolar arch. Inferior aspect.



The Middle Part of the Norma Basalis

The middle part of the external surface of the base of the skull (fig. 319) extends from the posterior border of the bony palate to an arbitrary line drawn transversely through the anterior margin of the foramen magnum. In the median plane anteriorly the *posterior border of the vomer* separates the two *posterior nasal apertures*. Immediately behind the vomer the posterior part of the inferior surface of the body of the sphenoid is directly continuous with the inferior surface of the *basilar part of the occipital bone*, which forms a broad bar of bone extending backwards and downwards to the foramen magnum. It is convex from side to side and wider behind than in front. A short distance in front of the foramen magnum it is marked in the median plane by a small elevation, termed the *pharyngeal tubercle*, which gives attachment to the highest fibres of the superior constrictor muscle of the pharynx.

Behind the third molar tooth the **pterygoid process** descends from the junction of the greater wing and the body of the sphenoid bone. It has two laminæ, termed the medial and lateral pterygoid plates, which are separated from each other by a V-shaped interval, directed backwards and somewhat laterally and named the *pterygoid fossa*. Anteriorly the two pterygoid plates are fused to each other, except inferiorly, where they are separated by a narrow gap which is occupied in the articulated skull by the *tubercle* (pyramidal process) of the palatine bone, and the suture lines can usually be identified. Above the pterygoid fissure the two plates are fused to each other On the medial side they articulate with the posterior border of the perpendicular plate of the palatine bone in front, and form with it the flattened

area of bone which lies in the lateral wall of the posterior nasal aperture and nasal part of the pharynx. On the lateral side the fused laminæ are separated from the posterior surface of the maxilla in front by the pterygomaxillary fissure (fig. 249). The *medial pterygoid plate* is the narrower of the two and projects directly backwards. Its medial surface is covered in the recent state with mucous membrane and forms the lateral boundary of the posterior nasal aperture and part of the lateral wall of the nasal part of the pharynx. The posterior border of the medial pterygoid plate is thin and sharp, and presents a small projection about its midpoint. Above this projection the border is curved and is attached to the pharyngeal end of the pharyngotympanic (auditory) tube. At its upper end the border divides to enclose the shallow, *scaphoid fossa* (fig. 323); below, it projects beyond the rest of the plate as the slender *pterygoid hamulus*. This process curves downwards and laterally and is grooved anteriorly at its root by the tendon of the tensor palati muscle. The *lateral pterygoid plate* projects backwards and laterally and its lateral surface forms the medial wall of the infratemporal fossa. Superiorly it is continuous with the *infratemporal surface of the greater wing of the sphenoid*, which forms the anterior part of the roof of the infratemporal fossa. This surface of the greater wing is directed downwards and, sometimes, slightly to the lateral side. It is roughly pentagonal; its anterior margin forms the posterolateral border of the inferior orbital fissure; and in front and to the lateral side it is limited by the infratemporal crest. Laterally it articulates with the squama of the temporal bone; medially it is continuous with the root of the pterygoid process and the side of the body of the sphenoid; and posteromedially it articulates with the petrous part of the temporal bone.

Two important foramina open on the infratemporal surface of the greater wing of the sphenoid. The **foramen ovale**, irregularly oval in outline, lies close to the posterior border and posterolateral to the upper end of the posterior margin of the lateral pterygoid plate. It transmits the mandibular division of the trigeminal nerve. Posterior and slightly lateral to the foramen ovale the **foramen spinosum** pierces the greater wing and transmits the middle meningeal artery to the middle cranial fossa. It is much smaller than the foramen ovale and is circular in outline. Immediately posterolateral to the foramen spinosum the posterolateral angle of this surface of the greater wing forms an irregular downward projection, termed the *spine of the sphenoid*. The medial surface of the spine is flattened, and together with the adjoining part of the posterior border of the greater wing forms the anterolateral border of a groove which is completed on the posteromedial side by the petrous part of the temporal bone. This groove lodges the cartilaginous part of the pharyngotympanic (auditory) tube, and leads backwards into the canal for the tube in the petrous part of the temporal bone and forwards to the upper part of the posterior border of the medial pterygoid plate. In the roof of the groove the posterior border of the greater wing and the anterior border of the petrous temporal come into apposition with each other. It will be apparent that immediately below the skull the mandibular nerve and the middle meningeal artery must be related to the anterolateral aspect of the pharyngotympanic tube.

Behind and medial to the groove for the tube the *inferior surface of the petrous temporal* occupies the interval between the infratemporal surface of the greater wing of the sphenoid and the basilar part of the occipital bone. The anterior part of this surface is rough and uneven, and its apex is separated from the posterolateral part of the body of the sphenoid by an irregular bony canal, termed the *foramen lacerum*. Behind this rough area a large and approximately circular foramen leads upwards into the bone. It is the lower opening of the *carotid canal*, which is traversed by the internal carotid artery. Within the bone the canal turns forwards and medially and opens on the posterior wall of the foramen lacerum. After passing through the canal the artery turns upwards to gain the interior of the skull. The lower part of the foramen lacerum is occupied in the recent state by fibrocartilage, and no large structure enters or leaves the skull through this opening.

Lateral to the base of the spine of the sphenoid the *squamotympanic fissure* runs laterally and slightly backwards between the upper part of the tympanic plate and the articular fossa of the squamous part of the temporal bone. The fissure can usually be traced to the upper part of the anterior margin of the orifice of the external auditory meatus, but it is sometimes obliterated near its lateral end. The *articular fossa* is deeply concave from before backwards and gently concave from

side to side, and is wider at its lateral than at its medial head. It lodges the head of the mandible when the mouth is closed. Anteriorly the articular surface passes on to a transverse rounded elevation, termed the *articular eminence*, which is continuous laterally with the anterior root of the zygoma. In front it becomes continuous with the part of the squamous temporal which lies in the roof of the infratemporal fossa. Behind the squamotympanic fissure the *tympanic part of the temporal bone* separates the articular fossa from the external auditory meatus. This part of the temporal bone is roughly triangular in outline, the apex being situated at the medial end of the squamotympanic fissure close to the root of the spine of the sphenoid. Its lower border is free and skirts the anterolateral margin of the lower opening of the carotid canal, extending backwards and laterally to reach the root of the styloid process. There it forms the *sheath of the styloid process*, which is longer and more apparent on the lateral than on the medial side. At its lateral margin the tympanic part is fused with the mastoid part of the temporal bone below and is free above, where it forms the anterior border of the orifice of the external auditory meatus.

Particular features.—The upper border of the *vomer*, which is applied to the inferior surface of the body of the sphenoid, is expanded into an *ala* on each side (fig. 319), and the groove between the alæ receives the *rostrum of the sphenoid*. The lateral border of each ala comes into relation with a thin lamella which projects medially from the root of the medial pterygoid plate and is termed the *vaginal process*. The two may come merely into contact or the edge of the ala may extend into the narrow interval between the body of the sphenoid above and the vaginal process below. The inferior surface of the vaginal process is marked by an anteroposterior groove, which is converted into a canal anteriorly by the upper surface of the sphenoidal process of the palatine bone. This canal is termed the *palatinovaginal (pharyngeal) canal* and opens anteriorly through the posterior wall of the pterygopalatine fossa. It transmits the pharyngeal branch of the sphenopalatine ganglion and a minute pharyngeal branch from the third part of the maxillary (internal maxillary) artery. A second canal may be present in this situation on the medial side of the palatinovaginal canal. It lies between the ala of the vomer and the upper surface of the vaginal process and is termed the *vomerovaginal canal*. When present it leads forwards into the anterior end of the palatinovaginal canal.

In front of the pharyngeal tubercle the *inferior surface of the basilar part of the occipital bone* is intimately related to the roof of the nasal pharynx and the nasopharyngeal tonsil. Lateral to the tubercle the bone receives the insertion of the longus capitis muscle, and the area extends forwards on each side beyond the tubercle. Behind the longus capitis the rectus capitis anterior is inserted into the bone in front of the occipital condyle and medial to the outer opening of the anterior condylar (hypoglossal) canal.

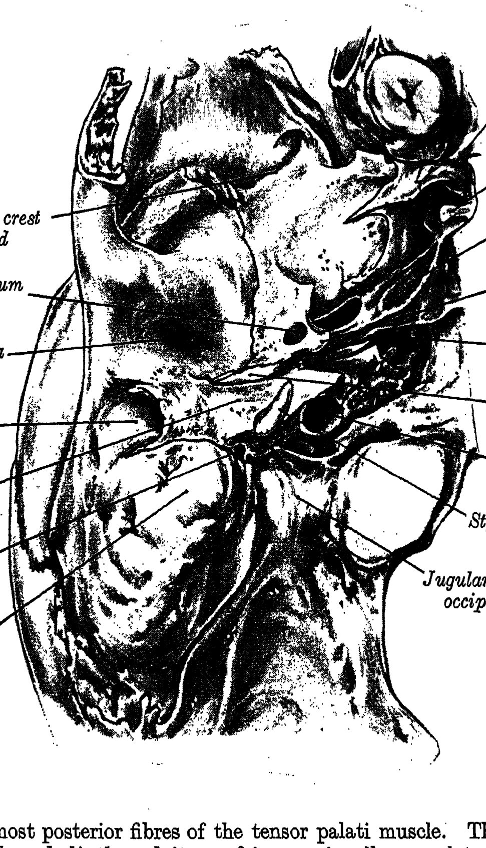
The medial surface of the **medial pterygoid plate** (fig. 328) is smooth and covered with the mucous membrane of the nasal pharynx in the recent state. At the upper part of its posterior border the *scaphoid fossa* gives origin to the anterior fibres of the tensor palati muscle, which descends along the lateral surface and posterior border of the plate to reach the *hamulus*. The tendon of the muscle twists medially round the lateral and anterior aspects of the process to gain the soft palate. The posterior border of the medial pterygoid plate, notched above by the pharyngotympanic (auditory) tube (p. 259), gives attachment to the pharyngobasilar fascia. Its lower part and the posterior aspect of the hamulus give origin to the highest fibres of the superior constrictor muscle of the pharynx, which curve upwards and medially to be inserted into the pharyngeal tubercle. The tip of the hamulus gives attachment to the pterygomandibular ligament (raphe). At its upper end the posterior border of the medial pterygoid plate is marked by a small tubercle, which lies on the medial side of the scaphoid fossa. This tubercle projects backwards below, and conceals the posterior opening of the *pterygoid canal*, which leads forwards to open on the posterior wall of the pterygopalatine fossa. It transmits the nerve and vessels of the pterygoid canal and lies in the line of fusion of the pterygoid process and greater wing with the body of the sphenoid bone.

The *pterygoid fossa* lies between the opposed surfaces of the two pterygoid plates and is completed below and in front by the tubercle (pyramidal process) of the palatine bone. The lateral wall of the fossa gives origin to the deep head of the medial pterygoid muscle. The **lateral pterygoid plate** (fig. 317) is a wider lamina than the medial plate, and its irregular posterior border may present a backward projection, termed the *pterygospinous process*, which is connected by a ligament (sometimes ossified) to the spine of the sphenoid. The lateral surface, which is the rougher of the two, gives origin to the lower head of the lateral pterygoid muscle; the medial surface gives origin to the deep head of the medial pterygoid muscle. The lateral aspect of the *tubercle (pyramidal process) of the palatine bone*, which appears between the tuberosity of the maxilla and the lower part of the lateral pterygoid plate, gives origin to some fibres of the superficial head of the medial pterygoid muscle.

The *infratemporal surface of the greater wing of the sphenoid* gives origin to the upper head

of the lateral pterygoid muscle, and is crossed by the deep temporal and the masseteric nerves, which run between the muscle and the bone. In addition to the mandibular nerve the **foramen ovale** transmits the accessory meningeal artery. Its posterior border is thin and sharp and gives origin to fibres of the tensor palati muscle, which intervenes between the mandibular nerve and the pharyngotympanic (auditory) tube. The **foramen spinosum** transmits the small nervus spinosus in addition to the middle meningeal artery. In the interval between the foramen ovale and the scaphoid fossa the bone sometimes presents a small foramen, termed the *emissary sphenoidal foramen* (foramen Vesalii), which transmits an emissary vein from the cavernous sinus. The *spine of the sphenoid*, which varies greatly in size, and may be sharply pointed or may be blunt at its extremity, gives attachment to the sphenomandibular ligament. It is related laterally to the auriculotemporal nerve and medially to the chorda tympani—by which its medial aspect is sometimes grooved—and to the pharyngotympanic tube. Anteriorly it gives

FIG. 322.—A portion of the norma basalis of the right side.



origin to the most posterior fibres of the tensor palati muscle. The groove for the tube varies in width and depth and its roof is occasionally completed by membrane. The lateral or sphenoidal wall of the groove gives origin, posteriorly, to fibres of the tensor tympani muscle.

The lateral part of the rough inferior surface of the petrous part of the temporal bone gives origin to the levator palati muscle. The **foramen lacerum** is bounded in front by the posterolateral part of the body of the sphenoid and the adjoining roots of the pterygoid process and greater wing; behind and laterally by the apex of the petrous part of the temporal bone; and medially by the basilar part of the occipital bone. It forms a canal nearly 1 cm. long, but no large structure passes through its whole length. The anterior orifice of the carotid canal opens on its posterior wall, and the vessel with its plexus of veins and its plexus of sympathetic nerves ascends through the upper end of the canal. In the foramen the deep petrosal nerve from the carotid sympathetic plexus is joined by the greater superficial petrosal nerve to form the nerve of the pterygoid canal, and this canal opens on the lower part of the anterior wall. Meningeal branches of the ascending pharyngeal artery, emissary veins from the cavernous sinus and a few meningeal lymphatics traverse the whole length of the foramen. The cartilage which fills its lower part is a remnant of the primitive chondrocranium.

The floor of the *articular fossa* is very thin and corresponds to the most lateral part of the floor of the middle cranial fossa. It is covered in the recent state by white fibrocartilage. The *tubercle of the root of the zygoma* gives attachment to the temporomandibular ligament. A thin edge of bone may be visible in the depths of the medial end of the *squamotympanic fissure*. It is the lower border of the down-turned lateral portion of the tegmen tympani and therefore is a part of the petrous temporal. It divides the upper part of the squamotympanic fissure into a petrotympanic and a petrosquamous fissure. Through the petrotympanic fissure the chorda tympani travels in its anterior canaliculus, as it passes downwards and forwards from the tympanic cavity. The anterior tympanic artery from the maxillary artery also traverses the petrotympanic fissure.

The **tympanic part of the temporal bone** (fig. 322) is separated from the capsule of the temporomandibular joint by a portion of the parotid gland, which is intimately related to the auriculotemporal nerve. It is thinnest near the centre of this surface and is occasionally deficient in this situation (p. 302). The grooved upper aspect of the plate forms the anterior wall, the floor and the lower part of the posterior wall of the external auditory meatus. Except where it ensheathes the styloid process its posterior surface is fused with the petrous part of the bone.

The Posterior Part of the Norma Basalis (fig. 319)

The median portion of the posterior subdivision of the external surface of the base of the skull is occupied in front by the **foramen magnum** of the occipital bone, which leads into the posterior cranial fossa. The foramen is oval in shape and its anteroposterior measurement exceeds its transverse. The curve of its margin is wider behind than in front. It transmits a large number of structures of which the most important is the lower end of the brain-stem. Anteriorly the margin of the foramen magnum is overlapped slightly on each side by the *occipital condyle*, which projects downwards to articulate with the superior articular facet on the lateral mass of the atlas. Oval in outline, the condyle is placed obliquely so that its anterior end is nearer the median plane than its posterior end. It shows a pronounced convexity from before backwards and a gentle convexity from side to side. The medial aspect is roughened for ligamentous attachments. Above the anterior part of the condyle the occipital bone is pierced by the *anterior condylar* (*hypoglossal*) *canal*, which runs laterally and slightly forwards from the posterior cranial fossa and transmits the hypoglossal nerve.

A depression of variable depth marks the occipital bone behind the condyle. It is termed the *condylar fossa*, and may be pierced by the *posterior condylar canal*, which, when present, transmits an emissary vein from the sigmoid sinus. Lateral to the condyle the *jugular process of the occipital bone* articulates with the petrous temporal. The anterior border of the process is free and forms the posterior boundary of the **jugular foramen**. This large foramen lies between the occipital bone and the jugular fossa of the petrous temporal and is placed at the posterior end of the petro-occipital suture. In front it is separated from the lower orifice of the carotid canal by a raised ridge of bone, and on its lateral side it is related to the medial aspect of the sheath of the styloid process. Medially it is separated from the anterior condylar canal by a thin bar of bone. The foramen is usually larger on the right side of the skull and its long axis is directed forwards and medially. The anterior part of the foramen transmits the inferior petrosal sinus; its intermediate part, the glossopharyngeal, vagus and accessory nerves; and its posterior part the internal jugular vein. When the superior bulb of the internal jugular vein is well developed the *jugular fossa of the temporal bone* is hollowed out in an upward and lateral direction to accommodate it.

The *styloid process* has been described already (p. 253). Posterior to its root the *stylomastoid foramen* transmits the facial nerve. Behind and lateral to the foramen the tip of the *mastoid process* projects downwards and forwards, and forms the lateral wall of the *mastoid* (digastric) *notch*, from which the posterior belly of the digastric muscle takes origin. Medial to the notch the mastoid part of the temporal bone may be grooved by the occipital artery.

In the median plane behind the foramen magnum the squamous part of the occipital bone presents the *external occipital crest*, which gives attachment to the upper end of the ligamentum nuchæ. It terminates behind at the external occipital protuberance. Near its midpoint the *inferior nuchal line* begins and curves backwards and laterally. It is nearly parallel to the *superior nuchal line*, which extends

in the same direction from the external occipital protuberance and may be raised into a distinct crest in its medial part.

Particular features.—The **foramen magnum** provides a wide communication between the posterior cranial fossa and the vertebral canal. Anteriorly it transmits the apical ligament of the odontoid process (dens) and the membrana tectoria, both of which gain attachment to the upper surface of the basilar part of the occipital bone. Its wider, posterior part transmits the lower end of the medulla oblongata and the meninges. In the subarachnoid space the spinal roots of the accessory nerves, and the vertebral arteries, with their plexuses of sympathetic nerves, ascend to gain the interior of the cranium, the posterior spinal arteries descend, one on each posterolateral aspect of the brain stem, and the anterior spinal artery descends on the front of the brain stem in the median plane. In addition, the lower parts of the tonsils of the cerebellum may project into the foramen on each side of the medulla oblongata. The *anterior margin* of the foramen gives attachment to the anterior atlanto-occipital membrane, which is continuous on each side with the capsular ligament of the atlanto-occipital joint. The *posterior margin* gives attachment to the posterior atlanto-occipital membrane, and the roughened medial aspect of the *condyle* to the alar ligament.

In addition to the hypoglossal nerve the *anterior condylar* (*hypoglossal*) *canal* transmits a meningeal branch of the ascending pharyngeal artery and a small emissary vein from the basilar plexus. Not uncommonly the canal is divided into two parts by a spicule of bone, a variation which is in keeping with the composite origin of the hypoglossal nerve. The inferior surface of the jugular process of the occipital bone provides insertion for the rectus capitis lateralis muscle.

The **jugular foramen** (fig. 319) is directed upwards, medially and backwards, and on the external surface of the base of the skull its apparent size is increased owing to the presence of the jugular fossa of the temporal bone on its lateral side. The floor of the fossa separates the superior bulb of the internal jugular vein from the tympanic cavity, and its lateral wall is pierced by a minute canal, termed the *mastoid canaliculus*, which transmits the auricular branch of the vagus nerve. Passing laterally through the bone this nerve comes into intimate relationship with the facial canal and finally emerges in the line of the tympanomastoid suture. It is extra-cranial at birth but becomes surrounded by bone as the tympanic plate and the mastoid process develop. On or near the ridge between the jugular fossa and the orifice of the carotid canal, the *canaliculus for the tympanic nerve* pierces the bone to transmit the tympanic nerve from the glossopharyngeal nerve to the middle ear. On the upper boundary of the jugular foramen near its medial end, there is a small notch—more easily identified on the internal surface—which lodges the inferior (petrous) ganglion of the glossopharyngeal nerve. The orifice of the *cochlear canaliculus* (p. 299) lies at the apex of the notch, the projecting edges of which may reach the occipital bone and divide the foramen into three parts.

The *stylomastoid foramen* lies behind the root of the styloid process and at the anterior end of the mastoid notch. As the facial nerve emerges from the foramen it is in close proximity to the posterior belly of the digastric, which it supplies before entering the parotid gland. In addition to the facial nerve the foramen transmits the stylomastoid branch of the posterior auricular artery. A vascular groove crosses the inferior aspect of the mastoid part of the temporal bone medial to the mastoid notch. It is caused by the occipital artery, and its absence indicates that the vessel lay at a lower level than usual and between the splenius capitis and longissimus capitis instead of deep to both muscles.

The area below the *inferior nuchal line* gives insertion medially to the rectus capitis posterior minor, and laterally to the rectus capitis posterior major (fig. 342). The interval between the inferior and the superior nuchal lines provides insertion medially for the semispinalis capitis and laterally for the obliquus superior. In its medial part the *superior nuchal line* gives origin to the highest fibres of the trapezius muscle; in its lateral part it gives insertion to fibres of the sternomastoid and, more anteriorly, splenius capitis.

THE INTERIOR OF THE SKULL

The **cranial cavity** contains the brain and its membranes and their blood-vessels. Its walls are formed by the frontal, parietal, sphenoid, temporal and occipital bones and, to a very small extent, by the ethmoid bone. They are lined with a fibrous membrane, termed the *endocranium*, which is the outer layer of the dura mater. It passes through the various foramina which lead to the exterior, and becomes continuous with the periosteum on the outer surfaces of the bones of the skull, often termed the *pericranium*. Both these fibrous membranes are continuous with the sutural ligaments, which occupy the narrow interosseous intervals at the sutures.

The walls of the cranial cavity vary in thickness in different skulls and in different parts of the same skull; but they tend to be thinner in situations where they

are well covered with muscles externally, e.g. the temporal and posterior cranial fossæ. Most of the cranial bones consist of an *outer* and an *inner table*, formed of compact substance and separated from each other by the *diploë*, which consists of spongy substance containing red bone marrow in its interstices. Many of the bones are so thin that the two tables are continuous, e.g. the vomer, pterygoid plates, etc. The inner table is thinner and more brittle than the outer table, which is often surprisingly resilient.

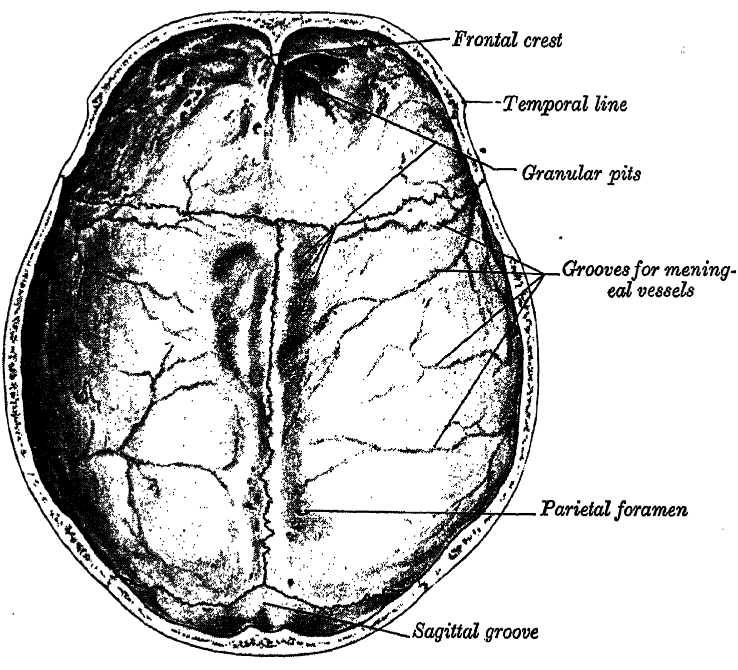
Although the skull tends to be thicker in primitive than in higher races no relationship exists between thickness of skull and mental capacity, and in all races the bones of the skull are thinner in women and children than in men.

The interior of the skull is described in two sections: (1) the internal surface of the skull-cap; and (2) the internal surface of the base of the skull.

The Internal Surface of the Skull-Cap (fig. 323)

The skull-cap comprises most of the frontal and parietal bones and the uppermost portion of the squamous part of the occipital bone. It is marked, therefore,

Fig. 323.—The internal surface of the skull-cap.



by the coronal, sagittal and lambdoid sutures, but they may or may not be visible for the cranial sutures tend to become obliterated in old age and the process commences on the cerebral surface. The skull-cap is deeply concave in all directions and presents numerous vascular furrows and other markings.

Anteriorly, in the median plane, the upper end of the *frontal crest* projects backwards. It gives attachment to the falx cerebri and is grooved by the commencement of the *sagittal sulcus*. This sulcus lodges the superior sagittal sinus, and widens progressively as it runs backwards in the median plane along the sagittal suture to the occipital bone. On each side of the sagittal sulcus the bone presents a number of irregular depressions, termed *granular pits*. They are more numerous and more obvious in aged skulls and are formed by the arachnoid granulations, which are tuft-like protrusions of the arachnoid mater.

The anterior branch of the middle meningeal artery grooves the bone deeply about 1 cm. behind the coronal suture, and its line corresponds more or less accurately to the precentral sulcus of the cerebrum. Its rami and those of the posterior branch of the same artery course upwards and backwards from the cut edge of the

skull-cap, grooving the inner surface of the parietal bone. Smaller grooves produced by meningeal vessels may be present on the inner surfaces of the frontal and occipital bones. When present, the *parietal foramina* open on this surface near the sagittal groove about 3·5 cm. in front of the lambdoid suture. Each transmits an emissary vein from the superior sagittal sinus.

The *impressions for the cerebral gyri* are less distinct on the skull-cap than on the base of the skull and are seen best near the cut edge.

The Internal Surface of the Base of the Skull [Basis Cranii Interna] (figs. 324, 325)

The internal surface of the base of the skull shows a natural subdivision into anterior, middle and posterior cranial fossæ. It is very irregular owing, partly, to the impressions for the cerebral gyri, which are especially conspicuous in the anterior and middle fossæ, where they reflect accurately the pattern of the surface of the corresponding parts of the cerebrum. The dura mater is firmly adherent to the whole area, and through the numerous foramina and fissures the endocranium is continuous with the periosteum on the exterior of the skull (pericranium).

The Anterior Cranial Fossa (figs. 324, 325)

The **anterior cranial fossa** is limited in front and on each side by the frontal bone. Its floor is formed by the orbital plates of the frontal bone, the cribriform plate of the ethmoid and the lesser wings and anterior part of the body of the sphenoid.

The *cribriform plate of the ethmoid*, which stretches across the median plane, lies between the two orbital plates of the frontal bone, and is depressed below the level of the rest of the floor. It separates the fossa from the nasal cavity, the roof of which it helps to form (fig. 330). Anteriorly it presents a median crest-like elevation, termed the *crista galli*, which projects upwards between the two cerebral hemispheres. A depression intervenes between the front of the crista galli and the *crest of the frontal bone*, the floor of which is crossed by the fronto-ethmoidal suture and is marked by the presence of the *foramen cæcum*. On each side the crista galli is separated from the orbital plate of the frontal bone by a narrow interval. The numerous small foramina which perforate the cribriform plate transmit the minute olfactory nerves from the nasal mucosa to the olfactory bulb. Posteriorly the cribriform plate articulates with the anterior part of the body of the sphenoid at the spheno-ethmoidal suture.

The *orbital plate of the frontal bone* forms the greater part of the floor of the fossa on each side of the median plane and separates the orbit and its contents from the inferior surface of the frontal lobe of the brain. Its surface is convex upwards and is marked by impressions for the cerebral gyri and by one or two small grooves for meningeal vessels. In its anteromedial part it is split into two laminæ to contain part of an air-space, termed the *frontal sinus*. The medial part of the orbital plate covers the ethmoidal labyrinth and shuts it out from the floor of the anterior cranial fossa. Posteriorly it articulates with the anterior border of the *lesser wing of the sphenoid bone*. In the median plane the cerebral surface of the frontal bone is marked by the *frontal crest*, which projects backwards into the interval between the two cerebral hemispheres and extends upwards on to the interior of the skull-cap.

Behind the cribriform plate the floor of the anterior cranial fossa is formed by the anterior portion of the upper surface of the body of the sphenoid. This part of the bone is termed the *jugum sphenoidale*, and it separates the fossa from an air-space contained in the body of the sphenoid and named the *sphenoidal sinus* (fig. 328). Anteriorly the jugum articulates with the posterior margin of the cribriform plate; posteriorly it is limited by the anterior border of a groove, termed the *optic groove* (*sulcus chiasmatis*), which crosses the body of the sphenoid in the forepart of the middle cranial fossa and leads from one optic foramen to the other. Lateral to the jugum the floor of the fossa is formed by the *lesser wing of the sphenoid*. The posterior margin of the lesser wing, which curves medially and backwards, is free and overhangs the most anterior part of the middle cranial fossa. Laterally the lesser wing tapers to a point and meets the suture between the frontal bone and the greater

wing at or near the lateral end of the superior orbital fissure. The medial extremity of its posterior border forms a projection termed the *anterior clinoid process*. Medially the lesser wing is connected to the body of the sphenoid by two roots, separated from each other by the *optic foramen*. The anterior root, broad and flat, is continuous with the jugum sphenoidale; the posterior root, smaller and thicker, lies in the middle cranial fossa and is connected to the body of the sphenoid opposite the posterior border of the optic groove.

Fig. 324.—The internal surface of the left half of the base of the skull. (Basis cranii interna.)

Particular features.—The *crista galli* and the *frontal crest* give attachment to the falx cerebri. The *foramen cæcum* between them usually ends blindly, but on rare occasions it is patent and transmits a vein from the nasal mucosa to the superior sagittal sinus. The narrow groove on the lateral side of the crista galli is related to the gyrus rectus, and the olfactory bulb lies on the medial edge of the orbital plate of the frontal bone. The *anterior ethmoidal canal* opens on the line of the suture between the orbital plate of the frontal bone and the cribriform plate of the ethmoid (fig. 314). It is placed behind the crista galli and is difficult to identify, for it is directed medially and is overlapped above by the medial edge of the orbital plate. It transmits the anterior ethmoidal nerve and vessels, which run forward under the dura mater and gain the nasal cavity by passing downwards through a slit-like foramen at the side of the crista galli. The *posterior ethmoidal canal* opens at the posterolateral corner of the cribriform plate and is overhung by the anterior border of the sphenoid. It transmits the posterior ethmoidal vessels, but the posterior ethmoidal nerve terminates by supplying the mucous lining of the sphenoidal and posterior ethmoidal sinuses.

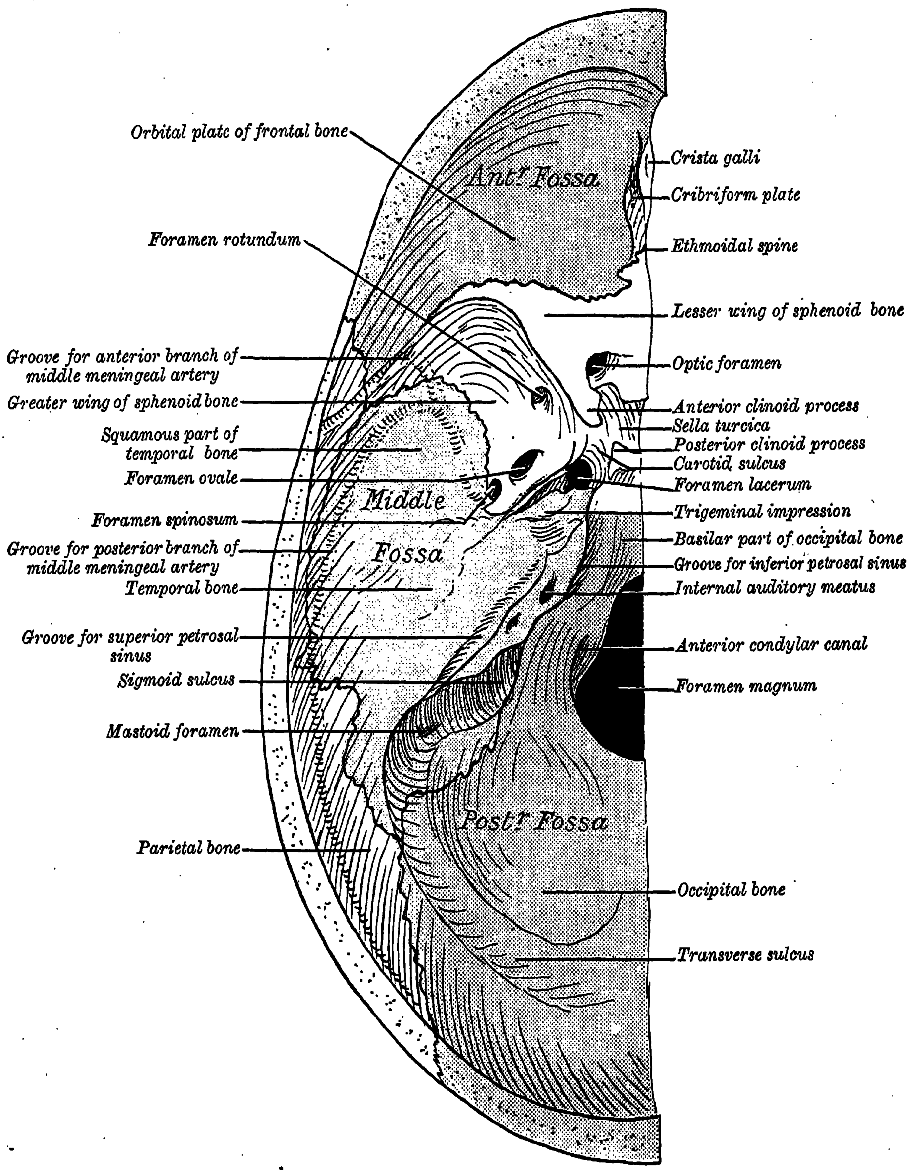
The free, posterior border of the *lesser wing* of the sphenoid fits into the stem of the lateral cerebral sulcus and may be grooved by the sphenoparietal sinus. Above, the lesser wing is related to the posterior part of the inferior surface of the frontal lobe and medially to the anterior perforated substance. Inferiorly it forms the upper boundary of the superior orbital fissure and helps to complete the roof of the orbit. The *anterior clinoid process* gives attachment to the free border of the tentorium cerebelli and is grooved on its medial aspect by the internal carotid artery as it pierces the roof of the cavernous sinus. Not infrequently the anterior clinoid process is connected to the middle clinoid process by a thin bar of bone, which completes a foramen around the internal carotid artery. The flat surface of the *jugum sphenoidale* supports the posterior ends of the gyri recti and the olfactory tracts.

The Middle Cranial Fossa (figs. 324, 325)

The **middle cranial fossa** is deeper than the anterior; it is more extensive on each side than in the median plane, and its walls bear some resemblance to a butterfly with outspread wings. In front it is bounded by the posterior borders of the

lesser wings, the anterior clinoid processes and the anterior margin of the optic groove; behind by the superior borders of the petrous parts of the temporal bones and the dorsum sellæ of the sphenoid bone; laterally by the temporal squamæ, the anterior inferior angles of the parietal bones and the greater wings of the sphenoid.

Fig. 325.—Key to fig. 324.



In the median area the floor is formed by the body of the sphenoid. In front, the *optic groove* (sulcus chiasmatis) leads on each side into the optic foramen. The sulcus does not lodge the optic chiasma, which lies above and behind it. The **optic foramen** is placed between the two roots of the lesser wing and is bounded medially by the body of the sphenoid. It is directed forwards, laterally and somewhat downwards and transmits the optic nerve and the ophthalmic artery. Immediately behind the groove the upper surface of the body of the sphenoid is shaped like a Turkish saddle and is termed the *sella turcica*. Its anterior slope is marked by a median elevation, termed the *tuberculum sellæ*, and behind that

the surface is hollowed out to form the *hypophyseal fossa* (fig. 328), which lodges the hypophysis cerebri—an important ductless gland. The floor of the hypophyseal fossa forms part of the roof of the sphenoidal sinus. (Pl. I, fig. 1.) Posterior to the fossa a plate of bone projects upwards and forwards to form the *dorsum sellæ.* On each side the superolateral angle of the dorsum sellæ is expanded to form the *posterior clinoid process.* Lateral to the sella turcica the body of the sphenoid presents a shallow *groove for the internal carotid artery*, as it runs forwards from the foramen lacerum. A small elevation marks the anterior part of the medial edge of the carotid groove and is termed the *middle clinoid process*; it may be joined to the anterior clinoid process by a thin bar of bone. Posteriorly the lateral edge of the carotid groove may be deepened by a small projection termed the *lingula.*

The **lateral part of the middle cranial fossa** is deep and its floor supports the temporal lobe of the brain. It is formed in front by the cerebral surface of the greater wing of the sphenoid and behind by the anterior surface of the petrous part of the temporal bone, while the cerebral surface of the temporal squama occupies the interval between these two bones in the lateral portion of the floor. It is related in front to the posterior part of the orbit: laterally, to the temporal fossa; and below, to the infratemporal fossa.

Anteriorly it communicates with the orbit through the **superior orbital fissure**, which is placed obliquely and is bounded above by the lesser wing, below by the greater wing, and medially by the side of the body of the sphenoid. The fissure is wider at its medial end than at its lateral end and its long axis is directed upwards, laterally and forwards. It transmits the terminal branches of the ophthalmic nerve, the ophthalmic veins, the oculomotor, trochlear and abducent nerves, and some smaller vessels.

The **foramen rotundum** pierces the greater wing of the sphenoid immediately below and a little behind the medial end of the superior orbital fissure. It leads forwards into the pterygopalatine fossa, to which it conducts the maxillary nerve.

The **foramen ovale** pierces the greater wing of the sphenoid posterior to the foramen rotundum and lateral to the lingula and the posterior end of the carotid groove. It leads downwards into the infratemporal fossa and transmits the mandibular nerve to that region.

The **foramen spinosum** lies close to the posterolateral margin of the foramen ovale, and transmits the middle meningeal artery from the infratemporal fossa to the middle cranial fossa. The artery, with its accompanying veins, runs laterally to gain the temporal squama on which it runs upwards, forwards and laterally. Crossing the temporosphenoidal suture for a second time it ascends on the greater wing and divides into anterior and posterior branches. The anterior branch proceeds upwards across the cerebral surface of the pterion and gains the anterior part of the parietal bone. In the region of the pterion the artery is often enclosed in a bony canal. The posterior branch runs backwards and upwards on to the upper part of the temporal squama and crosses the parietosquamosal suture to gain the posterior part of the parietal bone. These arteries and their branches produce conspicuous grooves in the floor and lateral wall of the middle cranial fossa.

At the posterior end of the carotid groove and posteromedial to the foramen ovale the **foramen lacerum** is situated. It is bounded behind by the apex of the petrous temporal and in front by the body of the sphenoid and the posterior border of its greater wing. This end of the foramen lacerum transmits the internal carotid artery and its accompanying nervous and venous plexuses, together with some smaller structures.

Behind the foramen lacerum the anterior surface of the petrous temporal presents a shallow depression adjoining the apex of the bone. It is occupied by the trigeminal (semilunar) ganglion, and is named the *trigeminal impression.* The ganglion lies in a special recess of the dura mater and extends forwards above the lateral part of the foramen lacerum. Posterolateral to the trigeminal impression the surface presents a shallow hollow, limited posteriorly by a transversely rounded elevation, termed the *arcuate eminence.* This elevation is produced by the superior semicircular canal, which is closely related to the floor of the middle cranial fossa in this situation.

Lateral to the trigeminal impression the anterior surface of the petrous temporal presents a narrow groove which is directed backwards and laterally and soon disappears into the *hiatus for the greater superficial petrosal nerve.* Anterolateral to the

arcuate eminence the anterior surface of the petrous temporal is formed by the **tegmen tympani**, a thin lamella of bone which forms the roof of the tympanic cavity, and extends forwards and medially above the pharyngotympanic (auditory) tube. Lateral to the arcuate eminence the posterior part of the tegmen tympani forms the roof of the tympanic antrum—an air-space in the bone which communicates in front with the tympanic cavity.

The *superior border of the petrous temporal* separates the middle cranial fossa from the posterior cranial fossa. Behind the trigeminal impression it is grooved by the superior petrosal sinus, which connects the posterior end of the cavernous sinus to the upper end of the sigmoid sinus.

Particular features.—The optic nerve carries with it through the **optic foramen** a sheath derived from the membranes of the brain. The ophthalmic artery lies below the nerve, and in contact with the posterior root of the lesser wing.

On each side of the body of the sphenoid the cavernous sinus extends from the medial end of the superior orbital fissure to the apex of the petrous part of the temporal bone. In addition to the internal carotid artery and its plexus of sympathetic nerves the sinus contains the oculomotor, the trochlear, abducent and ophthalmic nerves, but these structures do not come into contact with the bone. An anterior intercavernous sinus, which crosses the *tuberculum sellæ*, and a posterior intercavernous sinus, which crosses the front of the *dorsum sellæ*, connect the two cavernous sinuses to each other. An additional connexion is established by an irregularly loculated sinus which intervenes between the hypophysis cerebri and the floor of its fossa. The diaphragma sellæ, which surrounds the infundibulum, is connected to the tuberculum in front and to the dorsum sellæ behind. The *posterior clinoid process* gives attachment to the anterior extremity of the attached margin of the tentorium cerebelli and to the petrosphenoid ligament (p. 1057).

The **superior orbital fissure** (fig. 312) opens into the orbit between its roof and its lateral wall. Its lower border is marked by a small projection which gives attachment to the lateral part of the annulus tendinis communis. Lateral to this projection the fissure is narrow, and transmits the lacrimal, frontal and trochlear nerves, and, in addition, a small orbital branch from the middle meningeal artery and a meningeal branch from the lacrimal artery. The wider, medial end of the fissure transmits the upper and lower divisions of the oculomotor, the nasociliary—which usually lies between them—and the abducent nerve—which usually lies below them—and the ophthalmic veins. The veins pass directly into the anterior end of the cavernous sinus. At the lateral extremity of the fissure the greater wing and the orbital plate of the frontal bone articulate with each other.

The **foramen rotundum**, like the medial end of the superior orbital fissure, is intimately related to the lateral wall of the sphenoidal sinus. Originally a part of the fissure, it becomes separated secondarily. A small foramen may be present at the root of the greater wing medial to the foramen ovale; it transmits an emissary vein from the cavernous sinus and is termed the *emissary sphenoidal foramen*. In addition to the mandibular nerve the **foramen ovale** transmits the accessory meningeal artery, and, sometimes, the lesser superficial petrosal nerve. In addition to the middle meningeal artery the **foramen spinosum** transmits the nervus spinosus. Both these foramina are represented at first by notches on the margin of the greater wing, which subsequently become converted into foramina.

The **foramen lacerum**, as described above (p. 261), is a short bony canal, traversed in its whole extent only by minute meningeal branches from the ascending pharyngeal artery and a few small veins and meningeal lymphatic vessels. The internal carotid artery pierces its posterior wall (p. 261) and ascends through its upper opening. The greater superficial petrosal nerve emerges from its hiatus and runs forwards in the groove which marks the anterior surface of the petrous part of the temporal bone. It turns downwards through the foramen lacerum on the lateral side of the internal carotid artery and is joined by the deep petrosal nerve to form the nerve of the pterygoid canal. This nerve leaves the foramen lacerum above its lower opening by traversing the *pterygoid canal*, which opens on its anterior wall. The lesser superficial petrosal nerve lies to the lateral side of the greater as it emerges on the anterior surface of the petrous part of the temporal bone and may occupy a small groove.

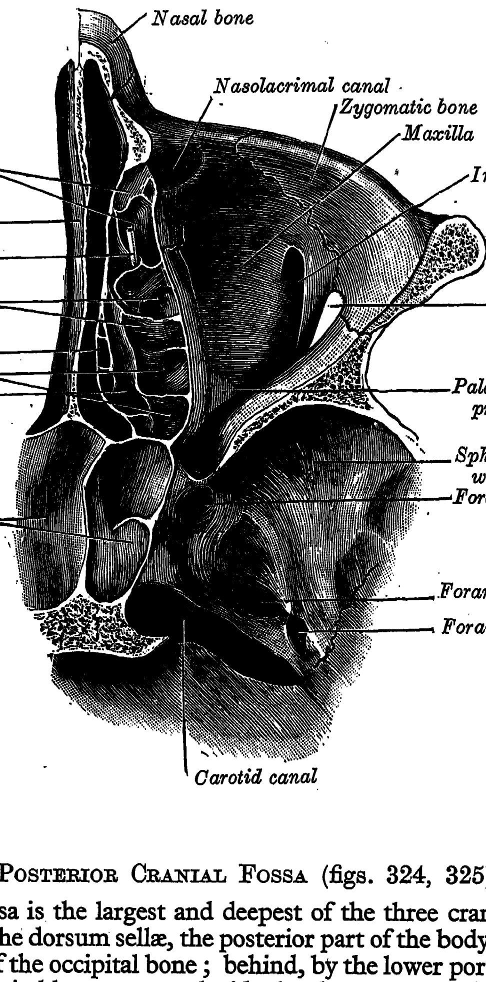
In a young skull the suture between the petrous and the squamous parts of the temporal bone may be visible at the lateral limit of the **tegmen tympani**, but it is usually obliterated in the adult skull. In this situation anteriorly, the lateral margin of the tegmen tympani turns downwards, forming the lateral wall of the bony part of the pharyngotympanic (auditory) tube, and its lower border may be visible in the floor of the squamotympanic fissure (p. 262).

Lateral to the anterior part of the tegmen tympani the part of the temporal squama which helps to form the floor of the middle cranial fossa is thin and translucent over a small area. This corresponds to the deepest part of the articular fossa on the external surface of the base of the skull.

In front of the commencement of the groove for the superior petrosal sinus the *upper*

border of the petrous temporal shows a shallow smooth notch, termed the *trigeminal notch*, which leads into the *trigeminal impression*. In this situation the roots of the trigeminal nerve intervene between the superior petrosal sinus and the bone. A tiny spicule, directed forwards and medially, marks the anterior extremity of the notch and gives attachment to the lower end of the petrosphenoidal ligament. The abducent nerve bends forwards sharply across the upper border of the temporal bone immediately in front of this bony spicule,* and so lies between the petrosphenoidal ligament and the side of the dorsum sellæ.

FIG. 326.—A horizontal section through the nasal and orbital cavities. Superior aspect.



THE POSTERIOR CRANIAL FOSSA (figs. 324, 325)

The posterior fossa is the largest and deepest of the three cranial fossæ. It is bounded in front by the dorsum sellæ, the posterior part of the body of the sphenoid and the basilar part of the occipital bone; behind, by the lower portion of the squamous part of the occipital bone; on each side, by the petrous and mastoid parts of the temporal bone, the condylar (lateral) part of the occipital bone and, above and behind, by a small part of the posterior inferior angle of the parietal bone. It contains the cerebellum behind and the pons and medulla oblongata in front.

The **foramen magnum** (p. 262) is in the floor of the fossa and is surrounded by the parts of the occipital bone. Its circumference is formed by the basilar part in front, by the condylar (lateral) part on each side and by a small portion of the squamous part behind. Just in front of its transverse diameter it is encroached on by the irregular, medial aspects of the occipital condyles, so that it is somewhat ovoid in shape and is wider behind than in front. Its narrower, anterior part lies above the odontoid process (dens) of the axis vertebra; its wider posterior part communicates below with the vertebral canal, and through it the medulla oblongata passes down to become continuous with the spinal cord.

* E. Wolff, *Journal of Anatomy*, vol. lxiii., p. 150.

In front of the foramen magnum the basilar part of the occipital bone, the posterior part of the body of the sphenoid bone and the dorsum sellæ form a sloping surface, gently concave from side to side, to support the medulla oblongata below and the pons above. On each side this area is separated from the petrous part of the temporal bone by the petro-occipital fissure, which is occupied in the recent state by a thin plate of cartilage. The fissure is limited behind by the jugular foramen, and its margins are grooved by the inferior petrosal sinus.

The **jugular foramen** (p. 262) lies at the posterior end of the petro-occipital suture, and leads forwards, downwards and laterally to the external surface of the base. Its upper border is sharp and irregular and presents a *notch for the glossopharyngeal nerve*. Its lower border is smooth and regular. The posterior part of the foramen transmits the sigmoid sinus, which is continuous below with the internal jugular vein. In front of the vein the accessory, vagus and glossopharnygeal nerves, in that order from behind forwards, traverse the foramen to gain the upper part of the neck. The most anterior part of the foramen transmits the inferior petrosal sinus.

Medial to the lower border of the jugular foramen a rounded elevation, termed the *jugular tubercle*, marks the condylar part of the occipital bone. It lies above and somewhat in front of the inner opening of the **anterior condylar (hypoglossal) canal**, which pierces the bone at the junction of the basilar with the condylar part and transmits the hypoglossal nerve.

The posterior surface of the petrous part of the temporal bone forms a large portion of the lateral (or anterolateral) wall of the posterior fossa. Above the anterior part of the jugular foramen the **internal auditory meatus** (fig. 325) runs transversely in a lateral direction. It is a short passage, about 1 cm. long, closed laterally by a perforated plate of bone which separates it from the internal ear. It transmits the facial and auditory nerves.

Behind the petrous temporal the lateral wall of the posterior cranial fossa is formed by the mastoid part of the temporal bone. Anteriorly it is marked by a wide groove, which runs forwards and downwards, then downwards and medially, and finally forwards to the posterior limit of the jugular foramen. This groove contains the sigmoid sinus and is termed the **sigmoid sulcus** (fig. 325). At its upper end, where it touches the postero-inferior angle of the parietal bone, the groove is continuous with that for the transverse sinus and crosses the parietomastoid suture. As it descends, it lies behind the tympanic antrum and forms a very important relation of that cavity. In this part of its course the *mastoid foramen* opens near its posterior margin and transmits an emissary vein from the sinus. In its lowest part the sigmoid sulcus crosses the occipitomastoid suture and grooves the jugular process of the occipital bone. It is usually deeper on the right than on the left side.

Behind the foramen magnum the squamous part of the occipital bone is marked in or near the median plane by the *internal occipital crest*, which ends above and behind in an irregular elevation named the *internal occipital protuberance*. On each side of the protuberance a wide shallow groove curves laterally with a slight upward convexity to the postero-inferior angle of the parietal bone. It is produced by the transverse sinus, is usually deeper on the right side, and at its lateral extremity is continuous with the groove for the sigmoid sinus. Below the groove for the transverse sinus the internal occipital crest divides the bone into two gently hollowed fossæ, which lodge the cerebellar hemispheres.

When the *posterior condylar canal* is present (fig. 343), its inner orifice usually lies behind and lateral to the orifice of the anterior condylar (hypoglossal) canal, but it may lie nearer to the jugular foramen. It transmits an emissary vein from the lower end of the sigmoid sinus.

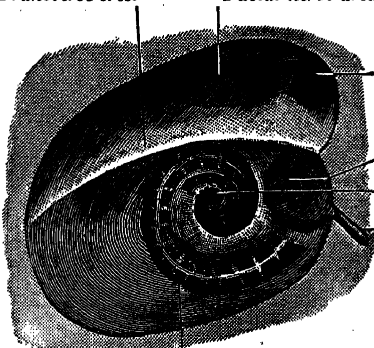
Particular features.—The anterior wall of the fossa is related to the network of basilar sinuses which connects the two inferior petrosal sinuses and communicates below with the internal vertebral venous plexus. A little in front of the foramen magnum the membrana tectoria is attached to the basilar part of the occipital bone (fig. 513), covering the attachment of the apical ligament of the odontoid process. The *jugular tubercle* is often grooved by the glossopharyngeal, vagus and accessory nerves, as they pass to the jugular foramen. In addition to the hypoglossal nerve the **anterior condylar canal** transmits a meningeal branch of the ascending pharyngeal artery. The canal is often subdivided into two parts by a small bar of bone, and this may be related to the composite origin of the hypoglossal

nerve (p. 1031). The roughened medial aspect of the *occipital condyle* (fig. 342) gives attachment to the alar ligament.

The lower and posterior borders of the **jugular foramen** (pp. 262, 263, and 271) are smooth and regular, but its upper border is sharp and interrupted by a notch, the ends of which may succeed in dividing the foramen into two or sometimes three compartments. The notch lodges the inferior (petrous) ganglion of the glossopharyngeal nerve and at its deepest part is pierced by the *cochlear canaliculus,* which contains the aqueduct of the cochlea.

The **internal auditory meatus** transmits the auditory nerve, both the motor and the sensory roots of the facial nerve and the internal auditory vessels. It is about 1 cm. in length and its *fundus* is separated from the internal ear by a vertical plate which is divided into two unequal portions by a *transverse crest* (fig. 327). Above the crest anteriorly the bone is pierced by the **facial canal,** which conducts the facial nerve through the petrous temporal to the stylo-mastoid foramen. Behind the opening of the facial canal there is a small depression, termed the *superior vestibular area,* which presents a number of small openings for the passage of the nerves to the utricle and the superior and lateral semi-

Fig. 327.—A diagrammatic view of the lateral end of the right internal auditory meatus. (Testut.)



circular ducts. Below the transverse crest anteriorly lies the *cochlear area,* in which a number of small, spirally arranged openings encircle the central canal of the cochlea and constitute the *tractus spiralis foraminosus.* Behind the cochlear area the *inferior vestibular area* presents several openings for the nerves to the saccule. Below and behind the inferior vestibular area the *foramen singulare* gives passage to the nerve to the posterior semicircular duct.

Behind the orifice of the internal auditory meatus a thin plate of bone with an irregularly curved margin projects backwards, and the slit which it bounds contains the external opening of the *aqueduct of the vestibule* (fig. 350). Within the aqueduct the saccus and ductus endolymphaticus are contained together with a small artery and vein. In the area between the internal auditory meatus and the external opening of the aqueduct of the vestibule there is a small depressed area, termed the *subarcuate fossa,* which lodges a small process of the dura mater. It lies nearer to the upper border of the bone (fig. 350) and is pierced by a small vein. In the infant the fossa is relatively large and extends as a short blind tunnel under the superior semicircular canal; it corresponds to the floccular fossa in some animals.

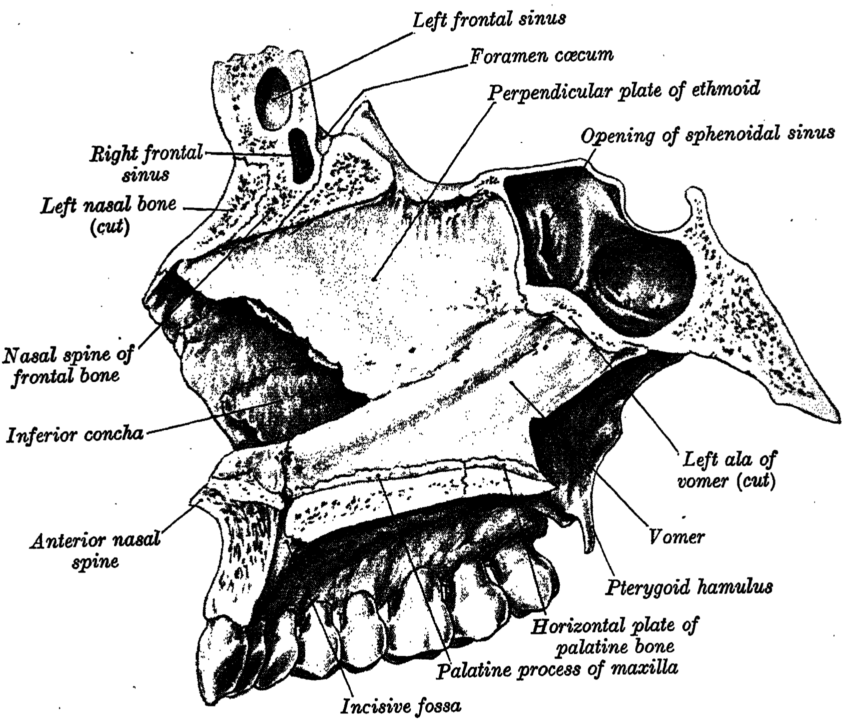
In addition to an emissary vein, the *mastoid foramen* transmits a meningeal branch of the occipital artery, which is sometimes large enough to produce a groove on the squamous part of the occipital bone.

The *internal occipital crest* gives attachment to the falx cerebelli and may be grooved by the occipital sinus, which is sometimes duplicated and is occasionally a large vessel. Its lower end is related to the inferior vermis of the cerebellum. The *internal occipital protuberance* is related to the confluence of sinuses and is grooved on each side by the commencement of the transverse sinus. The margins of the *groove for the transverse sinus* give attachment to the two layers of the tentorium cerebelli. Traced in a lateral direction, the groove reaches the lowest part of the posterior inferior angle of the parietal bone, where it becomes continuous with the groove for the sigmoid sinus (p. 271). On each side of the internal occipital crest the bone is thin and translucent, in marked contrast to the regions of the crest and of the internal occipital protuberance.

THE NASAL CAVITY

The **nasal cavity** is the first of the respiratory passages and is an irregularly shaped space which extends from the roof of the mouth upwards to the base of the skull. It is subdivided into right and left halves by a *septum* (fig. 328), which is approximately median in position. In the dried skull the septum is deficient anteriorly, and as a result a single *anterior nasal aperture* is present on the norma frontalis. The septum, however, reaches the posterior limit of the cavity, which communicates with the nasal part of the pharynx through a pair of *posterior nasal apertures*, placed immediately above the posterior border of the bony plate. The cavity is wider below than above and is widest and deepest in its central part. It communicates with the frontal, ethmoidal, maxillary and sphenoidal sinuses.

FIG. 328.—The nasal septum. Left side.



Each half of the nasal cavity has a roof, a floor, a lateral and a medial wall—the medial wall being formed by the corresponding side of the nasal septum.

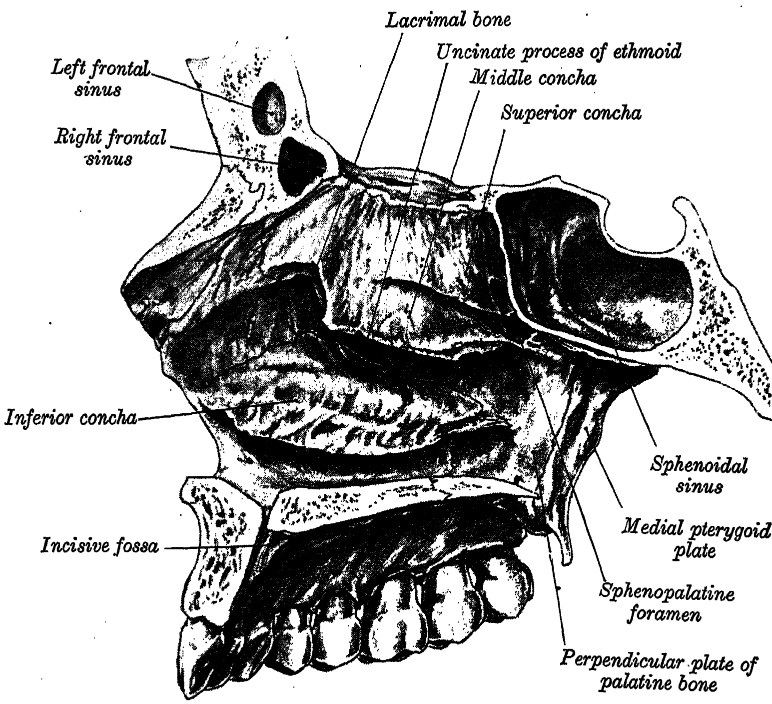
The **roof** (figs. 329, 330) is horizontal in its middle part but slopes downwards in front and behind. The anterior sloping part is formed by the frontal and nasal bones and contributes to the formation of the external nose. The horizontal part is formed by the cribriform plate of the ethmoid bone and separates the nasal cavity from the median part of the floor of the anterior cranial fossa. It presents numerous small openings for the passage of the olfactory nerves. The posterior sloping part is formed by the body of the sphenoid and is interrupted by the rounded orifice of the sphenoidal sinus.

The **floor** is smooth, gently concave from side to side, and slopes upwards a little as it passes backwards from the anterior aperture to the posterior aperture. It is formed by the upper surface of the bony plate and therefore intervenes between the nasal and oral cavities. Portions of four bones contribute to its formation. Anteriorly the palatine processes of the two maxillæ meet in the median plane, and behind them the horizontal plates of the palatine bones articulate with each other in the median plane and with the palatine processes of the maxillæ in front. In

its anterior part the floor close to the septum presents a small funnel-shaped opening which leads into the *incisive canal.*

The **medial wall** is formed by the *bony septum* (fig. 328), which extends between the roof and the floor. It is a thin sheet of bone and presents a wide deficiency in front, occupied in the recent state by the septal cartilage. It is formed almost entirely by the vomer and the perpendicular plate of the ethmoid. The *vomer* extends from the under surface of the body of the sphenoid to the bony palate and forms the lower and posterior part of the septum, including its free, posterior border. It is marked by small furrows for vessels and nerves. The *perpendicular plate of the ethmoid* forms the upper and anterior part of the septum (fig. 328) and is continuous above with the cribriform plate (p. 265). The septum is often deflected to one or other side, and the deviation occurs most commonly on the line of the vomero-ethmoidal suture.

FIG. 329.—The roof, floor and right lateral wall of the nasal cavity. Drawn from the same skull as fig. 328.



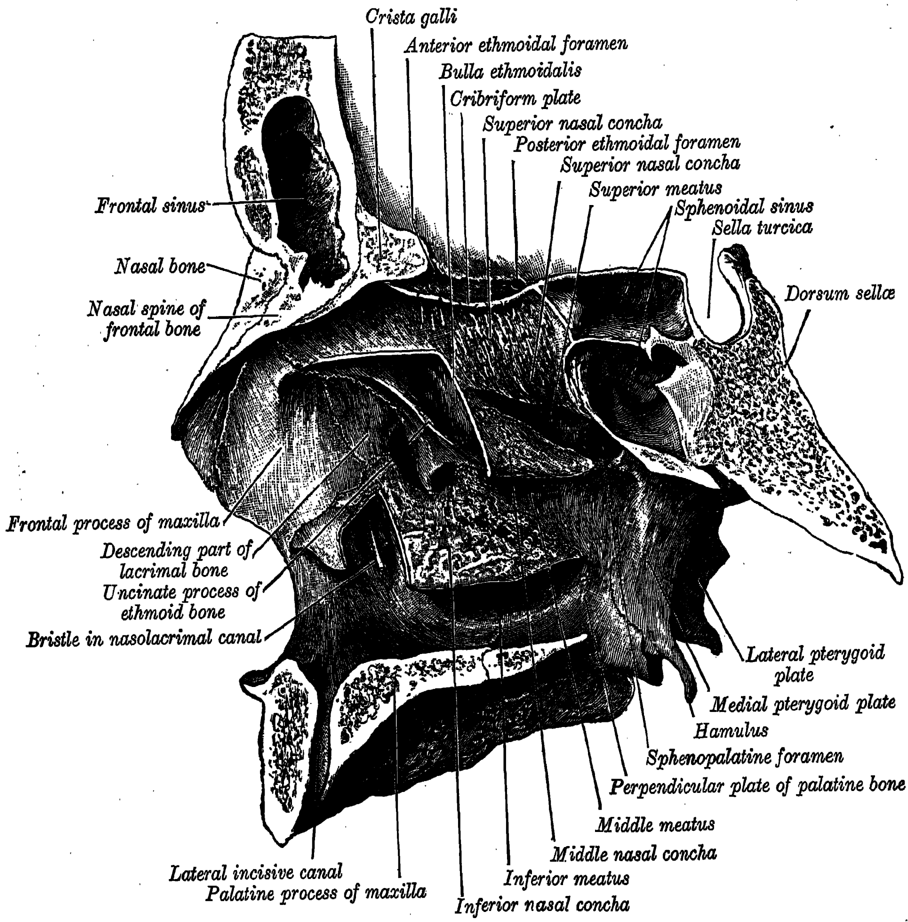
The **lateral wall** (figs. 329, 330) is very irregular owing to the presence of three bony projections termed the inferior, middle and superior nasal conchæ. It is formed, for the most part, by the nasal surface of the maxilla below and in front, by the perpendicular plate of the palatine bone posteriorly, and above by the nasal surface of the ethmoidal labyrinth, which intervenes between the nasal cavity and the orbit. The three conchæ project downwards and slightly medially, and each forms the roof of a passage which communicates freely with the nasal cavity. These passages are termed the meatuses of the nose.

The *inferior concha* is a curved lamina of thin bone and is an independent entity. It articulates with the nasal surface of the maxilla and the perpendicular plate of the palatine bone, and possesses a free lower border, which is gently curved. The *inferior meatus* lies under cover of the inferior concha and extends downwards to the floor of the nasal cavity. It is the largest of the three meatuses and extends almost the entire length of the lateral wall of the nose. The inferior meatus is deepest at the junction of its anterior and middle thirds, and in this situation it presents the lower orifice of the nasolacrimal canal.

The *middle* and *superior conchæ* are projections from the medial surface of the ethmoidal labyrinth. The *middle concha* is much the larger and extends backwards

to articulate with the perpendicular plate of the palatine bone. The *middle meatus* is placed between the middle and inferior conchæ. Its lateral wall displays several important features which can be examined only after the removal of the middle concha (fig. 330). Its upper part is occupied by a rounded elevation, termed the *ethmoidal bulla*, which contains the middle ethmoidal sinuses. Below and in front of the bulla a curved fissure passes downwards and backwards across the lateral wall of the meatus. It is named the *hiatus semilunaris*, and its upper or anterior end is continuous with a curved canal, termed the *infundibulum*. In its posterior part the

FIG. 330.—The lateral wall of the right nasal cavity, with parts of the middle and inferior nasal conchæ removed.



floor of the hiatus semilunaris receives the opening of the maxillary sinus, which is usually hidden by the edge of the fissure. The anterior ethmoidal sinuses open into the infundibulum, which, in fifty per cent. of skulls, opens above into the frontal sinus. It may, however, be closed above by the fusion of the bulla ethmoidalis with the edge of the hiatus semilunaris and, in that event, the frontal sinus opens independently into the anterior part of the middle meatus. The middle ethmoidal sinuses open above, or near, the bulla. The lateral wall of the meatus below the hiatus semilunaris may be partially deficient, and the gap or gaps lead into the maxillary sinus. In the recent state they are usually closed by the nasal mucosa.

The *superior concha* is a small curved lamina which lies above and behind the middle concha. It roofs in the *superior meatus*, which is much the shortest and shallowest of the three meatuses; it receives the opening of the posterior ethmoidal sinuses. Immediately behind the superior meatus the sphenopalatine foramen,

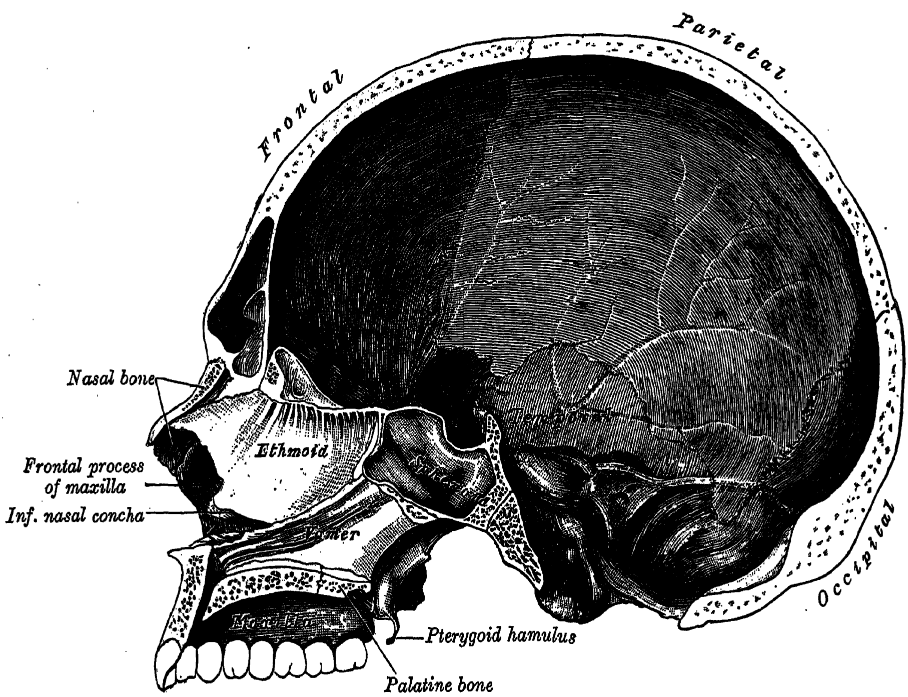
which opens into the pterygopalatine fossa, pierces the lateral wall of the nasal cavity. A narrow interval, termed the *spheno-ethmoidal recess*, separates the superior concha from the anterior surface of the body of the sphenoid, through which the sphenoidal sinus opens into the nasal cavity.

The **anterior nasal aperture** has been described on p. 246.

The **posterior nasal apertures (choanæ)** are separated from each other by the posterior border of the vomer. They are bounded below by the posterior border of the horizontal plate of the palatine bone, above by the base of the skull; and laterally, on each side, by the medial pterygoid plate.

Particular features.—The anterior sloping part of the **roof** (fig. 329) is formed by the nasal bone and the nasal spine of the frontal bone. In addition to the numerous small foramina for the transmission of the olfactory nerves, the horizontal part of the roof

FIG. 331.—A sagittal section through the skull.



presents a separate foramen, situated anteriorly, which gives passage to the anterior ethmoidal nerve and vessels. The posterior sloping part of the roof is formed above by the anterior aspect of the body of the sphenoid, with which the sphenoidal concha (p. 293) is fused, and below by the ala of the vomer and the sphenoidal process of the palatine bone.

The **floor** (fig. 328) is crossed at the junction of its middle and posterior thirds by the palatomaxillary suture. Close to the median plane anteriorly it is pierced by the incisive canal, which transmits the terminal part of the long sphenopalatine (nasopalatine) nerve and the greater palatine vessels. Both incisive canals open into the incisive fossa on the bony palate and they traverse the line of union of the os incisivum (premaxilla) with the maxilla; they represent a primitive communication between the mouth and the nose.

At the upper and lower borders of the **medial wall** (fig. 328) other bones, in addition to the vomer and the perpendicular plate of the ethmoid, make minor contributions to the septum. Above and in front, the nasal bones and the frontal spine, above and behind, the rostrum and crest of the sphenoid, and below, the nasal crests of the maxillæ and palatine bones all take small parts in its constitution. The vomer is grooved by the long sphenopalatine nerve, as it runs downwards and forwards to reach the incisive canal.

The **lateral wall** (figs. 329, 330) is formed anteriorly and above by the nasal bone and the frontal process of the maxilla. Behind the frontal process of the maxilla, and articulating with its posterior border, the lacrimal bone lies on the lateral wall of the middle meatus and articulates below with the lacrimal process of the inferior concha. These two bones form the medial wall of the **nasolacrimal canal** (fig. 330), which conducts the nasolacrimal duct to the inferior meatus. Posteriorly the lacrimal bone articulates with the ethmoidal labyrinth and

helps to close some of the ethmoidal sinuses. The *uncinate process of the ethmoid* springs from this part of the labyrinth and curves downwards and backwards in the lateral wall of the middle meatus. It is a very thin and fragile process, about 3 mm. wide, which curves across the maxillary hiatus and articulates near its extremity with the ethmoidal process of the inferior concha. The concave, posterior border of the process is free and forms the medial edge of the hiatus semilunaris; the convex anterior border is free in its upper part only. Owing to its position relative to the maxillary hiatus the uncinate process helps to form the medial wall of the maxillary sinus. The *maxillary hiatus*, which forms such a conspicuous opening on the nasal surface of the maxilla (fig. 382), is reduced in size very considerably by the neighbouring bones. Its lower part is covered by the inferior concha and its maxillary process; above the inferior concha the uncinate process of the ethmoid, as already stated, encroaches on the gap. Posteriorly the anterior part of the perpendicular plate of the palatine bone closes it in still further, and above and in front small portions of the ethmoidal labyrinth and the lacrimal bone overlap its margins (fig. 383). As a result, the maxillary hiatus is reduced sometimes to a single orifice in the floor of the posterior part of the hiatus semilunaris, although as a rule additional openings exist behind the uncinate process, and between its lower border and the upper border of the inferior concha. The *bulla ethmoidalis* is very variable in its size and shape and, as already mentioned, may be fused with the upper part of the uncinate process. In that event the duct of the frontal sinus opens into the upper part of the middle meatus medial to the blind end of the infundibulum. A third concha is often present on the medial surface of the ethmoidal labyrinth above and behind the posterior end of the superior concha; it is little more than a slight ridge, separated from the superior concha by a shallow depression. The *sphenopalatine foramen* (fig. 329) lies at the posterior limit of the superior meatus. It transmits the sphenopalatine artery and the long and short sphenopalatine nerves from the pterygopalatine fossa. The foramen is bounded above by the body of the sphenoid and the sphenoidal concha; below by the notched upper border of the perpendicular plate of the palatine bone, and in front and behind by its orbital and sphenoidal processes respectively.

THE MANDIBLE [MANDIBULA] (figs. 332, 333)

The **mandible**, which is the largest and strongest bone of the face, has a curved, horizontal *body*, which is convex forwards, and two broad *rami*, which project upwards from the posterior ends of the body.

The **body** of the mandible is curved like a horseshoe, and possesses an external and an internal surface, separated by upper and lower borders. The *external surface* is marked in the upper part of the median plane by a faint ridge, often indistinguishable, which indicates the line of fusion of the two halves of the fœtal bone. Inferiorly the ridge divides to enclose a triangular raised area, termed the *mental protuberance*, the base of which is depressed in the centre but raised on each side to form the *mental tubercle*. Below the interval between the two premolar teeth, or below the second premolar, the *mental foramen*, which gives exit to the mental nerve and vessels, opens on the surface. A faint ridge, termed the *oblique line*, runs upwards and backwards from the mental tubercle, to become salient behind, where it is continuous with the anterior border of the ramus.

The lower border of the body is termed the *base of the mandible*. It extends backwards and laterally from the symphysis menti, and becomes continuous with the lower border of the ramus behind the third molar tooth. Near the median plane it presents a small, roughened depression, named the *digastric fossa*. Behind the digastric fossa the base is thick and rounded and presents a slight downward convexity.

The upper border of the body is formed by the *alveolar part*, which is hollowed into sixteen *sockets* (alveoli) for the roots of the teeth. These sockets vary in size and depth, and are single or subdivided by septa according to the teeth which they contain.

The *internal surface* is divided into two areas by an oblique ridge termed the **mylohyoid line.** Sharp and distinct in the region of the molar teeth, it becomes almost undiscernible in front. It commences behind the third molar tooth, not quite 1 cm. from the upper border of the bone, and runs forwards and downwards to reach the symphysis menti in the interval between the two digastric fossæ. Below the mylohyoid line the surface is slightly hollowed out and forms the *submandibular fossa* for the lodgment of the submandibular (submaxillary) salivary gland. The area above the mylohyoid line widens as it is traced forwards and presents in front a triangular area, termed the *sublingual fossa*, which lodges the sublingual gland. Above the sublingual fossa and extending backwards to the third

FIG. 332.—The left half of the mandible. Lateral aspect.

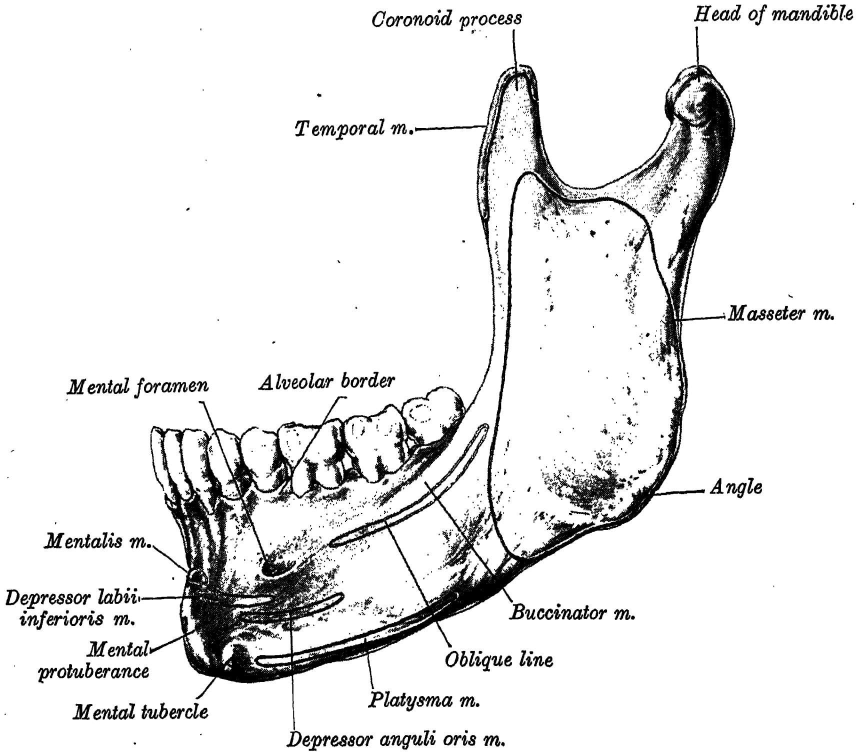


FIG. 333.—The right half of the mandible. Medial aspect.

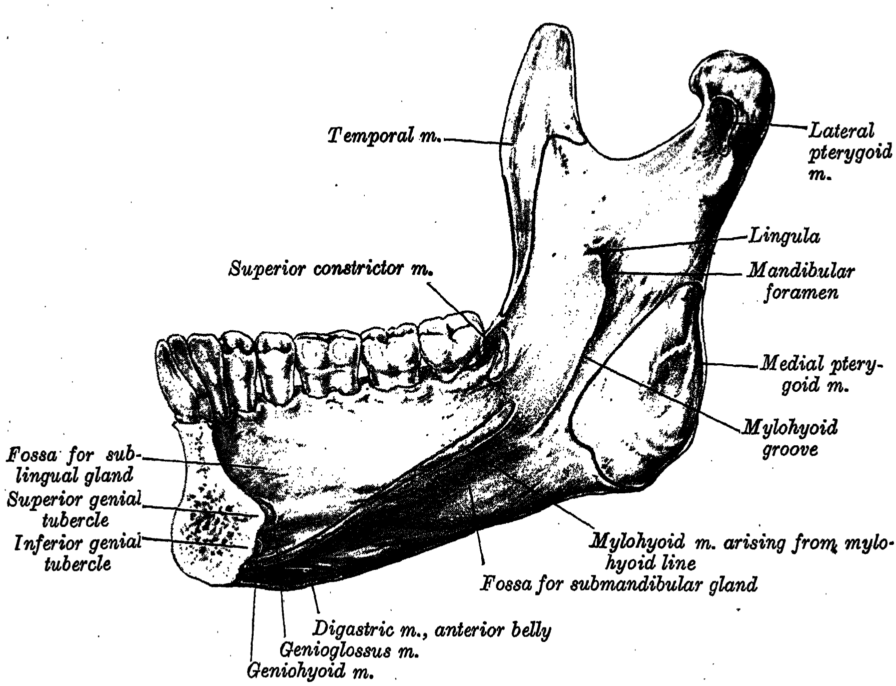

molar tooth a strip of the bone is closely covered with the mucous membrane of the mouth. Above the anterior ends of the mylohyoid lines the posterior surface of the symphysis menti is marked by a small irregular elevation, which may be divisible into two or more parts, termed the *genial tubercles* (mental spine). Posteriorly, a groove, termed the *mylohyoid groove*, extends downwards and forwards on to the body from the ramus and passes below the posterior end of the mylohyoid line.

The **ramus** (figs. 332, 333) of the mandible is quadrilateral in shape, and presents two surfaces, four borders and two prominent processes. The *lateral surface* is flat and marked by oblique ridges in its lower part. The *medial surface* presents, a little above its centre, an irregular opening, named the *mandibular foramen.* This opening leads into the *mandibular canal*, which curves downwards and forwards to open on the external surface of the body at the mental foramen. It transmits the nerve and vessels which supply the teeth of the mandible. In front and on the medial side the foramen is obscured by a thin triangular process termed the *lingula.* The *mylohyoid groove* commences behind the lingula and runs downwards and forwards to reach the internal surface of the body. The part of the medial surface which lies behind the groove is marked by a number of short rough ridges. The *inferior border* of the ramus is continuous in front with the base of the mandible; behind, it meets the posterior border at the **angle of the mandible.** When the angle is prominent the inferior border presents a concavity, directed downwards. Eversion of the angle is characteristic of the male mandible; in the female it is frequently inverted. The *upper border* is thin and bounds a wide notch, termed the *mandibular notch.* It is surmounted in front by a triangular, flattened projection, termed the coronoid process, and behind by a stout, articular process named the condyloid process. The *posterior border*, thick and rounded, extends from the back of the condyloid process to the angle of the mandible. It is gently curved, being convex backwards above and concave below, and is intimately related to the parotid gland. The *anterior border* is thin above, where it is continuous with the anterior border of the coronoid process, and thicker below, where it is continuous with the oblique line.

The **coronoid process** is a flattened triangular projection, directed upwards and slightly forwards. Its posterior border bounds the mandibular notch and its anterior border is continuous with the anterior border of the ramus. Its margins and medial surface provide insertion for most of the fibres of the temporalis muscle. The **condyloid process** is expanded above to form the *head* of the mandible, which is covered with fibrocartilage. It articulates with the articular fossa of the temporal bone—an articular disc intervening. It is convex in all directions and its transverse measurement is greater than its anteroposterior. The lateral aspect of the head forms a blunt point which projects beyond the lateral surface of the rest of the ramus and can be felt in the living subject just in front of the tragus of the auricle. When the mouth is opened the head passes downwards and forwards, and the examining finger sinks into a small depression. The constricted portion below the head is termed the *neck of the mandible.* It is slightly flattened from before backwards, and its anterior aspect is limited on the lateral side by the backward continuation of the margin of the mandibular notch. Medial to this ridge the anterior surface of the neck presents a rough muscular impression.

The **mandibular canal** runs from the mandibular foramen obliquely downwards and forwards in the ramus, and then horizontally forwards in the body below the sockets of the teeth, with which it communicates by small openings. It contains the inferior dental (alveolar) nerve and vessels, from which branches enter the roots of the teeth. Between the roots of the first and second premolars, or below the root of the second premolar tooth, the mandibular canal divides into *mental* and *incisive canals*; the mental canal runs upwards, backwards and laterally to reach the mental foramen; the incisive canal is continued forwards below the incisor teeth.

Particular features.—A small shallow fossa marks the bone below the incisor teeth and gives origin to the mentalis and a part of the orbicularis oris muscle. The anterior end of the oblique line gives origin to the depressor labii inferioris (quadratus labii inferioris) and the depressor anguli oris (triangularis) muscles. The platysma is inserted into the bone below these muscles and extends backwards beyond them. The lower margin of the **mental foramen** is sharp and the mental nerve is directed upwards and backwards as it emerges

from the bone. Adjoining the alveolar border the bone is closely covered with the mucous membrane of the mouth. Immediately below this area, in the region of the molar teeth, the buccinator muscle has a linear origin, which extends medially behind the last molar tooth to the attachment of the pterygomandibular ligament.

The **mylohyoid** line gives origin to the mylohyoid muscle. Above its posterior end the bone gives origin to fibres of the superior constrictor muscle of the pharynx, and the pterygomandibular ligament (raphe) is attached immediately behind the third molar tooth. The lingual nerve gains the tongue by passing above the posterior end of the mylohyoid line, and in this situation is closely related to the inner surface of the mandible. A strip of bone along the alveolar border is covered by the mucous membrane of the mouth, and the sublingual gland lies in contact with the bone anteriorly between this area and the mylohyoid line. The upper *genial tubercles* give origin to the genioglossi and the lower to the geniohyoid muscles; both tubercles are placed above the anterior ends of the mylohyoid lines. The *submandibular fossa* lodges some of the submandibular lymph glands in addition to the salivary gland, and the facial (external maxillary) artery may come into contact with this region as it descends to curl round the base of the mandible, where it sometimes produces a shallow groove. The *digastric fossa* gives origin to the anterior belly of the digastric and lies below the anterior end of the mylohyoid line.

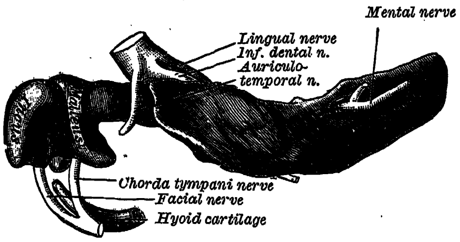

FIG. 334.—The right half of the mandible of a human embryo 24 mm. long. Lateral aspect. (From a model by Low.)

The **ramus** and its processes provide insertion for all the principal muscles of mastication. Its *lateral surface* gives insertion to the masseter muscle, except at its upper and posterior part, where it is covered by the parotid gland.

The *medial surface* gives insertion to the medial pterygoid muscle at the roughened area which lies behind and below the mylohyoid groove. The **mandibular foramen** admits the inferior dental (inferior alveolar) nerve and vessels to the mandibular canal. Its medial border is formed by the *lingula*, to which the lower end of the sphenomandibular ligament is attached. Posterior to the lingula the mylohyoid nerve and vessels enter the *mylohyoid groove*, which may be converted into a bony canal in a part of its extent. The groove reaches the body of the mandible below the posterior end of the mylohyoid line, and the nerve and vessels then pass on to the superficial aspect of the mylohyoid muscle. In front of the mylohyoid groove and below the lingula the medial surface of the ramus is related to the medial pterygoid muscle, but the lingual nerve intervenes between the muscle and the bone, as it runs downwards and forwards to reach the tongue The lowest fibres of insertion of the temporalis muscle descend beyond the coronoid process and are attached to the *anterior border* of the ramus and the adjoining part of the medial surface. The area above and behind the mandibular foramen is related to the maxillary (internal maxillary) artery and its inferior dental branch, and the part adjoining the mandibular notch is in relation with the lateral pterygoid muscle. The *mandibular notch* transmits the masseteric nerve and vessels from the infratemporal fossa.

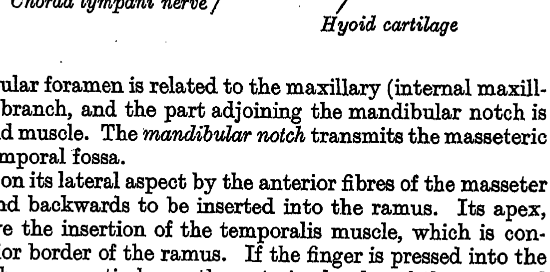

FIG. 335.—The right half of the mandible of a human embryo 24 mm. long. Medial aspect. (From a model by Low.)

The **coronoid process** is covered on its lateral aspect by the anterior fibres of the masseter muscle as they pass downwards and backwards to be inserted into the ramus. Its apex, margins and medial surface receive the insertion of the temporalis muscle, which is continued downwards along the anterior border of the ramus. If the finger is pressed into the yielding part of the cheek below the zygomatic bone, the anterior border of the coronoid process can be identified in the living subject when the mouth is opened. Owing to the way in which it is expanded, the **condyloid process** projects beyond the surfaces of the ramus, but more so on the medial than on the lateral side. The articular *head of the mandible* extends only for a short distance down the anterior surface of the process, but it covers the whole of its superior aspect and descends for 5 mm. or more on its posterior aspect. Its superior aspect slopes medially and slightly downwards and backwards. Its projecting

lateral part is separated from the cartilaginous part of the external auditory meatus by a portion of the parotid gland. The smooth lateral aspect of the *neck of the mandible* gives attachment to the temporomandibular ligament (fig. 504) and is covered by the parotid gland. The rough impression on the front of the neck receives the insertion of the lateral pterygoid muscle. The medial surface of the neck is related to the auriculotemporal nerve above and to the maxillary (internal maxillary) artery below.

The relation of the parotid gland to the mandible requires special mention. It occupies the interval below the external auditory meatus, bounded in front by the posterior border of the ramus, behind by the mastoid process and medially by the styloid process; but it extends forwards beyond this area and covers the lateral aspect of the temporomandibular joint and the part of the lateral surface of the ramus behind the masseter muscle. In addition it curls round the posterior border and comes into contact with the medial aspect of the ramus just above the insertion of the medial pterygoid muscle.

FIG. 336.—The right half of the mandible of a human embryo 95 mm. long. Lateral aspect. (The nuclei of cartilage are stippled.) (From a model by Low.)

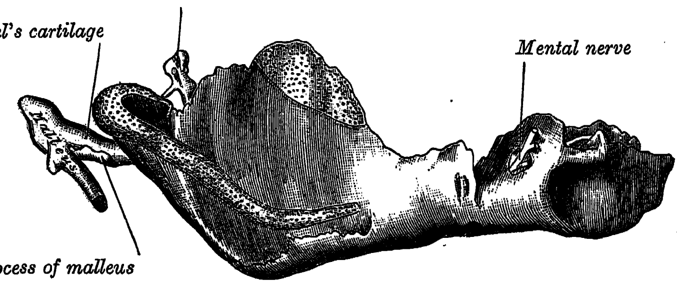

FIG. 337.—The right half of the mandible of a human embryo 95 mm. long. Medial aspect. (The nuclei of cartilage are stippled.) (From a model by Low.)

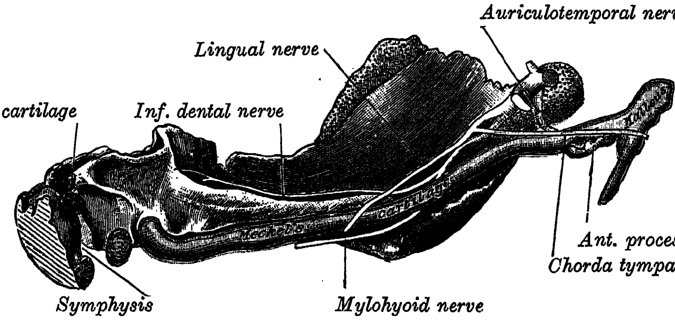

Ossification.—The mandible is ossified in the fibrous membrane covering the outer surfaces of Meckel's cartilages. This pair of cartilages form the cartilaginous bars, or skeletal elements of the mandibular arches (p. 99). Their dorsal or cranial ends are connected with the cartilaginous ear-capsules, and their ventral ends are joined to each other by mesenchymal tissue. They run forwards below the condyloid processes in the 95 mm. embryo and then, bending downwards, lie in a groove near the lower border of the bone; in front of the canine teeth they incline upwards to the symphysis menti. From the proximal end of each cartilage the malleus and incus—two of the three ossicles of the middle ear—are developed; the next succeeding portion, as far as the lingula of the mandible, disappears, but its sheath persists to form the sphenomandibular ligament. The part of the cartilage which stretches from the tooth-bud of the second milk molar to a point a little behind the anterior end of the mandible occupies, for a time, a tunnel in the bone, but is ultimately absorbed. The portion below the incisor teeth is ossified and incorporated with the mandible.

Ossification takes place in the membrane covering the outer surfaces of Meckel's cartilages (figs. 334 to 337), and each half of the bone is formed from one centre,* which appears near the mental foramen about the sixth week of fœtal life, i.e. just after the appearance of the primary centres for the clavicle (p. 340). By the tenth week the portion of Meckel's cartilage which lies below the incisor teeth is surrounded and invaded by the membrane-bone. Somewhat later, accessory pieces of cartilage make their appearance—viz. a wedge-shaped piece in the condyloid process and extending downwards through the ramus; a small patch along the anterior border of the coronoid process; and smaller nodules in the front part of both alveolar walls and along the front of the base of the bone. These accessory nodules of cartilage are invaded by the surrounding membrane-bone and undergo absorption. The inner alveolar border is formed in the human mandible by an ingrowth from the main mass of the bone.

A number of small ossicles, termed the *ossicula mentalia,* appear in the fibrous tissue of the symphysis about the seventh month of fœtal life. They enlarge and very soon fuse with one another and with the mandible in no fixed order. Usually two or four in number, they are responsible for the formation of the mental protuberance. Whether they ossify in the remains of the ventral ends of Meckel's cartilages or in the fibrous tissue of the symphysis is uncertain.

The Changes produced in the Mandible by Age

At birth (fig. 338 A, B) the body of the bone is a mere shell, enclosing the sockets of the deciduous teeth, imperfectly partitioned off from one another. The mandibular canal runs near the lower border of the bone, and the mental foramen opens below the socket of the first deciduous molar tooth. The angle is obtuse (175°), and the condyloid portion is nearly in line with the body. The coronoid process is relatively large and projects above the level of the condyle.

After birth (fig. 338 C, D) the two halves of the bone become joined at the symphysis from below upwards, in the first year; but a trace of separation may be visible in the beginning of the second year, near the alveolar margin. The body elongates, but more especially behind the mental foramen, to provide space for the three additional teeth developed in this part. The depth of the body increases by growth of the alveolar part of the bone, to afford room for the roots of the teeth, and by thickening of the subalveolar portion. After the second dentition the mandibular canal is situated a little above the level of the mylohyoid line, and the mental foramen occupies the position usual to it in the adult. By the fourth year the angle is reduced to about 140°. As the mandible increases in size, bone is laid down along the posterior borders of the ramus and the coronoid process, while at the same time absorption of bone is occurring along their anterior borders. This process of remodelling goes on continuously until the bone has reached its adult size, and it enables the alveolar part to lengthen sufficiently to provide the necessary space for the permanent molar teeth.

In the adult (fig. 338 E) the alveolar and subalveolar portions of the body are of about equal depth. The mental foramen opens midway between the upper and lower borders of the bone, and the mandibular canal runs nearly parallel with the mylohyoid line. The ramus is almost vertical in direction, the angle measuring from 110° to 120°.

In old age (fig. 338 F) the bone is reduced in size. Following the loss of the teeth the alveolar part is absorbed, and consequently the mandibular canal and the mental foramen are close to the alveolar border. The ramus is oblique in direction, the angle measures about 140°, and the neck of the mandible is more or less bent backwards.† The process of absorption affects chiefly the

thinner of the two alveolar walls and, after its completion, a linear *alveolar ridge* is found on the alveolar border of the bone. In the mandible the labial wall is the thinner in the incisor and canine regions, but it is the lingual wall which is the weaker in the molar region. The alveolar ridge lies therefore within the line of the teeth in the incisor region but lies outside that line in the molar region, forming a curve which is wider than the curve of the line of the teeth and intersects it on each side in the premolar region. In the maxilla, however, the labial wall is everywhere the thinner and, after absorption, the alveolar ridge lies wholly within the curve of the line of the teeth.

THE HYOID BONE [OS HYOIDEUM]

The **hyoid bone** (fig. 339) is U-shaped and is suspended from the tips of the styloid processes of the temporal bones by the stylohyoid ligaments. It has a body, two greater and two lesser cornua.

The **body** or middle part of the hyoid bone is of a quadrilateral form. Its *anterior surface* is convex and directed forwards and upwards. Its upper part is crossed by a well-marked ridge which has a slight downward convexity, and in many cases a vertical median ridge divides the body into lateral halves. The portion of the vertical ridge above the transverse line is present in the majority of specimens, but that below the transverse line is rarely seen. The *posterior surface* is smooth, concave, directed backwards and downwards, and separated from the epiglottis by the thyrohyoid membrane and a quantity of loose areolar tissue ; a bursa intervenes between the bone and the membrane. In early life the *lateral extremities* of the body are connected to the greater cornua by primary cartilaginous joints, but after middle life they are usually united by bone.

FIG. 339.—The hyoid bone. Antero-superior aspect.

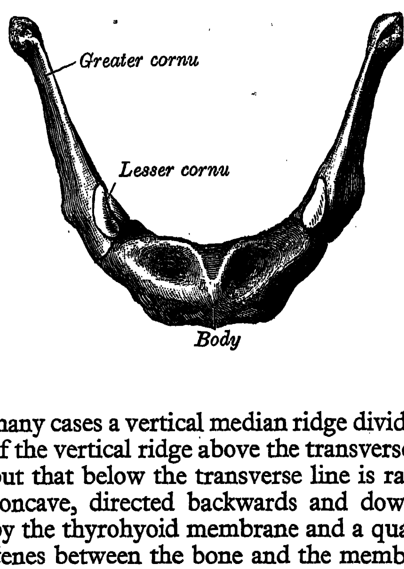

FIG. 340.—A sketch of left half of the hyoid bone to show the muscular attachments.

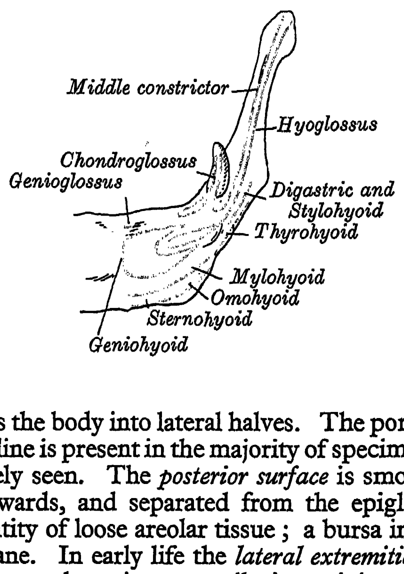


The **greater cornua** of the hyoid bone project backwards from the lateral limits of the body; they are flattened from above downwards and diminish in size from before backwards. Each cornu ends posteriorly in a tubercle. Close to its lateral border the *upper surface* is rough for muscular attachments.

The **lesser cornua** of the hyoid bone are two small, conical eminences attached by their bases at the angle of junction of the body and greater cornua. They are connected to the body of the bone by fibrous tissue and occasionally to the greater cornua by synovial joints, which usually persist throughout life, but occasionally become ankylosed.

Particular features.—The *anterior surface* of the **body** gives insertion to the geniohyoid muscle in the greater part of its extent both above and below the transverse ridge; a portion of the origin of the hyoglossus muscle invades the lateral margin of the geniohyoid area (fig. 340). The lower part of this surface gives insertion to the mylohyoid muscle, and below that to the sternohyoid medially and the omohyoid laterally. The *superior border*

of the body is rounded and gives attachment to the lowest fibres of the genioglossi, to the hyo-epiglottic ligament and to the thyrohyoid membrane. The *inferior border* gives insertion to the sternohyoid medially and the omohyoid laterally, and sometimes to the medial fibres of the thyrohyoid muscle. It gives attachment also to the levator glandulæ thyreoideæ, when that muscle is present.

The *upper surface* of the **greater cornu** gives origin to the middle constrictor of the pharynx and, more laterally, to the hyoglossus muscle, both of which extend throughout its whole length. Near the junction of the cornu with the body the stylohyoid muscle is inserted lateral to the hyoglossus muscle, and a little posterior to this insertion the fibrous loop through which the tendon of the digastric muscle runs is attached to the bone. The *medial border* gives attachment to the thyrohyoid membrane; the lateral border receives, anteriorly, the insertion of the thyrohyoid muscle. The inferior surface, which is oblique, is separated from the thyrohyoid membrane by some fibro-areolar tissue.

The posterior and lateral aspects of the **lesser cornu** give origin to fibres of the middle constrictor muscle of the pharynx. Its apex gives attachment to the stylohyoid ligament, which is often ossified in part. The medial aspect of its base gives origin to the chondroglossus muscle.

Ossification.—The hyoid bone is developed from the cartilages of the second and third branchial or visceral arches—the lesser cornua from the second, the greater cornua from the third, and the body from the fused ventral ends of both (p. 99). It is ossified from six centres: a pair for the body, and one for each cornu. Ossification commences in the greater cornua towards the end of intrauterine life, in the body before or shortly after birth, and in the lesser cornua during the first or second year, or later.

THE CRANIAL BONES [OSSA CRANII]

The Occipital Bone [Os Occipitale]

The **occipital bone** (figs. 341-343), situated at the posterior and inferior part of the cranium, is trapezoid in shape and concave forwards. It encloses a large oval aperture, termed the *foramen magnum*, through which the cranial cavity communicates with the vertebral canal. The expanded plate above and behind this foramen is named the *squamous part*; the thick, somewhat quadrilateral piece in front of it is called the *basilar part*; that on each side of the foramen is named the *condylar part* (lateral portion).

The **squamous part** of the occipital bone, situated above and behind the foramen magnum, is curved from above downwards and from side to side.

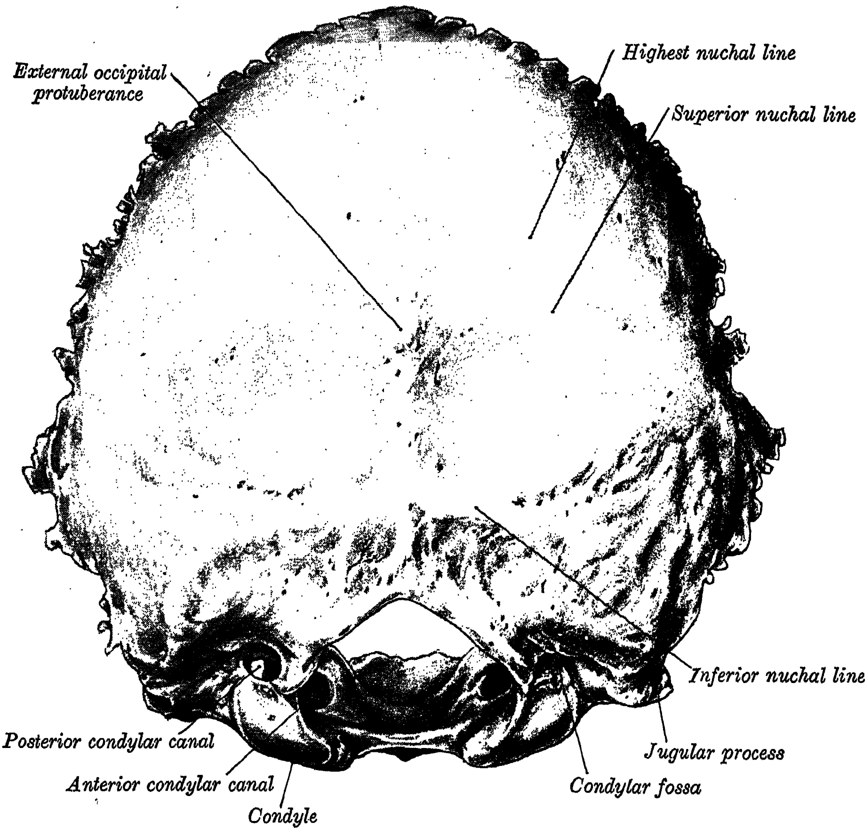
The *external surface* is convex and presents, midway between the summit of the bone and the foramen magnum, a prominence termed the *external occipital protuberance*. Extending laterally from this on each side are two curved lines, one a little above the other. The upper line, faintly marked and often absent, is named the *highest nuchal line*, and to it the epicranial aponeurosis (galea aponeurotica) is attached. The lower line is termed the *superior nuchal line*. The part of the external surface above the highest nuchal lines is smooth, and covered with the occipital belly of the occipitofrontalis muscle. The part below the highest nuchal lines is rough and irregular for the attachment of several muscles. From the external occipital protuberance a ridge, termed the *external occipital crest*, often faintly marked, descends to the foramen magnum, and affords attachment to the ligamentum nuchæ; running laterally from the middle of this line on each side is the *inferior nuchal line*. The superior nuchal line gives origin to the occipitalis and trapezius, and insertion to the sternomastoid and splenius capitis (fig. 342); into the surface between the superior and inferior nuchal lines the semispinalis capitis and the obliquus capitis superior are inserted; the inferior nuchal line and the area below it receive the insertions of the rectus capitis posterior major and minor muscles. The posterior atlanto-occipital membrane is attached around the posterolateral part of the foramen magnum, immediately outside the margin of the foramen.

The *internal surface* of the squamous part is deeply concave, and is divided into four fossæ by an irregular elevation, termed the *internal occipital protuberance*. The upper two fossæ are triangular, and lodge the posterior ends of the occipital lobes of the cerebrum; the lower two are quadrilateral and support the hemispheres of the cerebellum. A wide groove, with raised edges, extends upwards from the protuberance to the superior angle of the bone; it lodges the hinder part of the superior sagittal sinus and is termed the *sagittal sulcus*; to the margins of this sulcus the posterior part of the falx cerebri is attached. A prominent ridge, named the *internal occipital crest*, runs downwards and forwards from the protuberance; it gives attachment to the falx cerebelli, and bifurcates near the foramen

magnum; the occipital sinus, which is sometimes duplicated, lies in the attached margin of the falx. At the lower part of the internal occipital crest a small depression is sometimes distinguishable; it is termed the *vermian fossa,* since it is occupied by part of the inferior vermis of the cerebellum. On each side a wide *transverse sulcus* extends laterally from the internal occipital protuberance; these sulci accommodate the transverse sinuses, and their margins give attachment to the tentorium cerebelli. The right transverse sulcus is usually larger than the left and is continuous with the sagittal sulcus; but the left may be larger than the right, or the two may be almost equal in size. The angle of union of the superior sagittal and transverse sinuses is named the *confluence of the sinuses,* and its position is indicated by a depression on one or other side of the protuberance.

FIG. 341.—The occipital bone. Posterior aspect.

The posterior condylar canal was present on the left side only in this specimen.



The *superior angle* of the squamous part articulates with the posterior superior angles of the parietal bones, and corresponds in position with the *posterior fontanelle* (*occipital fonticulus*) of the fœtal skull. The *lateral angles* are at the ends of the transverse sulci; each is received into the interval between the parietal bone and the mastoid part of the temporal bone. The *lambdoid* or *superior borders* extend from the superior to the lateral angles; they are serrated for articulation with the occipital borders of the parietal bones, and by this union form the lambdoid suture. The *mastoid* or *inferior borders* extend from the lateral angles to the jugular processes; each articulates with the mastoid portion of the corresponding temporal bone.

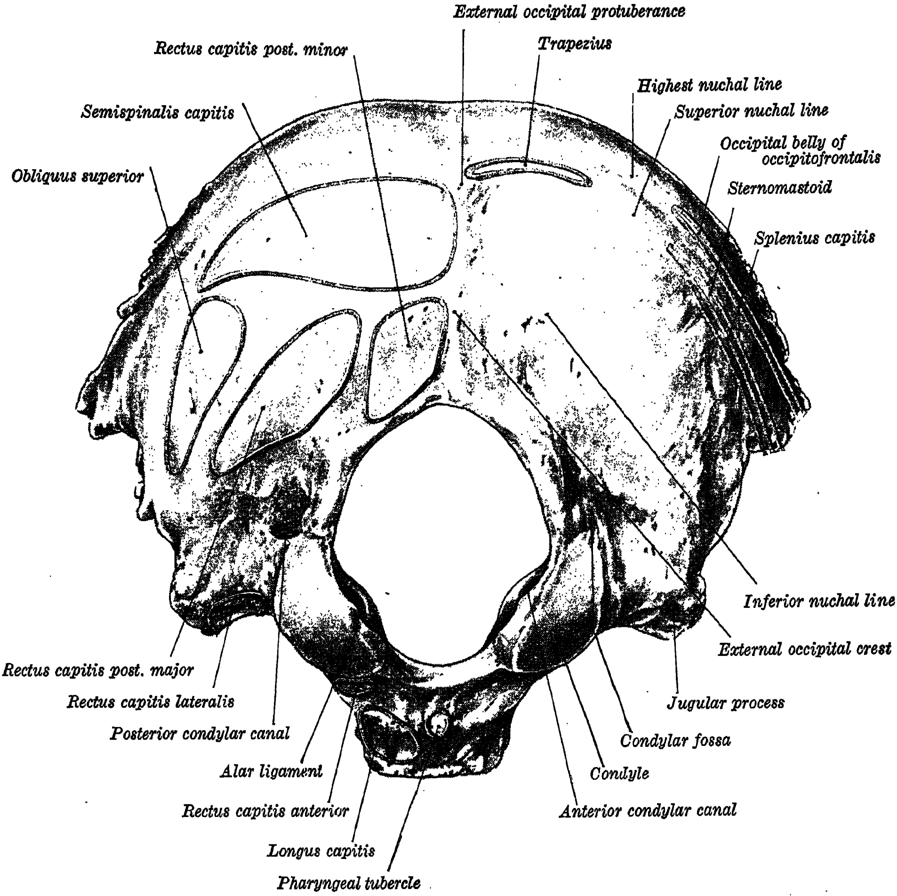
The **basilar part** of the occipital bone extends forwards and upwards from the foramen magnum, and presents *in front* a more or less quadrilateral surface. In the young skull this surface is rough and uneven and is joined to the body of the sphenoid bone by a plate of cartilage. By the twenty-fifth year this plate of cartilage has undergone ossification and the occipital and sphenoid bones are fused.

On the *inferior surface* of the basilar part, about 1 cm. in front of the foramen magnum, a small elevation, termed the *pharyngeal tubercle,* gives attachment to the fibrous raphe of the pharynx. The longus capitis is inserted into the bone lateral to the pharyngeal

tubercle, and the rectus capitis anterior into a small depression in front of the occipital condyle. The anterior margin of the foramen magnum gives attachment to the anterior atlanto-occipital membrane.

The *superior surface* of the basilar part consists of a broad, shallow groove which inclines upwards and forwards from the anterior border of the foramen magnum ; it supports the medulla oblongata and the lower part of the pons, and near the margin of the foramen gives attachment to the membrana tectoria and the apical ligament. On the lateral margins of this surface the *inferior petrosal sulci* are occupied by the inferior petrosal sinuses, and below each of these sulci the lateral margin of the basilar part is rough for articulation with the petrous part of the temporal bone.

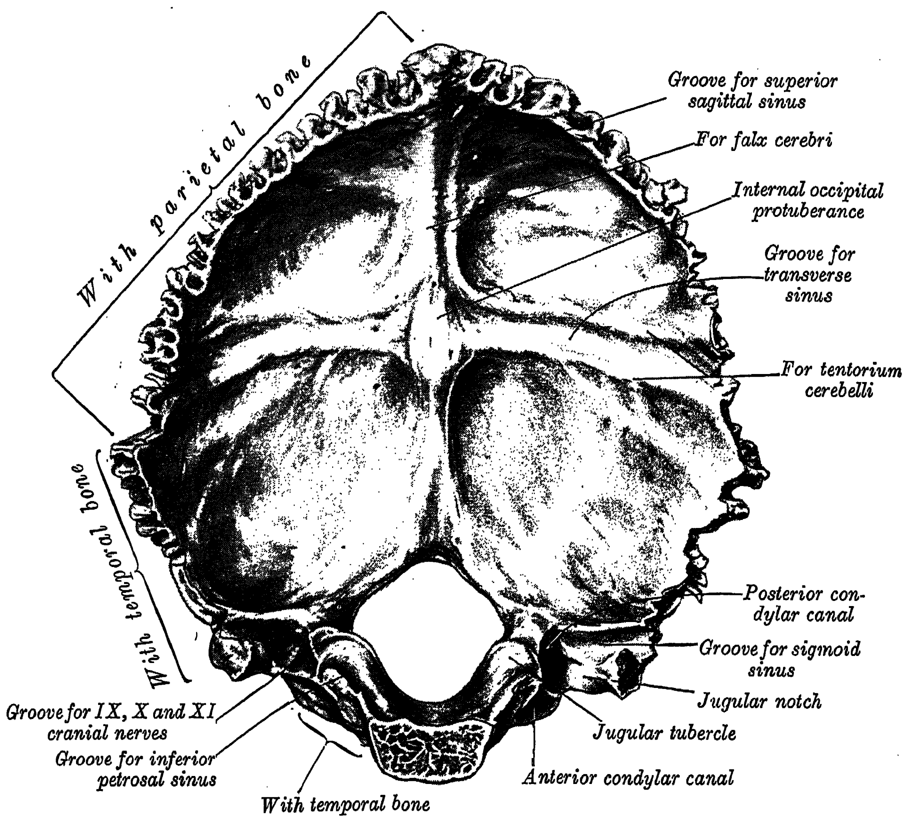
FIG. 342.—The occipital bone. Inferior aspect.
Drawn from the same specimen as fig. 341.



The **condylar parts** (**lateral parts**) of the occipital bone are situated at the sides of the foramen magnum ; on their *inferior surfaces* the *occipital condyles* form two oval processes for articulation with the superior facets of the atlas vertebra. They are oval or reniform in shape, with their long axes running forwards and medially, so that their anterior ends are closer together than their posterior and encroach on the basilar portion of the bone ; the posterior ends extend back to the level of the middle of the foramen magnum. The articular surfaces of the condyles are convex from before backwards and from side to side ; they look downwards and laterally, and are occasionally constricted near their centres. On the medial side of each a rough impression or tubercle gives attachment to the alar ligament. Above the anterior part of each condyle the bone presents the *anterior condylar* (*hypoglossal*) *canal,* which begins on the cranial surface of the bone a short distance above the anterior part of the foramen magnum, and is directed laterally and forwards. It may be partially or completely divided into two by a spicule of bone ; it gives exit to the hypoglossal nerve, and entrance to a meningeal branch of the ascending pharyngeal artery.

A depression, termed the *condylar fossa,* lies behind the condyle and receives the posterior margin of the corresponding superior facet of the atlas when the head is bent backwards; the floor of this fossa is sometimes perforated by the *posterior condylar canal,* through which an emissary vein passes from the sigmoid sinus. The *jugular process* extends laterally from the posterior half of the condyle. It is a quadrilateral plate of bone, indented in front by the *jugular notch,* which, in the articulated skull, forms the posterior part of the jugular foramen. The jugular notch is sometimes divided into two by a bony spicule named the *intrajugular process,* which projects forwards and laterally. The under surface of the jugular process is rough and gives attachment to the rectus capitis lateralis; from this surface an eminence, termed the *paramastoid process,* sometimes projects downwards, and may be of sufficient length to articulate with the transverse process of the atlas. Laterally the jugular process

FIG. 343.—The occipital bone. Internal aspect.



presents a rough quadrilateral or triangular area which is joined to the jugular surface of the temporal bone by a plate of cartilage; after the age of twenty-five this plate tends to ossify.

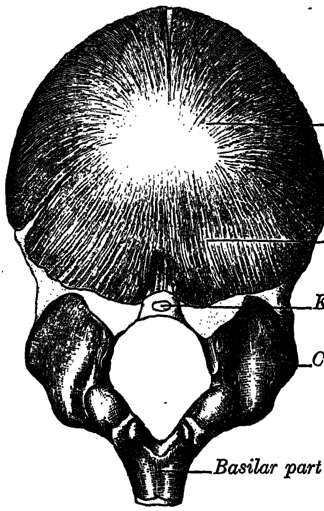
On the *superior surface* of the condylar part an oval eminence, termed the *tuberculum jugulare,* overlies the anterior condylar canal; its posterior part often presents a shallow furrow for the glossopharyngeal, vagus, and accessory nerves. On the superior surface of the jugular process a deep groove curves medially and forwards around an upwardly directed, hook-shaped process and ends at the jugular notch; it lodges the terminal part of the sigmoid sinus. Close to the medial margin of the groove the posterior condylar canal opens into the posterior cranial fossa.

The *foramen magnum* is a large oval aperture with its long diameter in the median plane. The foramen is wider behind than in front, where it is encroached upon by the occipital condyles. The structures which it transmits are enumerated on p. 263.

Structure.—The occipital, like the other cranial bones, consists of two compact lamellæ, called the *outer* and *inner tables,* between which there is spongy substance or *diploë*; the bone is thick at the ridges, protuberances and condyles, and at the anterior portion of the basilar part; in the lower parts of the inferior fossæ it is thin, semitransparent, and devoid of diploë.

Ossification (fig. 344).—Above the highest nuchal line the squamous part is developed in membrane, and is ossified from two centres, one appearing on each side of the median plane about the second month of intrauterine life; this part may remain separate throughout life, and is then known as the *interparietal bone*. The rest of the occipital bone is preformed in cartilage. Below the highest nuchal line, the squamous part is ossified from two centres, which appear about the seventh week of intrauterine life and soon unite to form a single piece. Union of the upper and lower portions of the squamous part takes place in the third month of intrauterine life, but their line of union can be recognised in the bone at birth (fig. 344). An occasional centre appears in the posterior margin of the foramen magnum about the sixteenth week (Kerckring); it unites with the rest of the squamous part before birth. Each of the condylar parts ossifies from a single centre, which appears during the eighth week of intrauterine life. The basilar portion is ossified from one centre, which appears about the sixth week of intrauterine life. About the fourth year the squamous part unites with the condylar portions, and about the sixth year the bone consists of a single piece. Between the eighteenth and twenty-fifth years the occipital and sphenoid bones unite to form a single bone.

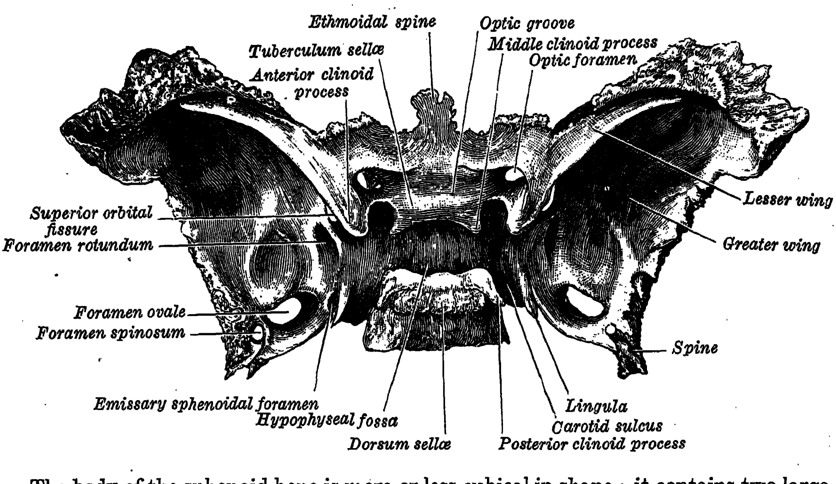
Fig. 344.—The occipital bone at birth. External surface.



The Sphenoid Bone [Os Sphenoideum]

The **sphenoid bone** (figs. 345 to 347) is situated at the base of the skull, in front of the temporal bones and the basilar part of the occipital bone. In shape it resembles a bat with wings outstretched, and consists of a central portion or body, two greater and two lesser wings, which pass laterally from the sides of the body, and two pterygoid processes, which are directed downwards from the adjoining parts of the body and greater wings.

Fig. 345.—The sphenoid bone. Superior surface.



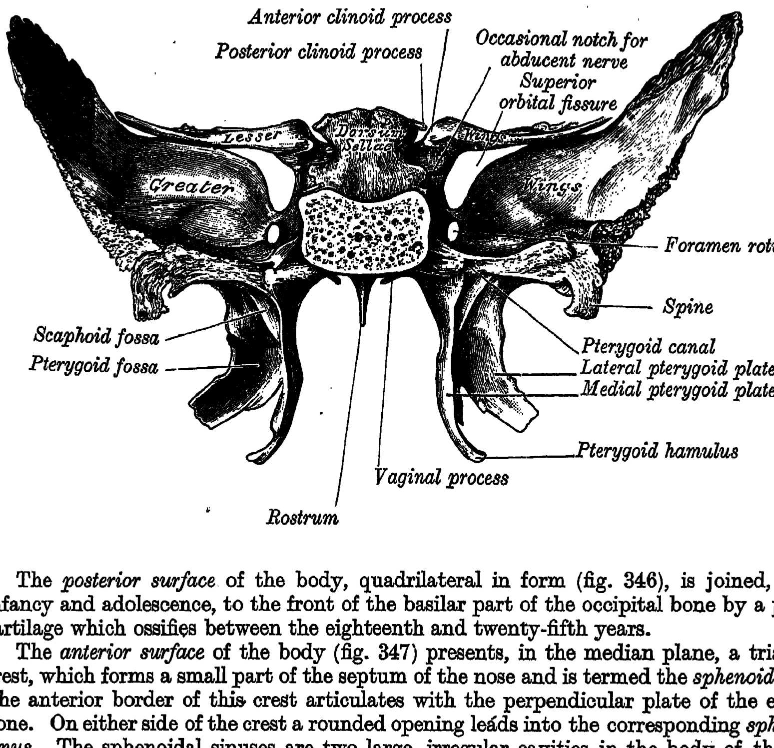
The body of the sphenoid bone is more or less cubical in shape; it contains two large air-sinuses, which are separated from each other by a septum.

The *cerebral* or *superior surface* of the body (fig. 345) articulates in front with the cribriform plate of the ethmoid bone. Anteriorly the surface is smooth and is termed the *jugum sphenoidale*; it supports the posterior ends of the gyri recti and the olfactory tracts. It is bounded behind by a ridge, which forms the anterior border of a transverse groove, termed the *optic groove* (sulcus chiasmatis); this sulcus leads laterally to the *optic foramen* on each

side. Posterior to the groove there is a more or less oval elevation, termed the *tuberculum sellæ*; and behind this a deep depression, termed the *sella turcica,* the deepest part of which lodges the hypophysis cerebri and is known as the *hypophyseal fossa.* The anterior boundary of the sella turcica is completed laterally by two small eminences, called the *middle clinoid processes,* whilst the posterior boundary is formed by a square plate of bone, termed the *dorsum sellæ*; the superior angles of this plate end in two tubercles, termed the *posterior clinoid processes,* which vary considerably in form and size and give attachment to the fixed margin of the tentorium cerebelli. On each side of the body below the dorsum sellæ a small projection articulates with the apex of the petrous portion of the temporal bone and is termed the *petrosal process.* The sloping area behind the dorsum sellæ is termed the *clivus,* and is uninterruptedly continuous with the superior surface of the basilar portion of the occipital bone in the adult skull; it supports the upper part of the pons.

The *lateral surfaces* of the body are united with the greater wings and with the medial pterygoid plates. Above the attachment of each wing a broad groove, termed the *carotid sulcus,* forms a curve somewhat like the italic letter *f*; it lodges the internal carotid artery and the cavernous sinus. The carotid sulcus is deepest at its posterior end, where it is overhung medially by the petrosal process, and is limited laterally by a sharp margin called the *lingula*; the latter is continued backwards to overlie the posterior opening of the pterygoid canal.

FIG. 346.—The sphenoid bone. Posterior aspect.



The *posterior surface* of the body, quadrilateral in form (fig. 346), is joined, during infancy and adolescence, to the front of the basilar part of the occipital bone by a plate of cartilage which ossifies between the eighteenth and twenty-fifth years.

The *anterior surface* of the body (fig. 347) presents, in the median plane, a triangular crest, which forms a small part of the septum of the nose and is termed the *sphenoidal crest.* The anterior border of this crest articulates with the perpendicular plate of the ethmoid bone. On either side of the crest a rounded opening leads into the corresponding *sphenoidal sinus.* The sphenoidal sinuses are two large, irregular cavities in the body of the bone, separated from each other by a bony septum which is commonly bent to one side or the other. They vary considerably in form and size,* are seldom symmetrical, and are often partially subdivided by bony laminæ. A lateral recess may extend from one or other sinus into the greater wing and lingula†; the sinuses occasionally reach into the basilar part of the occipital bone nearly as far as the foramen magnum. In the articulated skull they are closed in front and below by the *sphenoidal conchæ* (p. 293), but a round opening is

* Logan Turner (*The Accessory Sinuses of the Nose,* 1901) gives the following measurements for an adult sphenoidal sinus of average size: height, 2 cm.; breadth, 1·8 cm.; anteroposterior depth, 2·1 cm. Onodi (*The Accessory Sinuses of the Nose in Children,* 1911) states that in the new-born infant their height is 4 mm. and their width 2 mm., while at the eighth year of life their height is from 8 to 12 mm., and their width 11 mm.

† V. Z. Cope (*Journal of Anatomy and Physiology,* vol. li. part ii.) found a well-marked lateral recess in 72 out of 292 sinuses examined, and pointed out that the hypophysis cerebri, the anterior part of the internal carotid artery, the optic and maxillary nerves, and the nerve of the pterygoid canal may give rise to elevations in the walls of the sinuses.

left in the anterior wall of each sinus, by which it communicates with the spheno-ethmoidal recess of the nasal cavity, and occasionally with the posterior ethmoidal sinuses. Each half of the anterior surface of the body of the sphenoid bone consists of two parts: (*a*) an upper and lateral depressed area, which completes, with the labyrinth of the ethmoid bone, the posterior ethmoidal sinuses; its lateral margin articulates with the orbital plate (lamina papyracea) of the ethmoid bone above, and with the orbital process of the palatine bone below; (*b*) a lower and medial, smooth, triangular area, which forms the posterior part of the roof of the nose; near its superior angle is the orifice of the sphenoidal sinus.

The *inferior surface* of the body presents in the median plane a triangular spine, termed the *sphenoidal rostrum* (fig. 346), which, in the articulated skull, projects into a deep fissure between the anterior parts of the alæ of the vomer. The posterior, triangular parts of the sphenoidal conchæ extend backwards on the sides of the rostrum, and articulate with the alæ of the vomer. On each side of the posterior part of the rostrum, and immediately behind the apex of the sphenoidal concha, a thin lamina, named the *vaginal process*, projects medially from the base of the medial pterygoid plate, with which it will be described.

The **greater wings** of the sphenoid bone are two strong processes which curve upwards and laterally from the sides of the body. The posterior part of each is triangular and fits into the angle between the petrous portion of the temporal bone and the squamous part; a small, sometimes pointed, process named the *spine* projects downwards from the apex of this triangular portion; on its medial side there is usually a small groove, directed downwards and forwards, for the chorda tympani nerve. The tip of the spine gives attachment to the sphenomandibular ligament, and a part of the tensor palati muscle. The medial side of the spine forms part of the lateral wall of the groove which lodges the pharyngotympanic (auditory) tube on the external surface of the base of the skull.

The *cerebral surface* of the greater wing (fig. 345) forms part of the floor of the middle fossa of the skull; it is deeply concave and presents depressions corresponding with the convolutions of the anterior part of the temporal lobe of the brain. At its anteromedial part the *foramen rotundum* gives passage to the maxillary nerve. Behind and lateral to this foramen the *foramen ovale* transmits the mandibular nerve, the accessory meningeal artery, and sometimes the lesser superficial petrosal nerve.* Medial to the foramen ovale, a small aperture, termed the *emissary sphenoidal foramen* (*foramen Vesalii*) is present on one or both sides in nearly 40 per cent. of skulls; it opens below at the lateral side of the scaphoid fossa and transmits a small vein from the cavernous sinus. In the posterior angle, anteromedial to the spine, there is a short canal, termed the *foramen spinosum*, which transmits the middle meningeal artery and the nervus spinosus.

The *lateral surface* of the greater wing (fig. 317) is convex from above downwards, and is divided by a transverse ridge, termed the *infratemporal crest*, into an upper or temporal and a lower or infratemporal surface. The *temporal surface*, concave from before backwards, forms a portion of the temporal fossa and gives origin to a part of the temporalis muscle. The *infratemporal surface* is concave and directed downwards; it forms a part of the infratemporal fossa and, together with the infratemporal crest, gives origin to the upper head of the lateral pterygoid muscle. It is pierced by the foramen ovale and foramen spinosum, and its posterior part bears the spine of the sphenoid bone. Medial to the anterior extremity of the infratemporal crest a triangular process serves to increase the attachment of the lateral pterygoid muscle. A ridge runs downwards and medially from this triangular process to the front of the lateral pterygoid plate; it forms the anterior limit of the infratemporal surface and, in the articulated skull, the posterior boundary of the pterygomaxillary fissure.

The *orbital surface* of the greater wing (fig. 347), quadrilateral in shape, is directed forwards and medially and forms the posterior part of the lateral wall of the orbit. Its upper, serrated edge articulates with the orbital plate of the frontal bone; its lateral, serrated margin with the zygomatic bone. Its inferior smooth border forms the posterolateral boundary of the inferior orbital fissure. Its medial sharp margin constitutes the lower boundary of the superior orbital fissure; projecting from near the middle of this margin there is a small tubercle. This tubercle gives attachment to part of the annulus tendineus communis, from which the rectus muscles of the eyeball take origin. Below the medial end of the superior orbital fissure there is a grooved area which forms the posterior wall of the pterygopalatine fossa and is pierced by the foramen rotundum.

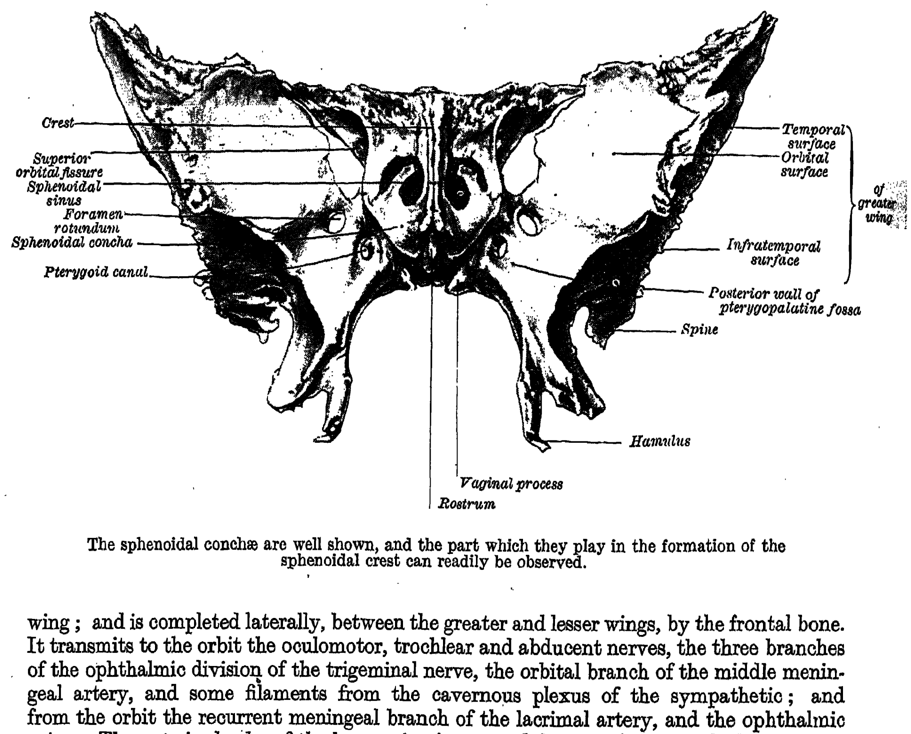
The margin of the greater wing (fig. 345).—The portion of the margin of the greater wing which extends from the body to the spine of the sphenoid is irregular. Its medial half forms the anterior boundary of the *foramen lacerum* and presents the posterior aperture of the pterygoid canal for the passage of the corresponding nerve and artery. Its lateral half articulates, by means of a cartilaginous joint, with the petrous portion of the temporal bone. Between the two bones, on the under surface of the skull, there is a furrow, named the

* The lesser superficial petrosal nerve may pass through a special canal (*canaliculus innominatus*) on the medial side of the foramen spinosum.

sulcus tubæ, which lodges the cartilaginous part of the pharyngotympanic (auditory) tube. Extending forwards from the sphenoidal spine the *squamosal margin* forms a concave, serrated edge, bevelled at the expense of the inner surface below and of the outer surface above, for articulation with the squamous part of the temporal bone. The tip of the greater wing is bevelled at the expense of the inner surface and articulates with the anterior inferior angle of the parietal bone at the pterion. Medial to this there is a triangular rough area, for articulation with the frontal bone; the medial angle of this area is continuous with the sharp edge which forms the lower boundary of the superior orbital fissure, and the anterior angle with the serrated margin for articulation with the zygomatic bone.

The **lesser wings** of the sphenoid bone are two triangular plates which project laterally from the upper and anterior parts of the body and end in sharp points (figs. 345, 346). The *cerebral surface* of each is smooth, and supports a small part of the frontal lobe of the brain. The *inferior surface* forms the posterior part of the roof of the orbit and the upper boundary of the *superior orbital fissure*; it overhangs the anterior part of the middle fossa of the skull. The **superior orbital fissure** is triangular in shape and leads from the cranial cavity into the orbit; it is bounded medially by the body of the sphenoid bone; above, by the lesser wing; below, by the medial margin of the orbital surface of the greater

FIG. 347.—The sphenoid bone of an eight years old child. Anterior aspect.



The sphenoidal conchæ are well shown, and the part which they play in the formation of the sphenoidal crest can readily be observed.

wing; and is completed laterally, between the greater and lesser wings, by the frontal bone. It transmits to the orbit the oculomotor, trochlear and abducent nerves, the three branches of the ophthalmic division of the trigeminal nerve, the orbital branch of the middle meningeal artery, and some filaments from the cavernous plexus of the sympathetic; and from the orbit the recurrent meningeal branch of the lacrimal artery, and the ophthalmic veins. The *anterior border* of the lesser wing is serrated for articulation with the posterior edge of the orbital plate of the frontal bone. The *posterior border* is smooth and projects into the lateral cerebral fissure; the medial end of this border forms the *anterior clinoid process*, which gives attachment to the anterior end of the free border of the tentorium cerebelli. The anterior and middle clinoid processes are sometimes united by a spicule of bone, and when this occurs the end of the groove for the internal carotid artery is converted into a foramen (*caroticoclinoid foramen*). The lesser wing is connected to the body by two roots, the anterior thin and flat, the posterior thick and triangular; the *optic foramen*, which lies between them, transmits the optic nerve and ophthalmic artery to the orbit.

The **pterygoid processes** of the sphenoid (figs. 346, 347), one on each side, descend perpendicularly from the regions where the greater wings unite with the body. Each process consists of a medial and a lateral plate, the upper parts of which are fused anteriorly. The plates are separated below by an angular cleft, termed the *pterygoid fissure*, the rough margins of which articulate with the tubercle (pyramidal process) of the palatine bone. The two plates diverge behind, and the wedge-shaped *pterygoid fossa* between them contains the medial pterygoid and tensor palati muscles. Above this fossa there is a small, oval, shallow depression, named the *scaphoid fossa*, which is formed by the division of the upper

part of the posterior border of the medial pterygoid plate; it gives origin to part of the tensor palati muscle. The anterior surface of the pterygoid process is broad and triangular near its root, where it forms the posterior wall of the pterygopalatine fossa; it is pierced by the anterior orifice of the *pterygoid canal.*

The *lateral pterygoid plate* is broad, thin, and everted; its *lateral surface* forms part of the medial wall of the infratemporal fossa and gives origin to the lower head of the lateral pterygoid; its *medial surface* forms the lateral wall of the pterygoid fossa and gives origin to the greater part of the medial pterygoid muscle. The upper part of the *anterior border* forms the posterior boundary of the pterygomaxillary fissure; the lower part articulates with the palatine bone; its *posterior border* is free.

The *medial pterygoid plate* is narrower and longer than the lateral; its lower extremity curves laterally into a hook-like process, termed the *pterygoid hamulus,* around which the tendon of the tensor palati glides, and to which the pterygomandibular ligament is attached. The *lateral surface* of this plate forms the medial wall of the pterygoid fossa, and the tensor palati lies against it; the *medial surface* constitutes the lateral boundary of the corresponding posterior nasal aperture. Superiorly the medial pterygoid plate is prolonged on to the under surface of the body as a thin lamina, named the *vaginal process,* which articulates anteriorly with the sphenoidal process of the palatine bone and medially with the ala of the vomer. On its under surface there is a furrow, the anterior part of which is converted into a canal by the sphenoidal process of the palatine bone; this canal is named the *palatinovaginal canal,* and transmits the pharyngeal branch of the maxillary (internal maxillary) artery and the pharyngeal nerve from the sphenopalatine ganglion. The posterior margin of the medial pterygoid plate gives attachment in its entire length to the pharyngobasilar fascia, and from the lower end of this margin the superior constrictor muscle of the pharynx takes origin. The upper end of this margin is marked by a small projection named the *pterygoid tubercle,* which lies immediately below the posterior opening of the pterygoid canal. Projecting backwards from near the middle of the margin is an angular process, sometimes termed the *processus tubarius,* which supports the pharyngeal end of the pharyngotympanic (auditory) tube. The anterior margin of the medial pterygoid plate articulates with the posterior border of the perpendicular plate of the palatine bone.

The **sphenoidal conchæ** (fig. 347) are two thin, curved plates, situated at the anterior and lower parts of the body of the sphenoid bone; the upper, concave surface of each forms the anterior wall and a part of the floor of the corresponding sphenoidal sinus. The sphenoidal conchæ are usually more or less destroyed in the process of disarticulating the skull, but, when seen *in situ,* each consists of an anterior, vertical, quadrilateral part and a posterior, horizontal, triangular part. The anterior, vertical portion consists of (*a*) an upper and lateral depressed area, which completes the posterior ethmoidal sinuses and articulates below with the orbital process of the palatine bone; and (*b*) a lower and medial area, smooth and triangular, which forms part of the roof of the nasal cavity, and is perforated near its superior angle by a round opening through which the sphenoidal sinus communicates with the spheno-ethmoidal recess of the nasal cavity. The anterior vertical portions of the two bones meet in the median plane and are protruded forwards as the sphenoidal crest. The horizontal triangular portion of the concha forms a part of the roof of the nasal cavity and completes the sphenopalatine foramen; its medial margin articulates with the rostrum of the sphenoid and with the ala of the vomer; its apex, directed backwards, lies medial to and above the vaginal process of the medial pterygoid plate, and articulates with the posterior part of the ala of the vomer. A small piece of the sphenoidal concha sometimes appears in the medial wall of the orbit, betweeen the orbital plate of the ethmoid in front, the orbital process of the palatine bone below, and the frontal bone above.

Ossification.—Until the seventh or eighth month of intrauterine life the body of the sphenoid consists of two parts—viz. one in front of the tuberculum sellæ, forming the *presphenoidal part,* with which the lesser wings are continuous; the other comprising the sella turcica and dorsum sellæ, forming the *postsphenoidal part,* with which the greater wings and pterygoid processes are associated. A considerable part of the bone is preformed in cartilage. There are six centres for the presphenoidal and eight for the postsphenoidal part.

Presphenoidal part.—About the ninth week a centre of ossification appears for each of the lesser wings, just lateral to the optic foramen; shortly afterwards two centres appear in the presphenoidal part of the body. The sphenoidal conchæ are each developed from a centre which makes its appearance about the fifth month *; at birth, they consist of small triangular laminæ; about the third year they become hollowed out and cone-shaped; about the fourth year they fuse with the labyrinths of the ethmoid, and between the ninth and twelfth years with the sphenoid bone.

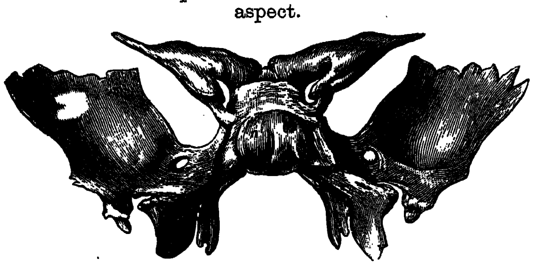
Postsphenoidal part.—The first centres of ossification are those for the greater wings. About the eighth week one appears below the foramen rotundum in the cartilage which forms the base of each wing. This centre forms only the root of the greater wing in the neighbourhod of the foramen rotundum and the pterygoid canal. The whole of the rest of the greater wing is ossified in membrane and the process extends downwards into the

* According to Cleland, each sphenoidal concha is ossified from four centres.

lateral pterygoid plate (Fawcett). About the fourth month, two centres appear in the postsphenoidal part of the body, one on each side of the sella turcica, and fuse about the middle of intrauterine life. Each medial pterygoid plate (with the exception of its hamulus) is ossified in membrane, and its centre probably appears about the ninth or tenth week; the hamulus is chondrified during the third month and almost at once begins to ossify.* The medial and lateral pterygoid plates join about the sixth month. About the fourth month a centre appears for each lingula and speedily joins the rest of the bone.

The presphenoidal and the postsphenoidal parts of the body fuse about the eighth month of intrauterine life, but a wedge-shaped piece of cartilage persists for some time after birth in the lower part of the line of fusion. At birth the bone is in three pieces (fig. 348): a central, consisting of the body and lesser wings, and two lateral, each comprising a greater wing and pterygoid process. In the first year after birth the greater wings and body unite around the margins of the pterygoid canal, and the lesser wings extend medially above the anterior part of the body and meet to form an elevated smooth surface, termed the *jugum sphenoidale*. By the twenty-fifth year the sphenoid and occipital bones are completely fused. In the anterior part of the hypophyseal fossa there are occasionally seen the remains of the *cranio-pharyngeal canal*, through which, in the embryo, the hypophyseal diverticulum of the buccal ectoderm is transmitted (p. 166).

FIG. 348.—The sphenoid bone at birth. Posterior aspect.



Traces of the sphenoidal sinuses are seen as early as the third month of intrauterine life, but they do not attain their full size until after puberty. Although they are usually restricted to the presphenoidal and postsphenoidal parts of the body, the sinuses may invade any part of the bone which is preformed in cartilage.

Certain parts of the sphenoid bone are connected by ligaments which occasionally ossify. The more important of these ligaments are: the *pterygospinous*, stretching between the spine of the sphenoid and the upper part of the lateral pterygoid plate (see *cervical fascia*); the *interclinoid*, joining the anterior to the posterior clinoid process; and the *caroticoclinoid*, connecting the anterior to the middle clinoid process.

Applied Anatomy.—Premature ossification or synostosis of the suture between the pre- and postsphenoidal parts (which normally begin to join at the eighth month) and of the sphenobasilar suture produces a characteristic physiognomy. This is best seen in profile, and consists in an abnormal depression of the bridge of the nose; it is a feature often observed in dwarfs.

The Temporal Bones (Ossa Temporalia)

The **temporal bones** are situated at the sides and base of the skull. Each consists of five parts, viz. the *squamous, mastoid, petrous,* and *tympanic parts*, and the *styloid process*. These represent four morphologically distinct elements which have become fused with one another. The squamous part is a dermal bone, developed to assist in the protection of the cerebrum. The petromastoid portion is preformed in cartilage as a protecting capsule for the membranous labyrinth. The tympanic part, formed in membrane, is homologous with the angular bone, which constitutes a part of the composite lower jaw of many reptilians and bony fishes; it has become incorporated in the skull and adapted to play a part in the provision of a satisfactory mechanism for the transmission of sound-waves in an air medium. The styloid process represents the dorsal end of the skeletal element of the hyoid arch. The fusion of these distinct elements to form the temporal bone and the inclusion of the tympanic cavity within the bone during the process have been dealt with on p. 130.

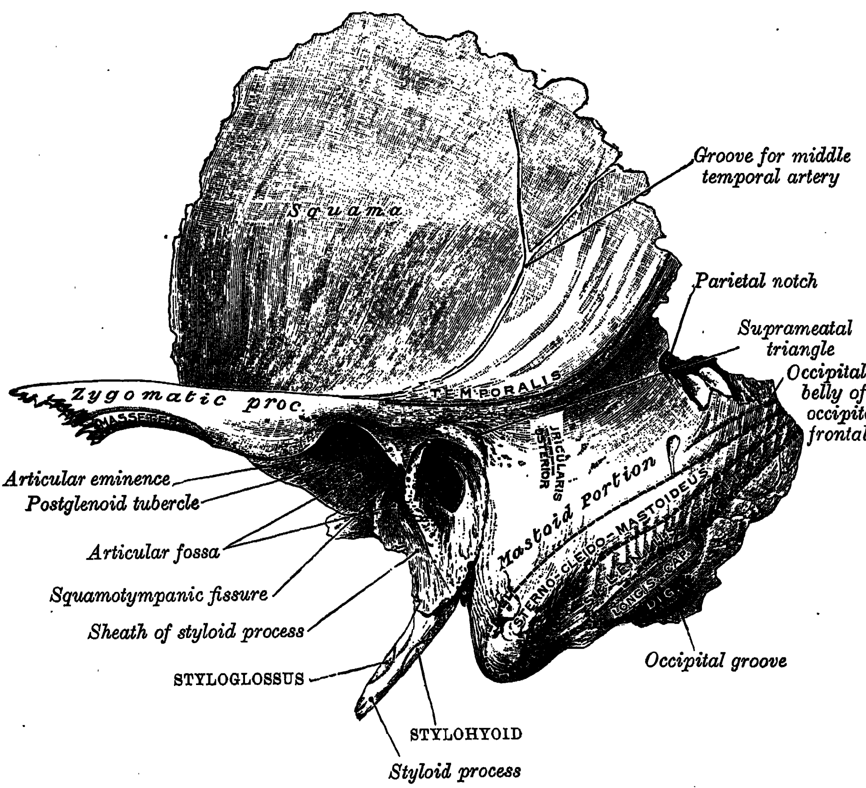
The **squamous part** of the temporal bone forms the anterior and upper part of the bone, and is scale-like, thin and translucent. Its *temporal surface* (fig. 349) is smooth and slightly convex; it forms part of the temporal fossa and gives origin to the temporal muscle; above the opening of the external auditory meatus it is marked by a vertical groove for the middle temporal artery. A curved line, termed the *supramastoid crest*, courses backwards and upwards across its posterior part; it serves for the attachment of the temporal fascia and limits the origin of the temporal muscle. The boundary between the squamous and mastoid portions of the bone lies about 1·5 cm. below the supramastoid crest and is frequently indicated by traces of the original squamomastoid suture; the external surface of this lower part is convex, and from its anterior part the auricularis

* E. Fawcett, *Anatomischer Anzeiger*, March 1905.

posterior takes origin. Between the anterior end of the supramastoid crest and the postero-superior sector of the opening of the external auditory meatus there is a depression, termed the *suprameatal triangle* ; this triangle is an important landmark for the tympanic antrum, which lies medial to it, at a depth of about 1·25 cm. The anterior part of the depression is usually marked by a small projection, termed the *suprameatal spine*.

A long, arched process, termed the *zygomatic process*, or *zygoma*, projects forwards from the lower portion of the temporal surface. The posterior part of this process is triangular in shape and springs from a broad base ; it is directed laterally, and its surfaces are superior and inferior. The process is then twisted forwards and medially, and the surfaces of its anterior portion are therefore medial and lateral. The superior surface of the posterior part is concave, and continuous with the temporal surface of the squamous part ; the inferior surface is bounded by two roots, a *posterior* and an *anterior*, which converge as they approach the anterior part of the process. At the meeting point of the two roots the *tubercle of the root of the zygoma* gives attachment to the temporomandibular ligament. The

FIG. 349.—The left temporal bone. Externa aspect.

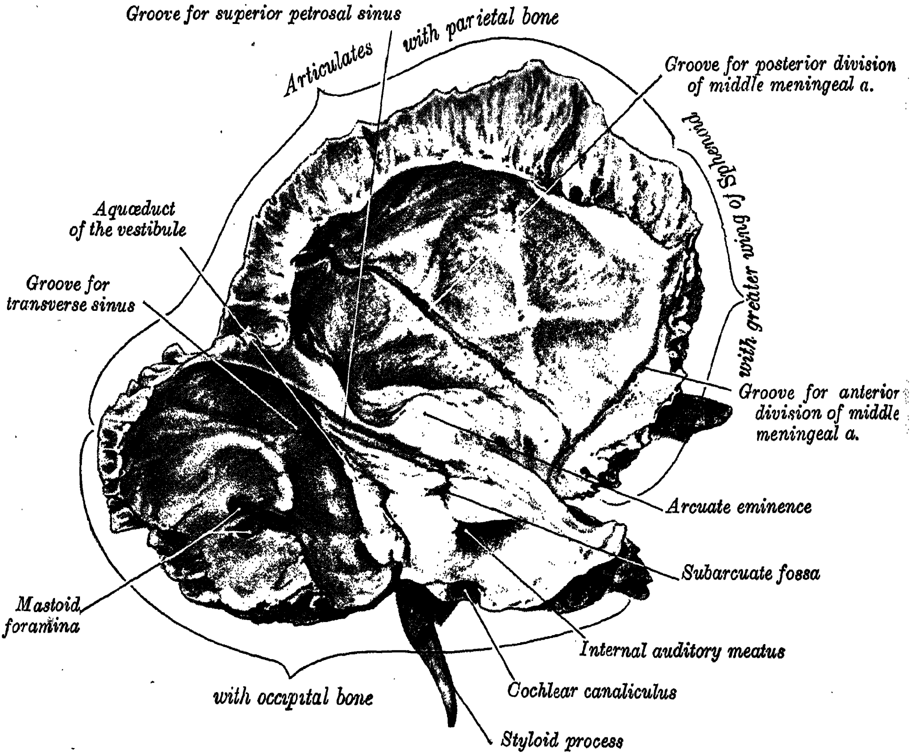


posterior root is prolonged forwards from the surface of the squamous part immediately above the opening of the external auditory meatus ; its upper border is continuous behind with the supramastoid crest. The anterior root juts almost horizontally from the side of the squamous part ; its inferior surface, convex from before backwards, is smooth for articulation with the articular disc of the mandibular joint, and the whole root presents the form of a short semicylindrical bar, named the *articular eminence* (tuberculum articulare). The articular eminence forms the anterior boundary of the articular (mandibular) fossa. Very rarely the squamous part is perforated just above the posterior root of the zygoma. When present, this *squamosal foramen* transmits the petrosquamous sinus (p. 817).

The anterior part of the zygomatic process is thin and flat. The superior border, long and thin, gives attachment to the temporal fascia ; the inferior, short and arched, gives origin to some fibres of the masseter muscle. The lateral surface is convex and subcutaneous ; the medial is concave and gives origin to part of the masseter. The anterior end is deeply serrated and cut obliquely at the expense of the lower border ; it articulates with the temporal process of the zygomatic bone. In front of the articular eminence a small triangular area forms a part of the roof of the infratemporal fossa and is separated from the temporal surface of the squamous part by a ridge ; this ridge is continuous behind with the anterior root of the zygomatic process, and in front, in the articulated skull, with the infratemporal

crest on the greater wing of the sphenoid bone. The *articular fossa* (mandibular fossa) is bounded in front by the articular eminence; it consists of an anterior, articular portion, formed by the squamous part of the temporal bone, and a posterior, non-articular portion, formed by the tympanic part. The articular portion, smooth, oval and deeply concave, articulates with the articular disc of the mandibular joint; the non-articular portion sometimes lodges a small part of the parotid gland. A small, conical eminence, termed the *postglenoid tubercle*, separates the lateral part of the articular portion from the anterior margin of the tympanic part of the bone, and is the representative of a prominent tubercle which, in some mammals, descends behind the condyle of the mandible and prevents its backward displacement; the postglenoid tubercle is sometimes described as the third root of the zygomatic process. The medial part of the articular portion of the fossa is separated from the tympanic part of the bone by the *squamotympanic fissure*, into which projects the lower edge of the downturned anterolateral part of the tegmen tympani of the petrous part of the bone; the *petrotympanic fissure* is situated between this plate and the tympanic

FIG. 350.—The left temporal bone. Internal surface.



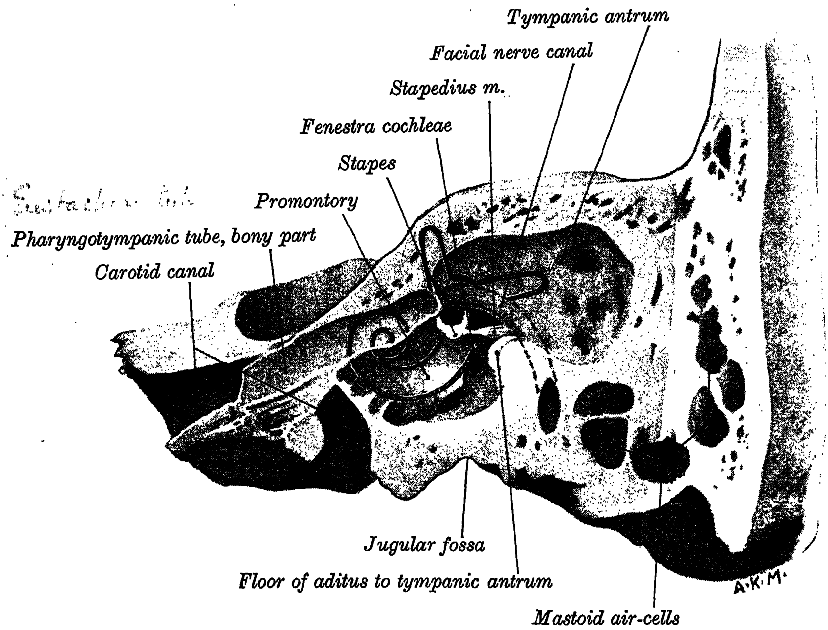
part. This fissure leads into the middle ear or tympanic cavity; it lodges the anterior ligament of the malleus and transmits the anterior tympanic branch of the maxillary (internal maxillary) artery. The medial end of the fissure presents the anterior opening of the *anterior canaliculus for the chorda tympani*. Very rarely a *postglenoid foramen* is present just in front of the external auditory meatus and in the line of fusion of the squamous and tympanic portions of the bone. It replaces the squamosal foramen, already mentioned, and transmits the petrosquamous sinus (p. 817).

The *cerebral surface* of the squama (fig. 350) is concave; it presents depressions corresponding to the convolutions of the temporal lobe of the brain, and grooves for the branches of the middle meningeal vessels; its lower border is united to the anterior surface of the petrous portion but traces of a petrosquamosal suture are frequently seen in the adult bone.

The *superior border* is thin, bevelled at the expense of the cerebral surface, and overlaps the inferior border of the parietal bone, forming with it the squamosal suture. Posteriorly the superior border forms an angle (B.N.A. *parietal notch*) with the mastoid portion of the bone. The *antero-inferior border*, thin above and thick below, articulates with the greater wing of the sphenoid bone; its upper part is bevelled at the expense of the cerebral surface, its lower at the expense of the temporal surface.

The **mastoid portion** forms the posterior part of the temporal bone. Its *outer surface* (fig. 349) is rough and gives attachment to the occipital belly of the occipitofrontalis, and the auricularis posterior muscle. It is frequently perforated near its posterior border by the *mastoid foramen,* which gives exit to a vein from the sigmoid sinus and entrance to a small branch of the occipital artery to the dura mater; the position and size of this foramen are very variable; it may be situated in the occipital bone, or in the suture between the temporal and the occipital bones. The mastoid portion is continued below into a conical projection, named the **mastoid process**; it is larger in the male than in the female. The lateral surface of this process gives insertion to the sternomastoid, splenius capitis, and longissimus capitis; on its medial side there is a deep groove, termed the *mastoid notch,* for the attachment of the posterior belly of the digastric muscle; medial to this notch the shallow *occipital groove* lodges the occipital artery.

FIG. 351.—A section through the left temporal bone in the long axis of the tympanic cavity. The lateral surface of the medial half of the bone is shown.
The duct of the cochlea and the superior and lateral semicircular ducts are shown in blue.



On the *inner surface* of the mastoid portion (fig. 350) there is a deep, curved groove termed the *sigmoid sulcus,* which lodges the sigmoid sinus; near its posterior border it receives the opening of the mastoid foramen. The sigmoid sulcus is separated from the innermost of the mastoid air-cells by a thin lamina of bone which may be partly deficient.

The *superior border* of the mastoid portion is thick and serrated for articulation with the postero-inferior angle of the parietal bone. The *posterior border,* also serrated, articulates with the inferior border of the occipital bone between the lateral angle and jugular process. The mastoid portion is fused with the descending process of the squamous part above; below, it enters into the formation of the posterior wall of the tympanic cavity.

A section of the mastoid process (fig. 351) exhibits a number of spaces, termed the *mastoid air cells,* which vary greatly in size and number. At the upper and front part of the process they are large and irregular, but towards the lower part they diminish in size, while those at the apex of the process are frequently quite small; occasionally they are entirely absent, and the mastoid is then solid throughout. In addition, a large, irregular air-sinus, termed the **tympanic antrum,** is situated at the upper and anterior part of the mastoid portion of the bone; it is lined with a prolongation of the mucous membrane of the tympanic cavity. It is bounded above by a thin plate of bone, termed the *tegmen tympani,* which separates it from the middle cranial fossa; laterally by the portion of the squamous part which lies below the supramastoid crest; its medial wall is related to the lateral semicircular canal of the internal ear. Below and behind, the tympanic antrum communicates with the mastoid air cells; in front, it opens into that portion of the tympanic cavity which is known as the *epitympanic recess.* The tympanic antrum is a cavity

of some considerable size at the time of birth; the mastoid air cells originate as diverticula from the antrum, and begin to appear at or before birth; by the fifth year they are of considerable size, but their development is not completed until puberty. (Pl. I, fig. 1.)

The **petrous portion** of the temporal bone is wedged between the sphenoid and occipital bones at the base of the skull (figs. 319, 324). It is directed medially, forwards, and a little upwards; it has a base, an apex, three surfaces, and three margins. The essential parts of the organs of hearing and equilibration are placed within it.

The *base* is fused with the squamous and mastoid portions, and is partially separated from them by the tympanic antrum.

The *apex*, rough and uneven, is received into the angular interval between the posterior border of the greater wing of the sphenoid bone and the basilar part of the occipital bone; it is pierced by the anterior orifice of the carotid canal and forms the posterolateral boundary of the foramen lacerum.

The *anterior surface* helps to form the floor of the middle cranial fossa and is continuous with the cerebral surface of the squamous part, although remains of the petrosquamosal suture are often distinct even at a late period of life.

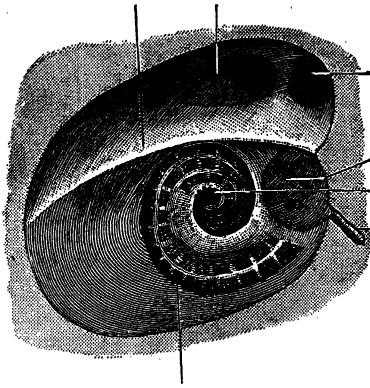
The whole surface is marked by impressions for the gyri of the inferior surface of the temporal lobe of the brain. Immediately behind the apex a slight hollow lodges the trigeminal (semilunar) ganglion and it is termed the *trigeminal impression.* The bone anterior and slightly lateral to the impression forms the roof of the anterior part of the carotid canal; it is often deficient in this situation. An irregular ridge separates the trigeminal impression posteriorly from a second hollow, which forms part of the roof of the internal auditory meatus and covers the cochlea. This concavity is limited behind by an elevation, termed the *arcuate eminence* (fig. 350), which is raised by the superior semicircular canal and, in its lateral part, roofs in the vestibule and the beginning of the facial canal. Between the squamous part on the lateral side and the arcuate eminence and the hollows just described on the medial side the surface is formed by the *tegmen tympani* (fig. 324). This thin plate of bone forms the roof of the tympanic antrum behind and extends forwards above the tympanic cavity and the canal for the tensor tympani muscle. Its lateral margin meets the squamous part at the site of the petrosquamosal suture and turns downwards in front to form the lateral wall of the canal for the tensor tympani and the bony part of the pharyngotympanic (auditory) tube; the lower edge of this downturned portion has already been observed in the floor of the squamotympanic fissure (p. 262). Anteriorly the tegmen tympani presents a narrow groove, which runs backwards and laterally and enters the bone through an opening placed in front of the lateral part of the arcuate eminence. This hiatus transmits the greater superficial petrosal nerve, which runs forwards to the foramen lacerum. A second groove may mark the bone on the lateral side of the one just described; it transmits the lesser superficial petrosal nerve from the tympanic plexus. The posterior slope of the arcuate eminence covers the posterior and lateral semicircular canals, and lateral to it the posterior part of the tegmen tympani roofs in the posterior part of the tympanic antrum.

The *posterior surface* (fig. 350) forms the anterior part of the posterior cranial fossa and is continuous with the inner surface of the mastoid portion. Near the centre of this surface an orifice of varying size leads into the *internal auditory meatus.* This canal, which is about 1 cm. in length, runs laterally; it transmits the facial and auditory nerves and the internal auditory artery. The lateral end of the internal auditory meatus is separated from the internal ear by a vertical plate, which is divided into two unequal portions by a horizontal crest, termed the *transverse crest* (fig. 352). Below the posterior part of the crest, and situated in the *inferior vestibular area,* several openings are present for the transmission of the nerves to the saccule; below and behind this area the *foramen singulare* gives passage to the nerve to the posterior semicircular duct. Below the anterior part of the transverse crest, a number of small spirally arranged openings constituting the *tractus spiralis foraminosus,* encircle the *central canal of the cochlea*; these openings together with the central canal transmit the nerves to the cochlea. The portion above the transverse crest displays, behind, the *superior vestibular area,* pierced by a series of small openings for the passage of the nerves to the utricle and the superior and lateral semicircular ducts, and in front, the *facial area,* with one large opening which is the commencement of the *canal for the facial nerve.* Behind the opening of the meatus there is a small slit almost hidden by a thin plate of bone; it leads to a canal, named the *aquæduct of the vestibule,* which contains the saccus and ductus endolymphaticus together with a small artery and vein. Above and between these two openings an irregular depression, termed the *subarcuate fossa,* lodges a process of the dura mater and transmits a small vein; in the infant this depression is represented by a large fossa which extends as a short, blind tunnel under the superior semicircular canal.

The *inferior surface* (fig. 353), rough and irregular, forms part of the external surface of the base of the skull. It presents the following parts for examination: (1) near the apex there is a quadrilateral rough surface, which serves partly for the attachment of the levator palati (levator veli palatini) muscle and the cartilaginous portion of the pharyngotympanic (auditory) tube, and partly for connexion with the basilar part of the occipital bone through the intervention of some dense fibrous tissue; (2) behind this a large, nearly circular

aperture, leads into the *carotid canal*; this canal runs at first vertically, and then, making a bend, is directed horizontally forwards and medially; it transmits into the cranium the internal carotid artery and the carotid plexus of nerves; (3) behind this opening there is a deep depression, termed the *jugular fossa*, of variable depth and size in different skulls; it lodges the superior bulb of the internal jugular vein; (4) in front of the medial part of the jugular fossa and directly below the internal auditory meatus, the bone is marked by a triangular depression, which lodges the inferior (petrous) ganglion of the glossopharyngeal nerve; at the apex of this notch a small opening leads into the *cochlear canaliculus*, which lodges the aqueduct of the cochlea and a tubular prolongation of the dura mater and transmits a vein from the cochlea to join the internal jugular vein; through the aqueduct the perilymph of the labyrinth is enabled to drain away into the subarachnoid space; (5) on the bony ridge dividing the carotid canal from the jugular fossa there is a small *canaliculus for the tympanic nerve*, which is derived from the glossopharyngeal nerve; (6) in the lateral part of the jugular fossa the bone is pierced by the *mastoid canaliculus* for the entrance of the auricular branch of the vagus nerve; (7) behind the jugular fossa the *jugular surface* forms a rough quadrilateral area covered with cartilage in the recent state and articulating with the jugular process of the occipital bone; (8) extending laterally from the carotid

FIG. 352.—A diagrammatic view of the lateral end of the right internal auditory meatus. (Testut.)



canal is the sharp lower border of the tympanic part of the bone; the lateral part of this border splits to ensheath the root of the styloid process and is therefore named the *sheath of the styloid process* (*vagina processus styloidei*); (9) emerging from its sheath the *styloid process*, which is about 2·5 cm. in length, is directed downwards and forwards; (10) between the styloid and mastoid processes the *stylomastoid foramen* forms the lower end of the facial canal and transmits the facial nerve and stylomastoid artery.

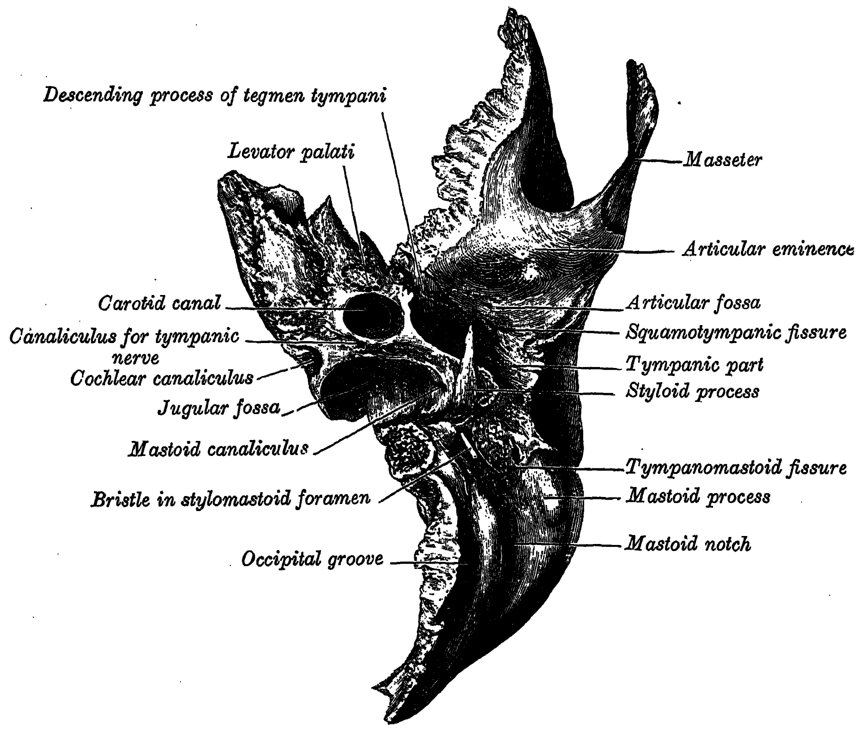
The *superior border*—the longest—is grooved for the superior petrosal sinus and gives attachment to the tentorium cerebelli, except at its medial extremity, where it is crossed by the roots of the trigeminal nerve. The *posterior border* is intermediate in length between the superior and the anterior. Its medial part is marked by a sulcus, which forms, with a corresponding sulcus on the occipital bone, the channel for the inferior petrosal sinus. Behind this there is the *jugular fossa*, which, with the jugular notch on the occipital bone, forms the jugular foramen; it presents a notch for the glossopharyngeal nerve, and either or both of the extremities of the notch may meet the occipital bone and divide the foramen into two, sometimes three, parts. The *anterior border* is divided into two parts—a lateral, joined to the squamous part at the *petrosquamosal suture*; a medial, free, for articulation with the greater wing of the sphenoid bone.

At the angle of junction of the petrous and squamous parts two canals are placed one above the other, and separated by a thin plate of bone. Both canals lead into the tympanic cavity; the upper transmits the tensor tympani; the lower forms the canal of the pharyngotympanic (auditory) tube.

The **tympanic part** of the temporal bone (fig. 353) is a curved plate lying below the squamous part and in front of the mastoid process. Internally, it is fused with the petrous portion, and appears in the angle between it and the squamous part, where it lies below and lateral to the orifice of the pharyngotympanic (auditory) tube. Behind, it fuses with the squamous part and the mastoid process, and forms the anterior boundary of the tympanomastoid fissure. Its *posterior surface* is concave and forms the anterior wall, the floor, and a

part of the posterior wall of the bony external auditory meatus ; at the medial end of this surface there is a narrow furrow, termed the *tympanic sulcus*, for the attachment of the circumference of the tympanic membrane. Its *anterior surface*, quadrilateral and slightly concave, constitutes the posterior wall of the articular fossa and is sometimes in contact with a part of the parotid gland. Its *lateral border* is free and roughened ; it forms a large part of the margin of the opening of the external auditory meatus and gives attachment to the cartilaginous part of the meatus. The lateral part of the *upper border* is fused with the back of the postglenoid tubercle ; its medial part forms the posterior boundary of the petro-tympanic fissure. The *lower border* is sharp ; its lateral part splits to enclose the root of the styloid process and is therefore named the sheath of the styloid process. The central portion of the tympanic part of the temporal bone is thin, and in a considerable percentage of skulls is perforated by a foramen.

FIG. 353.—The left temporal bone. Inferior surface.



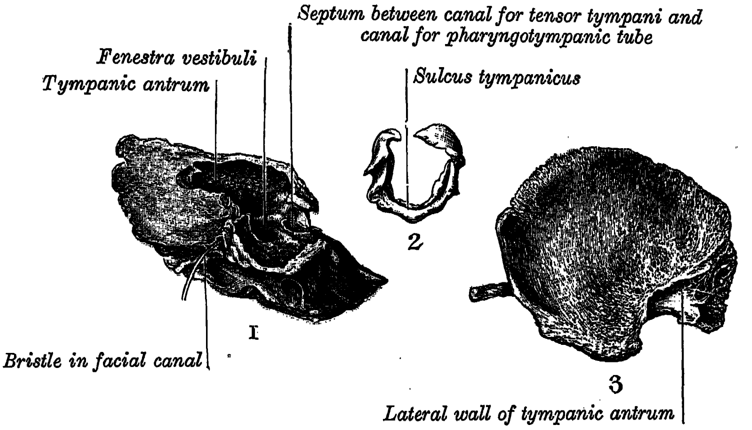
The *external auditory meatus*, which is about 16 mm. long, is directed inwards and slightly forwards and downwards; its floor is convex upwards. On sagittal section the meatus is oval or elliptical in shape with the long axis directed downwards and slightly backwards. Its anterior wall, its floor and the lower part of its posterior wall are formed by the tympanic part of the bone ; its roof and the upper part of its posterior wall by the squamous part. Its inner end is closed in the recent state by the tympanic membrane ; its outer end is bounded above by the posterior root of the zygomatic process, below which the small *suprameatal spine* is sometimes seen at the upper and posterior part of the orifice.

The **styloid process** of the temporal bone, slender, pointed, and averaging about 2·5 cm. in length, projects downwards and forwards, from the under surface of the bone. Its proximal part (tympanohyal) is surrounded by a bony sheath, derived from the tympanic plate and best marked on its anterolateral aspect, while its distal part (stylohyal) gives attachment to certain muscles and ligaments. The styloglossus arises from its anterior aspect close to the tip ; the stylohyoid springs by a delicate little tendon from its posterior surface midway between its tip and its base ; and the stylopharnygeus arises from the medial side close to its base. The stylomandibular ligament is attached to the lateral surface of the process, and the stylohyoid ligament to its tip. The process is covered by the parotid gland, and the facial nerve crosses its base and the external carotid artery its tip, as they lie within the gland. On its deep surface the process is separated from the commencement of the internal jugular vein by the origin of the stylopharyngeus muscle.

Structure.—The structure of the squamous part is like that of the other cranial bones : the mastoid portion is spongy, and the petrous portion dense and hard.

Ossification.—The temporal bone is ossified from eight centres (exclusive of those for the internal ear and the tympanic ossicles)—viz. one each for the squamous and the tympanic part, four for the petrous and mastoid parts, and two for the styloid process. Just before birth the bone consists of three principal parts, viz.: the squamous, the petromastoid part, and the tympanic ring (fig. 354). The *squamous part* is ossified in membrane from a single centre, which appears in the region of the root of the zygomatic process about

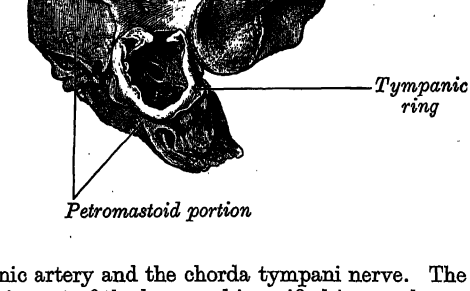
FIG. 354.—The three principal parts of the right temporal bone at birth.



1. External aspect of petromastoid part. 2. Internal aspect of tympanic ring. 3. Internal aspect of squama.

the seventh or eighth week and soon extends in an upward direction. The *petromastoid* part is developed from four centres, which make their appearance in the cartilaginous ear-capsule (p. 130) about the fifth or sixth month of intrauterine life. One (pro-otic) appears in the neighbourhood of the arcuate eminence, spreads in front of and above the internal auditory meatus and extends to the apex of the bone; it covers part of the cochlea, vestibule, superior semicircular duct, and medial wall of the tympanic cavity. A second (opisthotic) appears at the promontory on the medial wall of the tympanic cavity and surrounds the fenestra cochleæ; it forms the floor of the tympanic cavity and vestibule, surrounds the carotid canal, invests the lateral and lower parts of the cochlea, and spreads below the internal auditory meatus. A third (pterotic) forms the roof of the tympanic cavity and antrum; while the fourth (epiotic) appears near the posterior semicircular duct and extends to form the mastoid process (Vrolik). The *tympanic ring* is an incomplete circle, deficient above, the concavity of which is grooved by the tympanic sulcus, for the attachment of the circumference of the tympanic membrane. Two crests, the *superior* and *inferior tympanic crests,* run obliquely downwards and forwards across the anterior part of the inner surface of the ring. Between them an obliquely directed furrow, termed the *sulcus malleolaris,* lodges the anterior process of the malleus, the anterior tympanic artery and the chorda tympani nerve. The tympanic ring expands to form the tympanic part of the bone and is ossified in membrane from a single centre which appears about the third month. The *styloid process* is developed from the cranial end of the cartilage of the second visceral or hyoid arch (p. 99) by two centres: one for the proximal part of the process, termed the tympanohyal, appears before birth; the other, for the distal part of the process, termed the stylohyal, does not appear until after birth. The tympanic ring unites with the squamous part shortly before birth; the petromastoid fuses with the squamous part during the first year, and with the

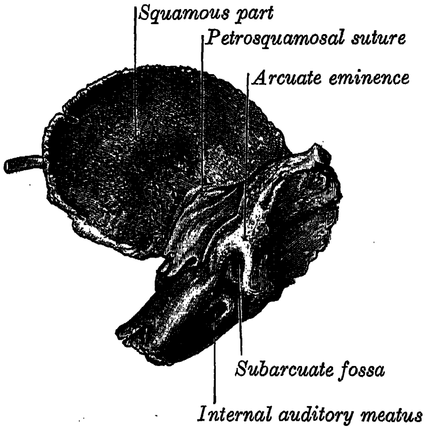
FIG. 355.—The right temporal bone at birth. External aspect.



tympanohyal portion of the styloid process about the same time (figs. 316, 317). The stylohyal does not unite with the rest of the bone until after puberty, and in some skulls never at all.

Subsequently the chief changes in the temporal bone, apart from increase in size, are: (1) The tympanic ring grows laterally and backwards to form the tympanic part of the bone. This growth does not, however, take place at an equal rate all round the ring, but occurs most rapidly on its anterior and posterior portions, and these outgrowths meet and blend, and thus, for a time, there exists in the floor of the meatus a foramen, named the *foramen of Huschke*: this foramen is usually closed about the fifth year, but may persist throughout life. (2) The articular fossa is at first extremely shallow and looks more laterally than downwards; it becomes deeper and is ultimately directed downwards. Its change in direction is accounted for as follows. The portion of the squamous part which forms the fossa lies at first below the level of the zygomatic process and is nearly vertical, but in consequence of the subsequent increase in the width of the base of the skull this portion of the squamous part comes to be directed horizontally inwards, and its surfaces therefore upwards and downwards; the attached portion of the zygomatic process also becomes everted and projects like a shelf at right angles to the squamous. The postero-inferior portion of the squamous part grows downwards behind the tympanic ring and forms the lateral bony wall of the tympanic antrum. (3) The mastoid portion is at first flat, and the stylomastoid foramen and rudimentary styloid process lie immediately behind the tympanic ring. With the development of the mastoid air cells the lateral part of the mastoid portion grows downwards and forwards to form the mastoid process, and the styloid process and stylomastoid foramen come to lie on the under surface of the bone. The descent of the stylomastoid foramen is necessarily accompanied by a corresponding increase in the length of the canal for the facial nerve. It is not until the latter part of the second year that the mastoid process forms a definite elevation on the surface of the skull. (4) The subarcuate fossa on the posterior surface of the petrous portion is gradually filled and almost obliterated.

FIG. 356.—The right temporal bone at birth. Internal aspect.



Applied Anatomy.—The external auditory meatus is relatively as long in the child as in the adult, but in the child the canal is fibro-cartilaginous, whereas in the adult the inner two-thirds of it are osseous. When it is necessary to open the tympanum for suppuration, it is approached through the tympanic antrum. In the child only a thin scale of bone requires to be removed from the suprameatal triangle to open into the tympanic antrum.

The Parietal Bones (Ossa Parietalia)

The parietal bones form, by their union, the sides and the roof of the cranium. Each bone is irregularly quadrilateral in shape, and has two surfaces, four borders, and four angles.

The *external surface* (fig. 357) is convex, smooth, and marked near the centre by a slight elevation, termed the *parietal eminence*. Two curved lines, termed the *superior* and *inferior temporal lines*, cross the middle of the bone, forming an arch which is convex upwards and backwards; the former gives attachment to the temporal fascia; the latter marks the upper limit of the origin of the temporal muscle. The part of the bone above these lines is covered, in the recent condition, with the epicranial aponeurosis (galea aponeurotica); that below the lines forms a part of the temporal fossa. At the posterior part, and close to the upper or sagittal border, the *parietal foramen* transmits a vein from the superior sagittal sinus and, sometimes, a small branch of the occipital artery; the foramen is not constantly present, and its size varies considerably.

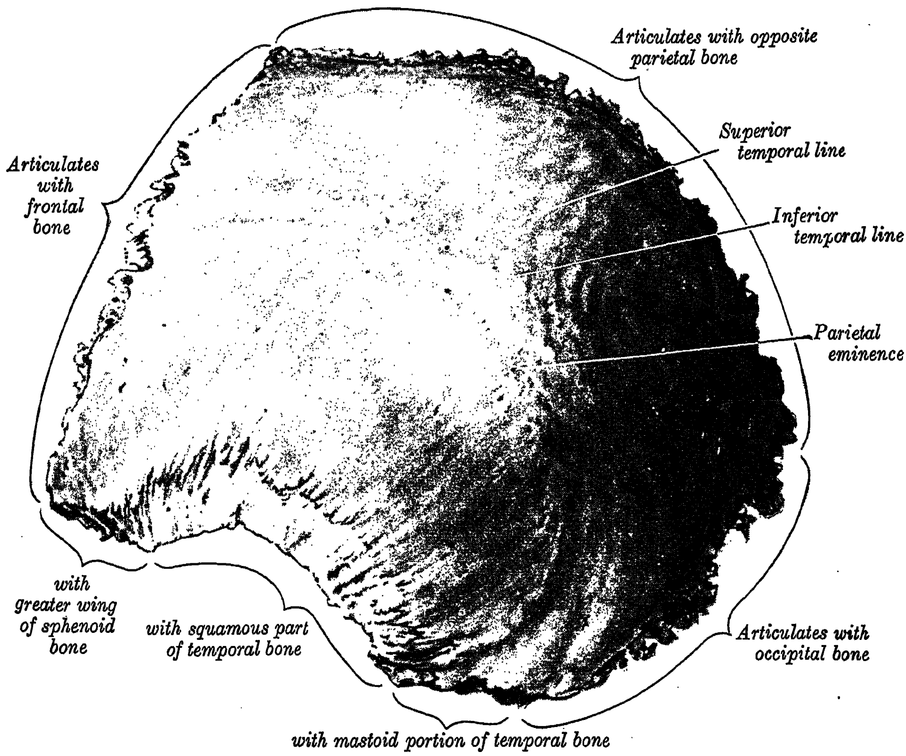
The *internal surface* (fig. 358) is concave; it presents *impressions for the cerebral gyri*, and numerous furrows for the ramifications of the middle meningeal vessels;* these furrows run upwards and backwards from the anterior inferior angle, and from the middle

* Consult articles by F. Wood Jones, *Journal of Anatomy and Physiology*, vol. xlvi., and B. Coen, *Journal of Anatomy and Physiology*, vol. xlviii.

and posterior part of the inferior border. Along the upper or sagittal border there is a shallow groove, which, with that on the opposite parietal bone, forms the *sagittal sulcus* for the superior sagittal sinus; to the edges of this sulcus the falx cerebri is attached. A number of *granular pits*, which lodge arachnoid granulations, mark the bone in the neighbourhood of the sagittal sulcus; they are best marked in the skulls of old persons.

The *upper border*—the longest and thickest—is dentated; it articulates with the corresponding border of the opposite parietal bone to form the sagittal suture. The *lower border* is divided into three parts: of these, the anterior is short, thin and pointed; it is bevelled at the expense of the external surface, and is overlapped by the tip of the greater wing of the sphenoid; the middle portion is arched, bevelled at the expense of the external surface, and overlapped by the squamous part of the temporal bone; the posterior part is short, thick and serrated, and articulates with the mastoid portion of the temporal bone. The *anterior border* is deeply serrated, and bevelled at the expense of the external surface above

FIG. 357.—The left parietal bone. External surface.



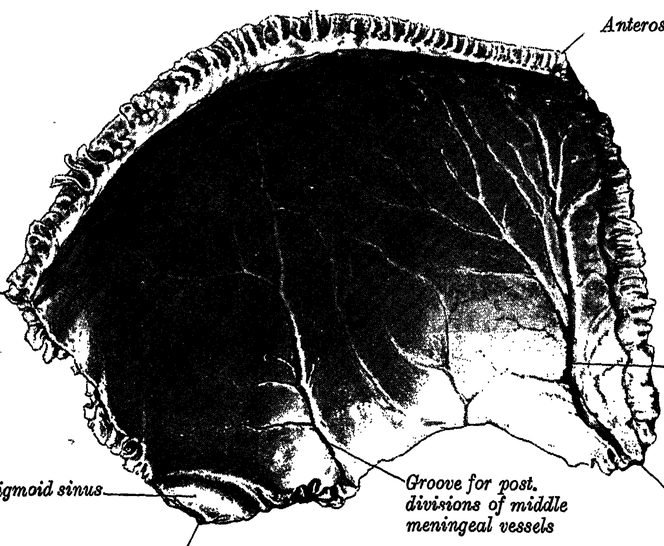
and of the internal below; it articulates with the frontal bone, forming one-half of the coronal suture. The *posterior border*, which is deeply dentated, articulates with the occipital bone, forming one-half of the lambdoid suture.

The *anterior superior angle* is almost a right angle, and corresponds with the *bregma* or point of meeting of the sagittal and coronal sutures. The *anterior inferior angle* is received into the interval between the frontal bone and the greater wing of the sphenoid. Its internal surface is marked by a deep groove—sometimes a canal—for the anterior divisions of the middle meningeal vessels. In some skulls the frontal bone articulates with the squama of the temporal bone, and the parietal bone then fails to reach the greater wing of the sphenoid. The region where these four bones approach closely to one another is termed the *pterion* (p. 251). The *posterior superior angle* is rounded and corresponds with the *lambda* or point of meeting of the sagittal and lambdoid sutures. The *posterior inferior angle* is blunt and articulates with the occipital bone and with the mastoid portion of the temporal bone, the meeting point of the three bones being named the *asterion*. On the internal surface of this angle there is a broad, shallow groove, which lodges the end of the transverse sinus and the commencement of the sigmoid sinus.

At birth there are unossified or membranous intervals in the skull at the angles of the parietal bones; they are named fontanelles (fonticuli) and are described on pp. 326, 327.

Ossification.—The parietal bone is ossified in membrane from two centres, which appear one above the other at the parietal eminence about the seventh week of intrauterine life. These centres unite early, and ossification gradually extends in a radial manner towards the margins of the bone ; the angles are consequently the parts last formed, and it is here that the fontanelles are found. At birth the temporal lines are situated low down ; they reach their permanent position only after the eruption of the molar teeth. Occasionally the parietal bone is divided into upper and lower parts by an anteroposterior suture.

Fig. 358.—The left parietal bone. Internal surface.



The Frontal Bone (Os Frontale)

The **frontal bone** resembles a cockle-shell in shape, and forms the region of the forehead ; on each side it has a horizontal *orbital plate*, which enters into the formation of the roof of the orbital cavity.

The frontal bone has four surfaces, viz.—frontal, right and left temporal and cerebral.

The *frontal surface* (fig. 359) usually exhibits, in the lower part of the median plane, the remains of the *frontal* or *metopic suture* ; in infancy this suture divides the bone into two—a condition which persists in about 9 per cent. of skulls. On each side of the median plane, about 3 cm. above the supra-orbital margin, there is a rounded elevation, termed the *frontal eminence*. These eminences vary in size in different individuals, are occasionally asymmetrical, and are especially prominent in young skulls. Below the frontal eminences, and separated from them by a shallow groove, there are two curved *superciliary arches*, the medial parts of which are prominent and joined to each other by a smooth elevation named the *glabella*. These arches are larger in the male than in the female, and their degree of prominence depends to some extent on the size of the frontal sinuses ; prominent superciliary arches are, however, occasionally associated with small sinuses. Beneath the superciliary arches the curved *supra-orbital margins* form the upper portions of the orbital openings. The lateral two-thirds of each supra-orbital margin are sharp ; the medial one-third is rounded. At the junction of these two parts the *supra-orbital notch*, or *foramen*, is situated ; it transmits the supra-orbital vessels and nerve. Medial to this notch, and present in about 50 per cent. of skulls, is the small *frontal notch* or *foramen*. The supra-orbital margin ends laterally in the *zygomatic process*, which is strong and prominent, and articulates with the zygomatic bone. From this process a line curves upwards and backwards and soon divides into the *superior* and *inferior temporal lines*. It separates the frontal surface from the temporal.

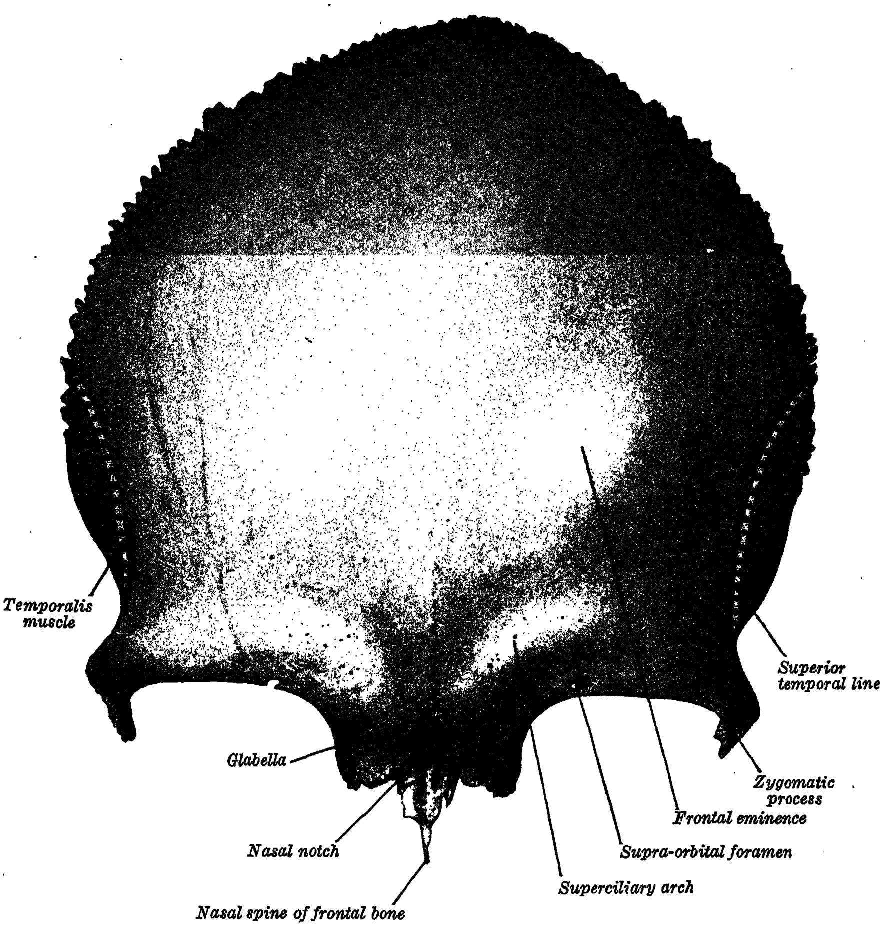
The portion of the bone which projects downwards between the supra-orbital margins is named the *nasal part*. It presents an uneven interval, sometimes termed the *nasal notch*, which articulates on each side of the median plane with the nasal bone, and lateral to this with the frontal process of the maxilla and with the lacrimal bone. From the centre of the notch the *nasal part* projects downwards and forwards behind the nasal bones (fig. 330) and

frontal processes of the maxillæ, and supports the bridge of the nose. The nasal part ends below in a sharp *nasal spine,* and on each side of this there is a small grooved surface which forms a part of the roof of the corresponding nasal cavity. The nasal spine forms a part of the septum of the nose; in front it articulates with the crest of the nasal bones, behind with the perpendicular plate of the ethmoid bone (fig. 328).

The *temporal surface,* below and behind the temporal lines, forms the anterior part of the temporal fossa and gives origin to a part of the temporal muscle.

The *cerebral surface* (fig. 360) of the frontal bone is concave. In the upper part of the median plane it is marked by a vertical groove, termed the *sagittal sulcus,* the edges of which unite below to form the *frontal crest*; the sulcus lodges the anterior part of the

Fig. 359.—The frontal bone. External surface.



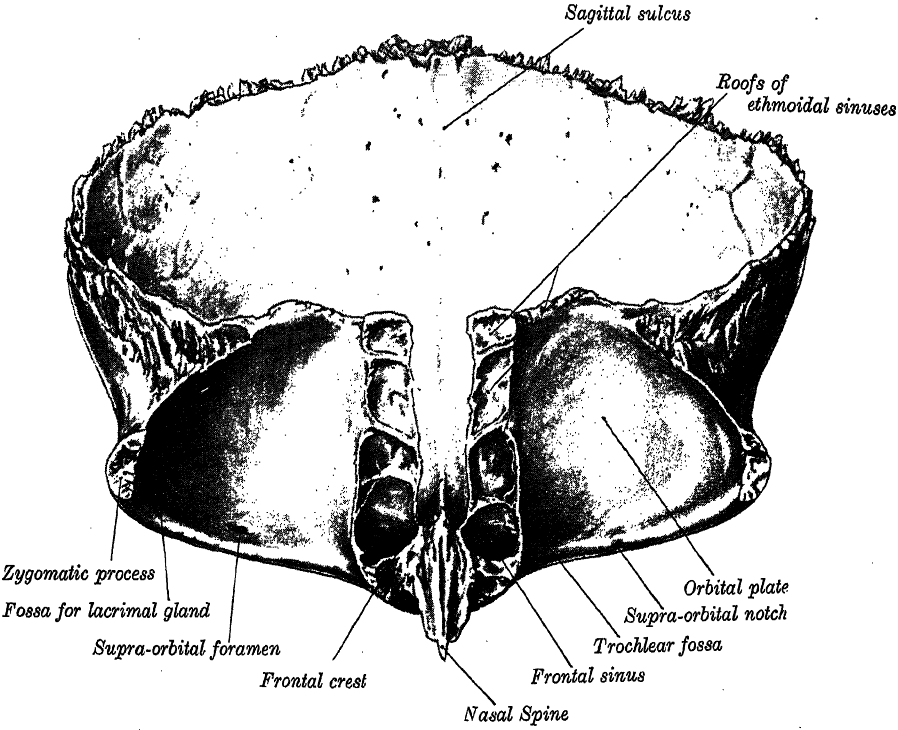
superior sagittal sinus, while to its margins and to the frontal crest the anterior part of the falx cerebri is attached. The crest ends below in a small notch, which is converted into the *foramen cæcum* by articulation with the ethmoid bone. The foramen cæcum varies in size in different skulls, and is rarely pervious; in these rare cases, it transmits a vein from the nose to the superior sagittal sinus. On each side of the median plane the surface is marked by *impressions for the cerebral gyri,* and minute furrows for meningeal vessels. Several small, irregular fossæ may be seen on each side of the sagittal sulcus, for the reception of arachnoid granulations. They are termed *granular pits.*

The *parietal margin* is thick, strongly serrated, bevelled at the expense of the cerebral surface above, where it rests upon the parietal bones, and at the expense of the temporal surface on each side, where it receives the lateral pressure of the parietal bones; it is continued below into a triangular, rough surface, for articulation with the greater wing of the sphenoid bone.

The orbital plates of the frontal bone consist of two thin triangular lamellæ, which form the vaults of the orbits, and are separated from each other by a wide gap named the *ethmoidal notch.*

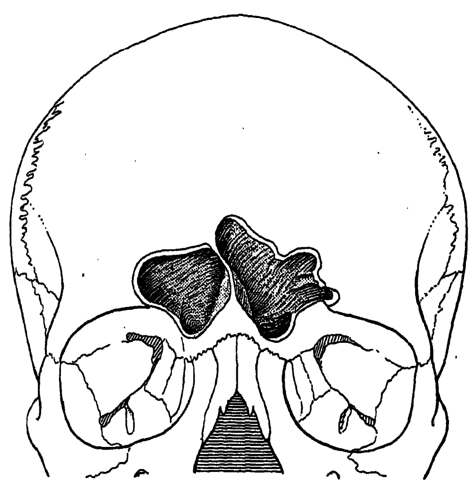
The *orbital surface* (fig. 360) of each orbital plate is smooth and concave, and presents, in its anterolateral part, a shallow depression which lodges the lacrimal gland and consequently is termed the *fossa for the lacrimal gland*; below and behind the medial end of the

FIG. 360.—The frontal bone. Viewed from below.



supra-orbital margin, about midway between the supra-orbital notch and the fronto-lacrimal suture, there is a small depression or spine [the *fossa vel spina trochlearis*], for the attachment of the fibrocartilaginous pulley of the superior oblique muscle. The *cerebral*

FIG. 361.—Frontal sinuses. Anterior aspect. The left sinus is larger than the right and the septum between them is obliquely placed.

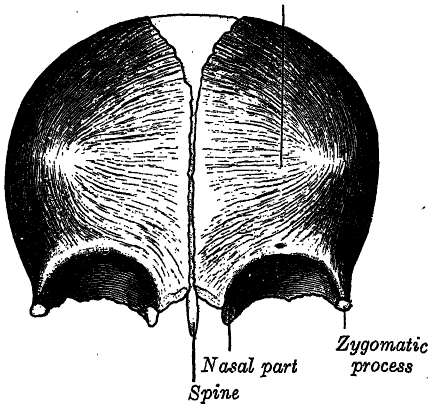


surface is convex, and marked by impressions for the gyri on the inferior surface of the frontal lobe of the brain, and by faint grooves for the meningeal branches of the ethmoidal vessels.

The *ethmoidal notch* (fig. 360) separates the two orbital plates; it is quadrilateral in outline and is filled, in the articulated skull, by the cribriform plate of the ethmoid bone. On the margins of the notch portions of several air-sinuses are present: they complete the ethmoidal sinuses when the ethmoid bone is in position. Two transverse grooves cross each margin of the notch; they are converted into the *anterior* and *posterior ethmoidal canals* by the ethmoid bone, and open on the medial wall of the orbit; they transmit the anterior and posterior ethmoidal nerves and vessels.

The openings of the *frontal sinuses* (fig. 360) are situated in front of the ethmoidal notch, and lateral to the nasal spine. These sinuses are two irregular cavities, which extend backwards, upwards, and laterally for a variable distance between the tables of the frontal bone; they are separated from each other by a thin bony septum, which is often deflected to one or other side of the median plane, with the result that the sinuses are seldom symmetrical. Rudimentary at birth, the frontal sinuses are usually fairly well-developed between the seventh and eighth years, but reach their full size only after puberty. They vary in size in different persons and are larger in men than in women.* Occasionally they extend backwards in the roofs of the orbital cavities as far as the optic foramina. Each communicates with the middle meatus of the corresponding nasal cavity by means of a passage called the *fronto-nasal duct*. (Pl. I.)

FIG. 362.—The frontal bone at birth. External aspect.



The *posterior borders of the orbital plates* are thin and serrated, and articulate with the lesser wings of the sphenoid; the lateral part of each usually appears in the middle cranial fossa between the greater and lesser wings of the sphenoid bone.

Structure.—The frontal bone is thick and consists of spongy substance contained between two compact laminæ; the spongy substance is absent in the regions occupied by the frontal sinuses. The orbital plate, composed entirely of compact bone, is thin and translucent in its posterior two-thirds.

Ossification (fig. 362).—The frontal bone is ossified in membrane from two primary centres which appear in the seventh or eighth week of intrauterine life, one above each supra-orbital margin. From each of these centres ossification extends upwards to form the corresponding half of the bone, and backwards to form the orbital plate. The nasal spine is ossified from two secondary centres, one on each side of the median plane; secondary centres also appear in the nasal parts and zygomatic processes. At birth the bone consists of two pieces separated by the frontal suture, but union of the pieces begins in the second year, and the frontal suture is usually obliterated, except at its lower part, by the eighth year.

THE ETHMOID BONE (OS ETHMOIDALE)

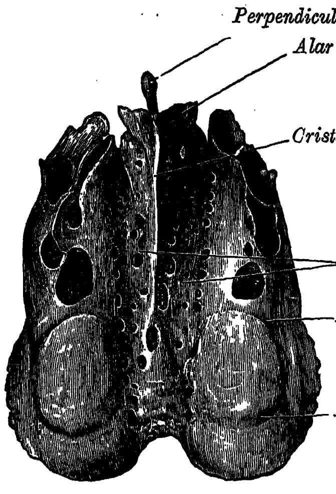
The **ethmoid bone** is cuboidal in shape, and exceedingly light; it is situated at the anterior part of the base of the cranium, and assists in forming the medial walls of the orbits, the septum of the nose, and the roof and lateral walls of the nasal cavity. It consists of four parts: a horizontal, perforated plate named the cribriform plate, a perpendicular plate and two lateral masses named the labyrinths.

The **cribriform plate** of the ethmoid (fig. 363) occupies the ethmoidal notch of the frontal bone and forms a part of the roof of the nasal cavity. A thick, smooth, triangular process, called the *crista galli* from its resemblance to a cock's comb, projects upwards from this lamina in the median plane. Its posterior border, long, thin, and curved, gives attachment to the falx cerebri. Its anterior border, short and thick, articulates with the frontal bone by two small projecting *alæ* which complete the foramen cæcum. Its sides are smooth, and sometimes bulging owing to the presence of a small air-sinus in the interior. On each side of the crista galli the cribriform plate is narrow and depressed; it supports the gyrus rectus and presents numerous foramina for the passage of the olfactory nerves. The foramina in its middle part are small and transmit the nerves from the mucous membrane of the roof

* Logan Turner (*op. cit.*) gives the following measurements for an adult sinus of average size: height, 3·16 cm.; breadth, 2·58 cm.; depth from before backwards, 1·8 cm. Onodi (*op. cit.*) states that in infants of from one to twelve months the height of the frontal sinus varies from 3·5 mm. to 8 mm., and its width from 2 mm. to 6 mm., and that in the eighth year of life the height is from 14 mm. to 17 mm., and the width from 7 mm. to 9 mm.

of the nasal cavity; those in the medial and lateral parts are larger—the former transmit the nerves from the mucous membrane on the upper part of the nasal septum, the latter the nerves from the mucous membrane on the superior nasal concha. At the front part of the cribriform plate, on each side of the crista galli, there is a small slit-like fissure, which is occupied by a process of dura mater. The foramen which transmits the anterior ethmoidal nerve to the nasal cavity is placed lateral to the anterior end of the fissure, and from it a groove runs backwards to the orifice of the anterior ethmoidal canal.

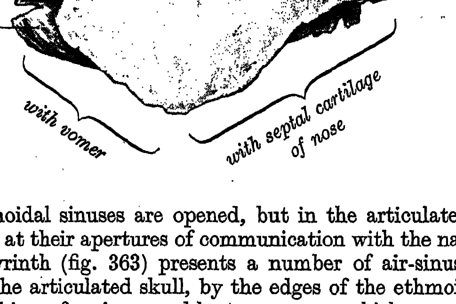
FIG. 363.—The ethmoid bone. Superior aspect.



The **perpendicular plate** of the ethmoid (figs. 364, 365), is thin, flat and quadrilateral in form. It descends from the under surface of the cribriform plate and forms the upper part of the nasal septum; it is generally deflected a little to one or other side. The *anterior border* articulates with the nasal spine of the frontal bone and the crest of the nasal bones. The *posterior border* articulates with the sphenoidal crest above and with the vomer below. The *superior border* is attached to the cribriform plate. The *inferior border* is thick, and serves for the attachment of the septal cartilage of the nose. The surfaces of the lamina are smooth, except above, where numerous grooves and canals are seen; these lead to the medial foramina in the cribriform plate and lodge filaments of the olfactory nerves.

Each **labyrinth** of the ethmoid bone consists of a number of thin-walled *ethmoidal sinuses,* arranged in three groups—*anterior, middle,* and *posterior*—and interposed between two vertical plates of bone; the lateral or *orbital plate* forms part of the medial wall of the orbit, the medial plate, part of the lateral wall of the nasal cavity.* In the disarticulated bone many of these ethmoidal sinuses are opened, but in the articulated skull they are everywhere closed, except at their apertures of communication with the nasal cavity. The *upper surface* of the labyrinth (fig. 363) presents a number of air-sinuses, the walls of which are completed, in the articulated skull, by the edges of the ethmoidal notch of the frontal bone (fig. 360). This surface is crossed by two grooves which are converted into the *anterior* and *posterior ethmoidal canals* by articulation with the frontal bone. On the *posterior surface* of each labyrinth (fig. 365) large air-sinuses are visible, and their walls

FIG. 364.—The perpendicular plate of the ethmoid bone. Right lateral aspect. Shown after removal of the right labyrinth.

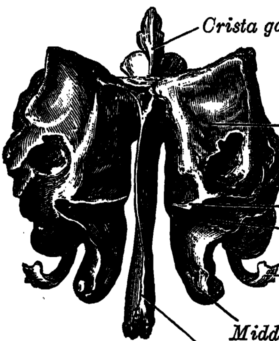


* Some anatomists divide the ethmoidal sinuses into two groups, an *anterior,* comprising those which open into the middle meatus, and a *posterior,* those which open into the superior meatus of the nose.

are completed by the sphenoidal concha and the orbital process of the palatine bone. The *lateral surface* (fig. 366) consists of a thin, smooth, oblong plate, named the *orbital plate,* which covers the middle and posterior ethmoidal sinuses and forms a large part of the medial wall of the orbit; it articulates above with the orbital plate of the frontal bone, below with the maxilla and the orbital process of the palatine bone, in front with the lacrimal bone, and behind with the sphenoid bone (fig. 314).

A few sinuses lie in front of the orbital plate and their walls are completed by the lacrimal bone and the frontal process of the maxilla. A curved lamina, termed the *uncinate process,* which is subject to considerable variation in size, projects downwards and backwards from

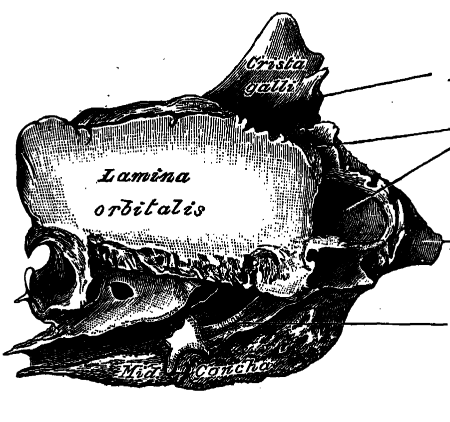
FIG. 365.—The ethmoid bone. Posterior aspect.



this part of the labyrinth; it forms a small part of the medial wall of the maxillary sinus (fig. 314), and articulates with the ethmoidal process of the inferior nasal concha. The upper edge of this process is free and forms the medial boundary of the hiatus semilunaris.

The *medial surface* of the labyrinth (fig. 367) forms part of the lateral wall of the corresponding half of the nasal cavity; it consists of a thin lamella, which descends from the under surface of the cribriform plate and ends in a free, convoluted portion, named the *middle nasal concha.* The upper part of the medial surface is marked by numerous grooves, directed nearly vertically downwards; they lodge branches of the olfactory nerves. The posterior part of the medial surface is subdivided by a narrow, oblique fissure, termed the

FIG. 366.—The ethmoid bone. Right lateral aspect.

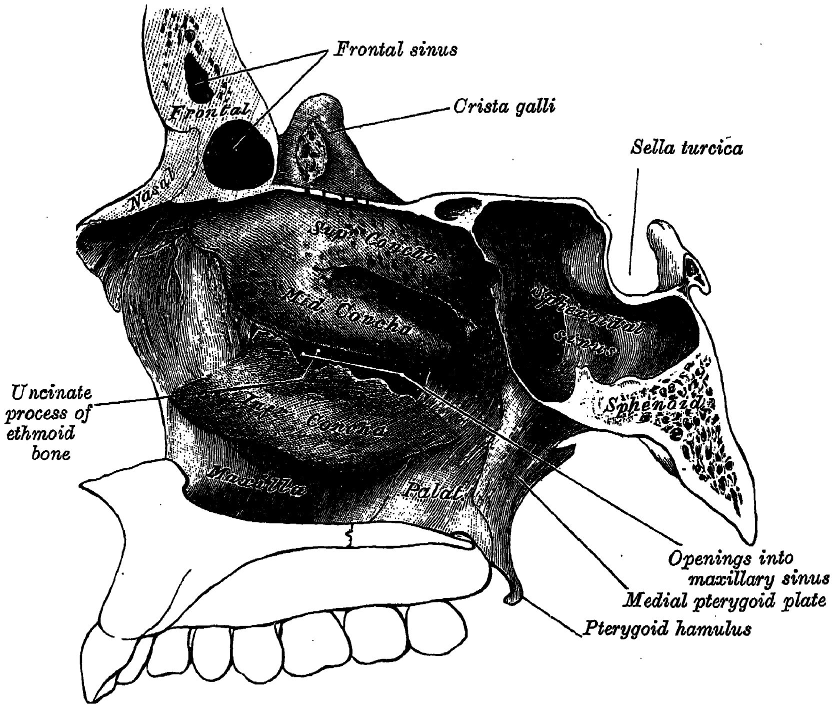


superior meatus of the nose, which is bounded above by a thin, curved plate, named the *superior nasal concha*; the posterior ethmoidal sinuses open into this meatus. Below and in front of the superior meatus the convex surface of the middle nasal concha extends along the whole length of the medial surface of the labyrinth. Its lower margin is free and thick, while its lateral surface is concave and assists in forming the *middle meatus* of the nose. The middle ethmoidal sinuses produce a rounded swelling, named the *bulla ethmoidalis,* on the lateral wall of the middle meatus (fig. 368); on the bulla, or immediately above it, these sinuses open into the meatus. A curved passage, named the *infundibulum,*

extends upwards and forwards from the middle meatus; it communicates with the anterior ethmoidal sinuses, and in rather more than 50 per cent. of skulls is continued upwards as the frontonasal duct into the frontal sinus.

Ossification.—The ethmoid bone is ossified in the cartilaginous nasal capsule from three centres; one for the perpendicular plate, and one for each labyrinth.

FIG. 367.—The lateral wall of the right half of the nasal cavity, showing the ethmoid bone (coloured red) and the inferior nasal concha (coloured blue) in position.



The centre for each labyrinth appears in the region of the orbital plate between the fourth and fifth months of intrauterine life, and extends into the conchæ. At birth, the two labyrinths, which are small and ill-developed, are partially ossified, but the rest of the bone is cartilaginous. During the first year after birth, the perpendicular plate and crista galli begin to ossify from a single centre, and they are joined to the labyrinths about the beginning of the second year. The cribriform plate is ossified partly from the perpendicular plate and partly from the labyrinths. The ethmoidal sinuses begin to develop during intrauterine life, and in the new-born infant have the form of narrow pouches.

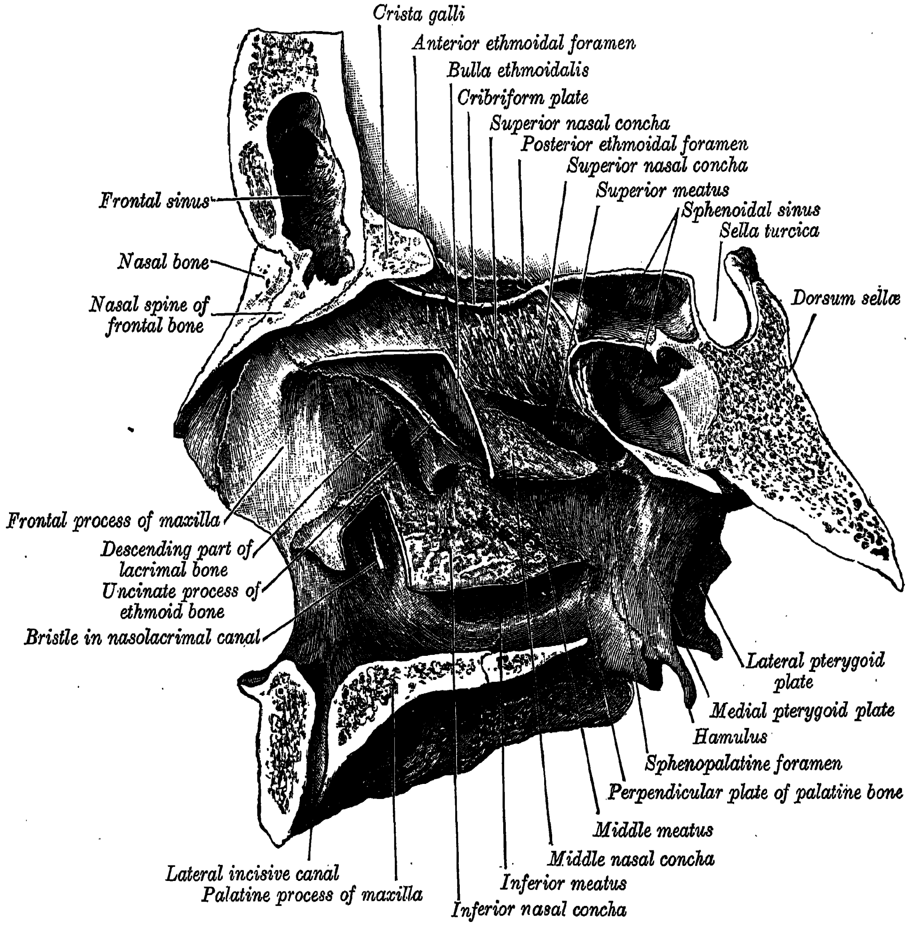
The Inferior Nasal Conchæ (Conchæ Nasales Inferiores)

The **inferior nasal conchæ** are curved laminæ which lie horizontally in the lateral walls of the nasal cavity (fig. 367). Each bone has two surfaces, two borders, and two ends.

The *medial surface* (fig. 369) is convex, perforated by numerous apertures, and traversed by longitudinal grooves for the lodgement of vessels. The *lateral surface* is concave (fig. 370), and forms part of the inferior meatus of the nasal cavity. The *superior border* is thin and irregular, and may be divided into three portions: of these, the anterior articulates with the conchal crest of the maxilla, and the posterior with the conchal crest of the palatine bone. The middle portion presents three processes, which vary in size and form. Of these, the *lacrimal process* is small and pointed and is situated at the junction of the anterior one-fourth with the posterior three-fourths of the bone: it articulates, by its apex, with a descending process from the lacrimal bone (fig. 368) and, by its margins, with the edges of the nasolacrimal groove on the medial surface of the body of the maxilla; it thus assists in forming the canal for the nasolacrimal duct. Behind this process a thin plate, named the *ethmoidal process*, ascends to join the uncinate process of the ethmoid (fig. 368). From the middle part of the superior border a thin lamella, termed the *maxillary process*, curves

downwards and laterally; it articulates with the maxilla and the maxillary process of the palatine bone, and forms a part of the medial wall of the maxillary sinus (fig. 383). The

FIG. 368.—The lateral wall of the right half of the nasal cavity, after removal of parts of the middle and inferior nasal conchæ.



inferior border is free, thick, and spongy in structure, more especially in the middle of the bone. Both *ends* are more or less pointed, the posterior being the more tapered.

Ossification.—The inferior nasal concha is ossified from one centre; this appears about

FIG. 369.—The right inferior nasal concha. Medial surface.

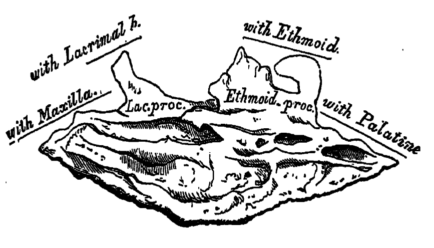


FIG. 370.—The right inferior nasal concha. Lateral surface.

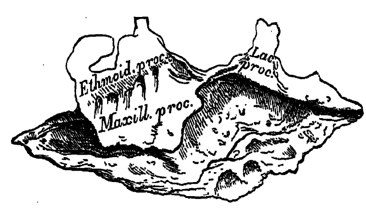

the fifth month of intrauterine life in the incurved lower border of the lateral wall of the cartilaginous nasal capsule. It is detached from the remainder of the nasal capsule during ossification.

The Lacrimal Bones (Ossa Lacrimalia)

The **lacrimal bones**, which are the smallest and most fragile of the cranial bones, are situated at the front parts of the medial walls of the orbits (figs. 373, 383). Each lacrimal bone has two surfaces and four borders. The *lateral* or *orbital surface* (fig. 371) is divided by a vertical ridge, termed the *crest of the lacrimal bone*. In front of this crest there is a vertical groove, the anterior border of which articulates with the posterior border of the frontal process of the maxilla to complete the *lacrimal groove* for the lodgment of the lacrimal sac. The medial wall of the groove is prolonged downwards as a descending process (fig. 372) to assist in forming the bony canal for the nasolacrimal duct by articulating with the lips of the naso-lacrimal groove of the maxilla, and with the lacrimal process of the inferior nasal concha. The portion behind the crest is smooth and forms a part of the medial wall of the orbit. The crest, with a part of the orbital surface immediately posterior to it, gives origin to the lacrimal part of the orbicularis oculi muscle. The crest ends below in a small hook, termed the *lacrimal hamulus*, which articulates with the maxilla and completes the upper orifice of the bony canal for the nasolacrimal duct; the lacrimal hamulus sometimes exists as a separate piece, and is then called the *lesser lacrimal bone*. On the *medial* or *nasal surface* a vertical furrow corresponds to the crest on the lateral surface. The area in front of this furrow forms part of the middle meatus of the nose; that behind the furrow articulates with the ethmoid bone and completes some of the anterior ethmoidal sinuses. The *anterior border* of the lacrimal bone articulates with the frontal process of the maxilla: the *posterior border* with the orbital plate of the ethmoid; the *superior border* with the frontal bone. The posterior part of the *inferior border* articulates with the orbital surface of the maxilla.

Fig. 371.—The left lacrimal bone. Lateral aspect. (Enlarged.)

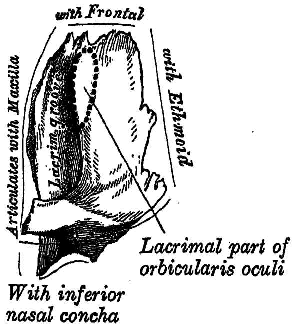

Fig. 372.—A sketch showing how the medial wall of the nasolacrimal canal is completed by the articulation of the descending process of the lacrimal bone with the lacrimal process of the inferior nasal concha. (After Whitnall.)

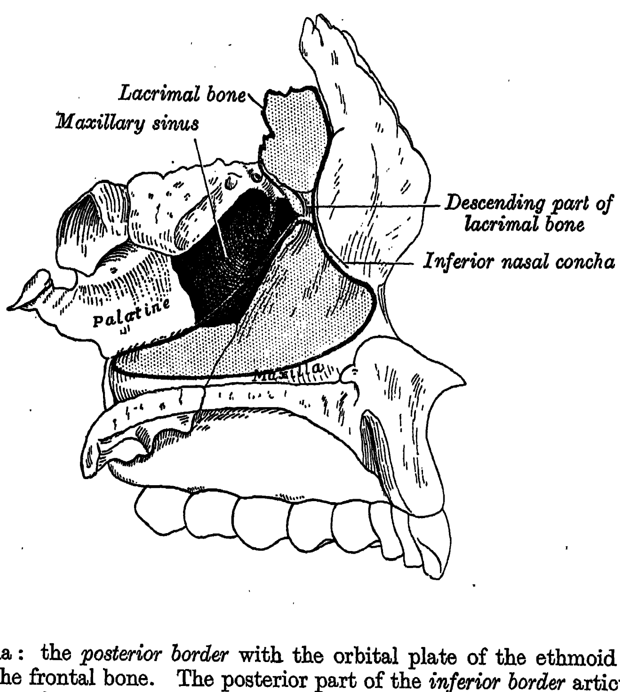
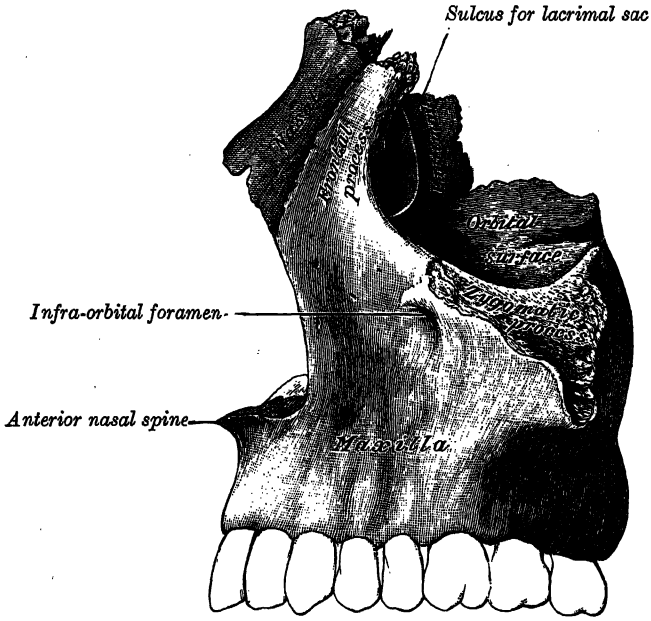


Ossification.—The lacrimal bone is ossified from one centre, which appears about the twelfth week of intrauterine life in the membrane covering the cartilaginous nasal capsule.

THE NASAL BONES (OSSA NASALIA)

The **nasal bones** are two small oblong bones, varying in size and form in different individuals; they are placed side by side between the frontal processes of the maxillæ, and form, by their junction, 'the bridge' of the nose (figs. 311, 373).

FIG. 373.—The articulation of the nasal and lacrimal bones with the maxilla. Left lateral aspect.



Each nasal bone has two surfaces and four borders. The *external surface* (fig. 374) is concavo-convex from above downwards, and convex from side to side; it is covered by the procerus and compressor naris, and is perforated near its centre by a foramen for the transmission of a small vein. The *internal surface* (fig. 375) is concave from side to side, and is

FIG. 374.—The left nasal bone. External surface.

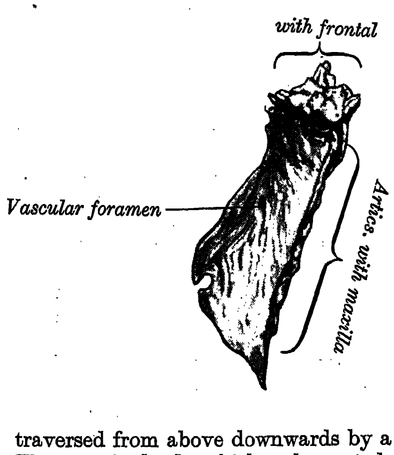


FIG. 375.—The left nasal bone. Internal surface.

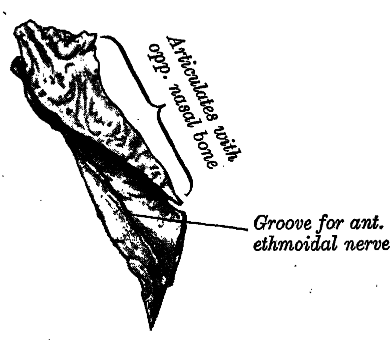


traversed from above downwards by a groove which lodges the anterior ethmoidal nerve. The *superior border*, thick and serrated, articulates with the nasal notch of the frontal bone. The *inferior border*, thin and notched, gives attachment to the lateral cartilage of the nose. The *lateral border* articulates with the frontal process of the maxilla. The *medial border*, thicker above than below, articulates with the opposite nasal bone and is prolonged behind

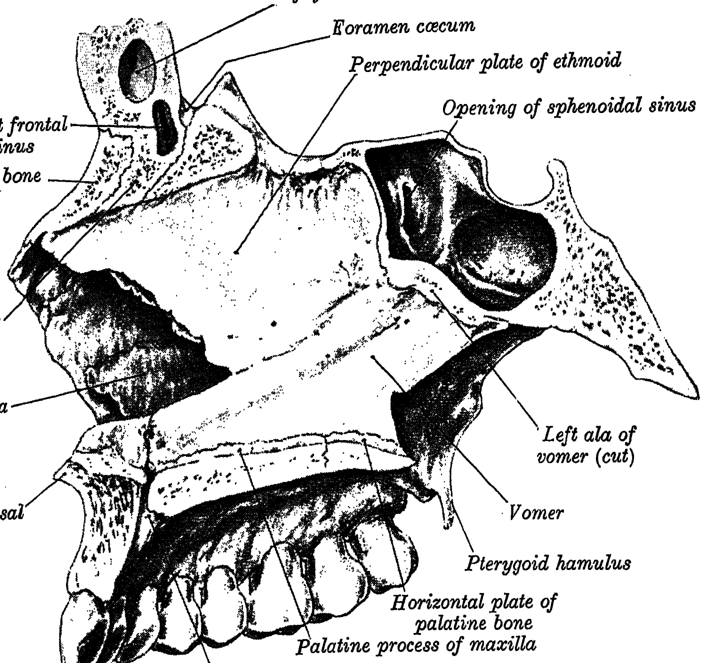
into a vertical crest, which forms a small part of the septum of the nose, and articulates, from above downwards, with the nasal spine of the frontal, the perpendicular plate of the ethmoid, and the cartilage of the septum of the nose.

Ossification.—The nasal bone is ossified from one centre, which appears at the beginning of the third month of intrauterine life in the membrane overlying the anterior part of the cartilaginous nasal capsule.

The Vomer

The **vomer** is thin, flat bone, almost quadrilateral in shape; it forms the hinder and lower part of the septum of the nose (fig. 376) and has two surfaces and four borders. Each *surface* (fig. 377) is marked by small furrows for blood-vessels, and is traversed by a groove which runs obliquely downwards and forwards, and lodges the corresponding long spheno-palatine nerve and vessels. The *superior border* is the thickest, and presents a deep furrow, bounded on each side by a projecting *ala*: the furrow receives the rostrum of the sphenoid; the alæ articulate with the sphenoidal conchæ, the sphenoidal processes of the palatine

Fig. 376.—The medial wall of the left half of the nasal cavity, showing the vomer *in situ*.



bones and the vaginal processes of the medial pterygoid plates. When the edge of the ala occupies the interval between the body of the sphenoid and the vaginal process, its lower surface takes part in the formation of the vomerovaginal canal (p. 260). The *inferior border* articulates with the nasal crest formed by the maxillæ and palatine bones. The *anterior border* is the longest; its upper half articulates with the perpendicular plate of the ethmoid, its lower is cleft for the reception of the inferior margin of the cartilage of the septum of the nose. The *posterior border* is free, concave, and separates the posterior nasal apertures; it is thick and bifid above, thin below. The anterior end of the vomer articulates with the posterior margin of the incisor crest of the maxillæ and projects downwards between the incisive canals.

Ossification.—At an early period the septum of the nose consists of a plate of cartilage. The superior part of this cartilage is ossified to form the perpendicular plate of the ethmoid; its antero-inferior portion persists as the septal cartilage, whilst the vomer is ossified in the membrane covering its postero-inferior part. About the eighth week of intrauterine life two centres of ossification, one on each side of the median plane, appear in this part of the membrane, medial to and a little behind the paraseptal cartilages (p. 90). About the third month these centres unite below the cartilage, and thus a deep groove is formed (fig. 378) in which the cartilage of the septum of the nose is lodged. As growth proceeds, the union of the bony

lamellæ extends upwards and forwards and at the same time the intervening plate of cartilage undergoes absorption. By the age of puberty the lamellæ are almost completely united, but evidence of the bilaminar origin of the bone is seen in the everted alæ of its upper

FIG. 377.—The vomer. Left lateral aspect.

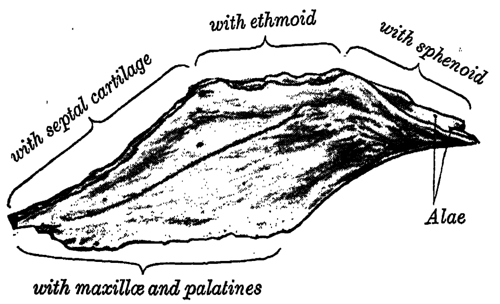


FIG. 378.—The vomer of an infant.

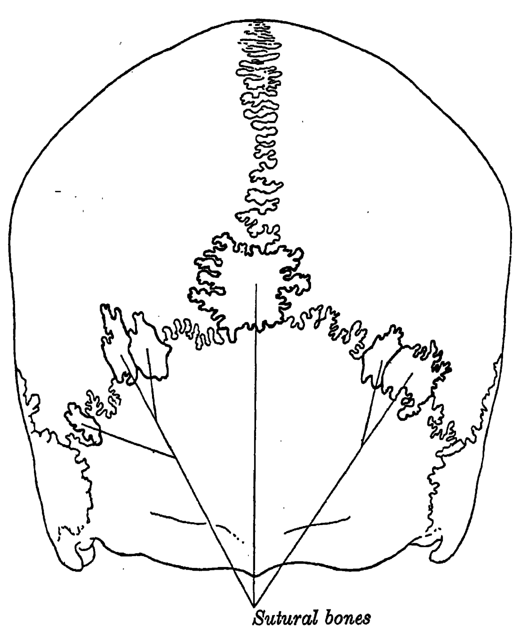
border and the groove on its anterior margin. Up to a certain stage the vomer is entirely derived from membrane, but 'it becomes added to by the ossification of the hinder end of the anterior paraseptal cartilage.' *

THE SUTURAL BONES (OSSA SUTURARUM)

In addition to the usual centres of ossification of the cranial bones, others may occur in the course of the sutures, giving rise to irregular, isolated, *sutural bones* (fig. 379). They occur most frequently in the course of the lambdoid suture, but are occasionally seen at the

FIG. 379.—A sketch showing sutural bones in the lambdoid and sagittal sutures.



fontanelles, especially the posterior. One—the *pterion ossicle*—sometimes exists between the anterior inferior angle of the parietal bone and the greater wing of the sphenoid bone. These bones vary much in size, but have a tendency to be more or less symmetrical on the two sides of the skull. Their number is generally limited to two or three; but more than a hundred have been found in the skull of a hydrocephalic subject.

* E. Fawcett, *Journal of Anatomy and Physiology*, vol. xlv.

THE FACIAL BONES (OSSA FACIEI)

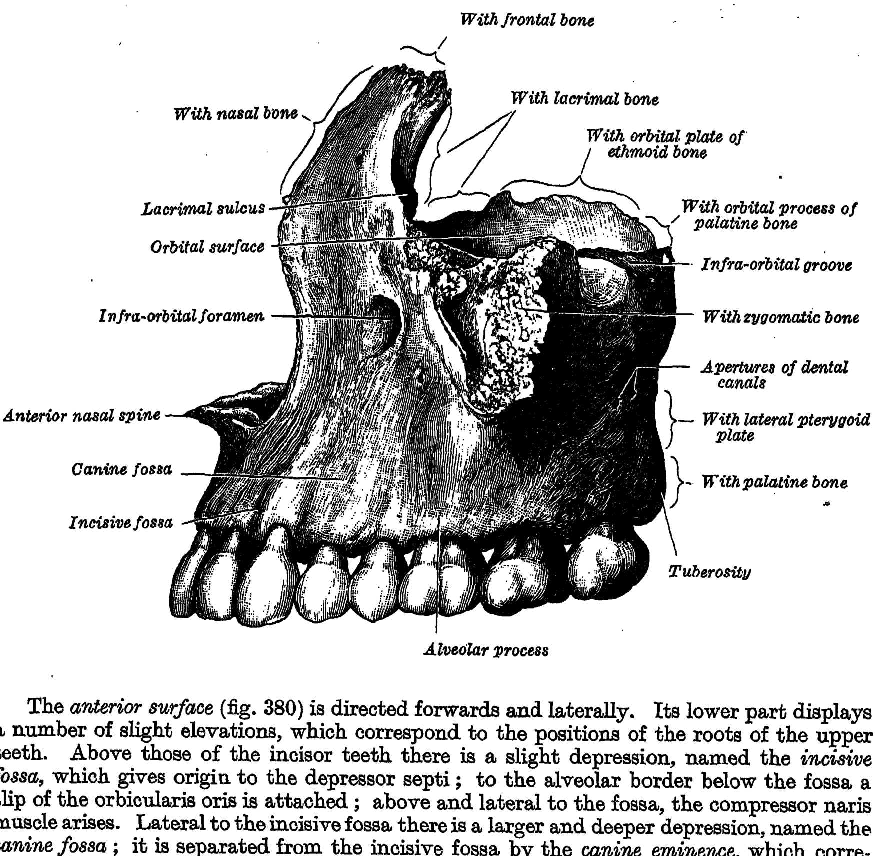
The Maxillæ

The maxillæ are the largest bones of the face, excepting the mandible, and by their union form the whole of the upper jaw (fig. 311). Each assists in completing the roof of the mouth, the floor and lateral wall of the nasal cavity, and the floor of the orbit; it also enters into the formation of the infratemporal and pterygopalatine fossæ, and the inferior orbital and pterygomaxillary fissures.

Each maxilla consists of a body and four processes—zygomatic, frontal, alveolar, and palatine.

The body of the maxilla is pyramidal in shape. It has four surfaces—anterior, posterior, orbital, and nasal—and encloses a large cavity, termed the maxillary sinus.

Fig. 380.—The left maxilla. Lateral aspect.



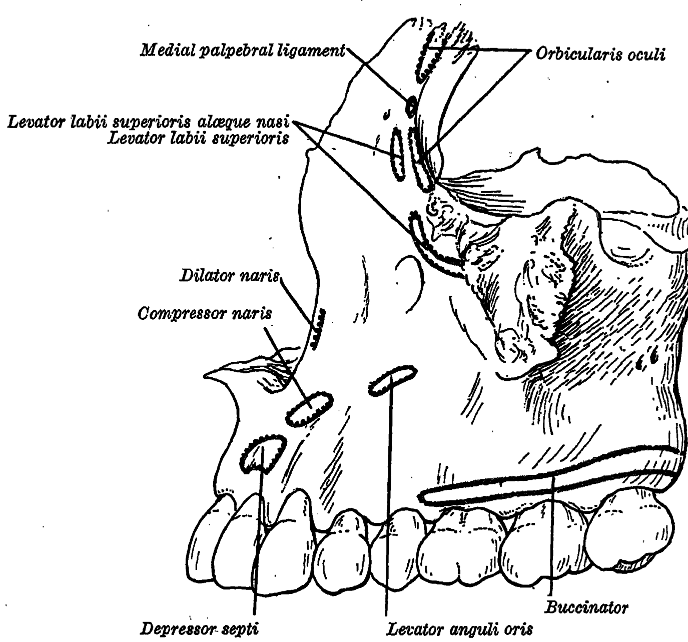
The *anterior surface* (fig. 380) is directed forwards and laterally. Its lower part displays a number of slight elevations, which correspond to the positions of the roots of the upper teeth. Above those of the incisor teeth there is a slight depression, named the *incisive fossa*, which gives origin to the depressor septi; to the alveolar border below the fossa a slip of the orbicularis oris is attached; above and lateral to the fossa, the compressor naris muscle arises. Lateral to the incisive fossa there is a larger and deeper depression, named the *canine fossa*; it is separated from the incisive fossa by the *canine eminence*, which corresponds to the socket of the canine tooth; the fossa gives origin to the levator anguli oris (caninus) muscle. Above the canine fossa the *infra-orbital foramen* marks the anterior end of the infra-orbital canal; it transmits the infra-orbital vessels and nerve. Above the foramen a sharp border marks the junction of the anterior and orbital surfaces. This border forms a small part of the circumference of the orbital opening, and gives origin to the levator labii superioris (infra-orbital head of the quadratus labii superioris). On the medial side, the anterior surface is limited by a deep concavity, termed the *nasal notch*; the margin of the notch gives attachment to the dilator naris and ends below in a pointed process which, with the corresponding process of the opposite maxilla, forms the *anterior nasal spine*.

The *posterior surface* (*infratemporal surface*) (fig. 380) is convex, directed backwards and laterally, and forms the anterior wall of the infratemporal fossa. It is separated from the anterior surface by the zygomatic process and by a ridge which runs upwards to that process from the socket of the first molar tooth. It presents near its centre the apertures of

two or three *dental canals*, which transmit the posterior superior dental vessels and nerves. At the lower part of this surface there is a round eminence, termed the *maxillary tuberosity*, which is rough for articulation with the tubercle (pyramidal process) of the palatine bone (fig. 380); it gives origin to a few fibres of the medial pterygoid muscle and, in some cases, articulates with the lateral pterygoid plate of the sphenoid bone. Above this a smooth surface forms the anterior boundary of the pterygopalatine fossa and is grooved for the maxillary nerve; the groove for this nerve is directed laterally and slightly upwards and is continuous with the infra-orbital groove on the orbital surface.

The *orbital surface* (fig. 380) is smooth and triangular, and forms the greater part of the floor of the orbit. Its *medial border* presents anteriorly a notch, termed the *lacrimal notch*, behind which it articulates from before backwards with the lacrimal bone, the orbital plate of the ethmoid, and the orbital process of the palatine bone (fig. 383). Its *posterior border* is smooth and rounded; it forms the greater part of the anterior margin of the inferior orbital fissure, and its middle part is notched by the commencement of the infra-orbital

FIG. 381.—Outline of left maxilla, showing muscular attachments.



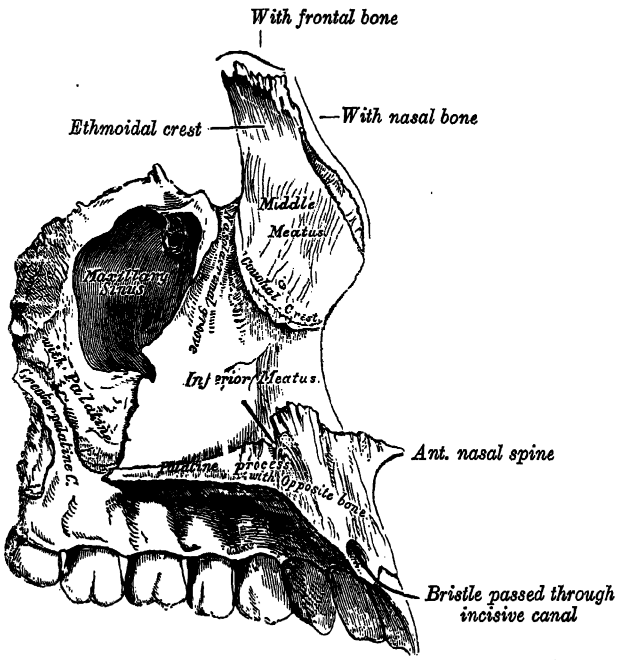
groove. The *anterior border* forms a small part of the circumference of the orbital opening and is continuous medially with the lacrimal crest on the frontal process (p. 314). The *infra-orbital groove*, for the passage of the infra-orbital vessels and nerve, begins at the middle of the posterior border, where it is continuous with the groove near the upper edge of the posterior surface; it passes forwards and ends in the *infra-orbital canal*, which opens on the anterior surface of the bone just below the infra-orbital margin. At the medial and front part of the orbital surface, and lateral to the lacrimal groove, the origin of the inferior oblique muscle of the eyeball may be marked by a small depression.

The *nasal surface* (fig. 382) presents in its upper and posterior part a large, irregular opening, termed the *maxillary hiatus*, which leads into the maxillary sinus. At the upper border of this aperture there are some broken air-sinuses, which, in the articulated skull, are closed by the ethmoid and lacrimal bones. Below the maxillary hiatus a smooth concave surface forms part of the inferior meatus of the nasal cavity, and behind it there is a rough surface for articulation with the perpendicular plate of the palatine bone; this rough surface is traversed by a groove, which begins near the middle of the posterior border, runs obliquely downwards and forwards, and is converted into the *greater palatine canal* (*pterygopalatine canal*) by the perpendicular plate of the palatine bone. In front of the maxillary hiatus a deep groove, which is continuous above with the lacrimal groove (p. 312), constitutes about two-thirds of the circumference of the nasolacrimal canal, the remaining one-third being formed by the descending part of the lacrimal bone and the lacrimal process of the inferior nasal concha (fig. 372); this canal opens into the inferior meatus of the nose (fig. 368) and transmits the nasolacrimal duct. More anteriorly the bone is marked by an oblique ridge, termed the *conchal crest*, for articulation with the inferior nasal concha.

The shallow concavity below this ridge forms part of the inferior meatus of the nose, and the surface above the ridge part of the atrium of the middle meatus.

The **maxillary sinus** (figs. 382, 383) is a large pyramidal cavity within the body of the maxilla. Its walls are thin and correspond to the nasal, orbital, anterior, and posterior surfaces of the body of the bone. Its *apex*, which is directed laterally, is formed by the zygomatic process; its *base*, or nasal wall, which faces medially, is formed by the lateral wall of the nose and presents the maxillary hiatus in the disarticulated bone. In the articulated skull this aperture is much reduced in size by the following bones: the uncinate process of the ethmoid and the descending part of the lacrimal bone above, the maxillary process of the inferior nasal concha below, and the perpendicular plate of the palatine bone behind (figs. 368, 383). The maxillary sinus communicates with the middle meatus of the nose, generally by two small apertures, one of which is usually closed by mucous membrane in the recent state. The *posterior wall* is pierced by the *dental canals*, which transmit the posterior superior dental vessels and nerves to the molar teeth; these canals occasionally project ridges into the maxillary sinus. The floor is formed by the alveolar

FIG. 382.—The left maxilla. Medial aspect.



process of the maxilla, and its lowest part is usually about 1·25 cm. below the level of the floor of the nasal cavity. In a large proportion of bones radiating septa of varying sizes spring from the floor of the sinus in the intervals between adjacent teeth; in some cases the floor is perforated by the fangs of the molar teeth.* The infra-orbital canal usually projects into the sinus a well-marked ridge extending from the *roof* to the *anterior wall*. The size of the cavity varies in different skulls, and even on the two sides of the same skull.† (Pl. I.)

Applied Anatomy.—The extreme thinness of the walls of this cavity affords an explanation of the fact that a tumour growing from the maxillary sinus and encroaching upon the adjacent parts may push up the floor of the orbit, and displace the eyeball; may project into the nose; may protrude forwards on to the cheek; or may make its way backwards into the infratemporal fossa, or downwards into the mouth.

The **zygomatic process** of the maxilla is a rough, pyramidal eminence, situated at the angle of separation of the anterior, posterior and orbital surfaces. *In front* it forms part

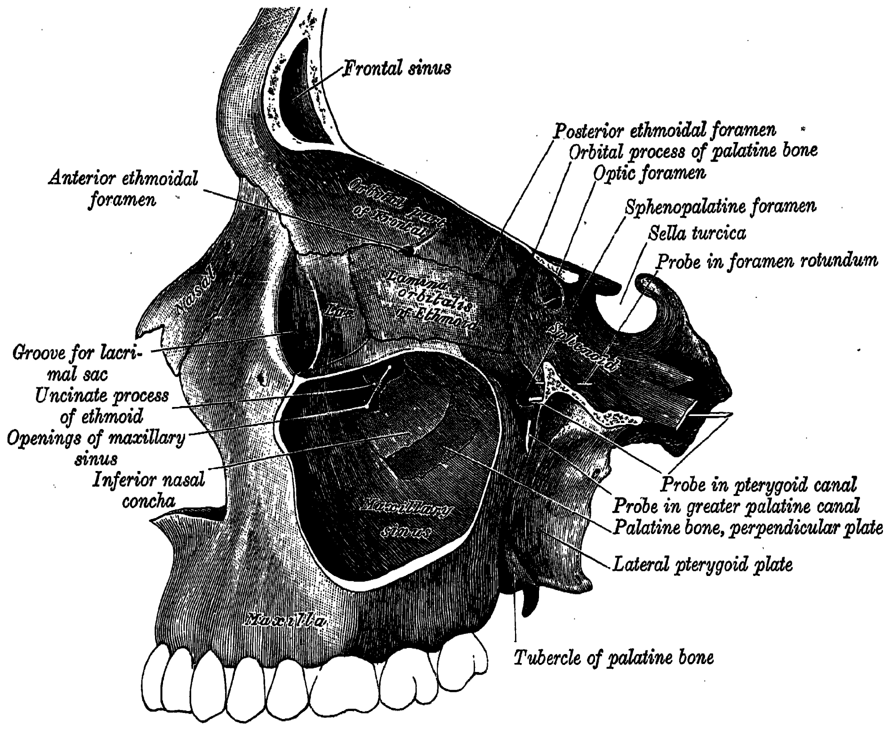
* The number of teeth whose roots are in relation with the floor of the maxillary sinus is variable. The sinus may extend so as to be in relation to all the teeth of the true maxilla, from the canine to the third molar.—(Salter.)

† Logan Turner (*op. cit.*) gives the following measurements for an adult sinus of average size: vertical height opposite first molar tooth, 3·5 cm.; transverse breadth, 2·5 cm.; and anteroposterior depth, 3·2 cm.

of the anterior surface of the body of the bone; *behind*, it is concave, and continuous with the posterior surface; *above*, it is rough and serrated for articulation with the zygomatic bone; *below*, it presents a prominent arched border, which separates the anterior from the posterior surface.

The **frontal process** of the maxilla projects upwards and backwards between the nasal and lacrimal bones (figs. 330, 383). Its *lateral surface* (fig. 380) is divided by a vertical ridge, termed the *lacrimal crest*, which gives attachment to the medial palpebral ligament and is continuous below with the infra-orbital margin. At the junction of the crest with the orbital surface there is a small tubercle, which serves as a guide to the position of the lacrimal sac. The part in front of the lacrimal crest is smooth and merges below with the anterior surface of the body; it gives attachment to a portion of the orbicularis oculi and to the levator labii superioris alæque nasi (angular head of the quadratus labii superioris). Behind the lacrimal crest there is a vertical groove which assists the groove on the lacrimal bone to complete the *lacrimal groove* for the lodgement of the lacrimal sac.

FIG. 383.—The left maxillary sinus. Opened from the lateral side.



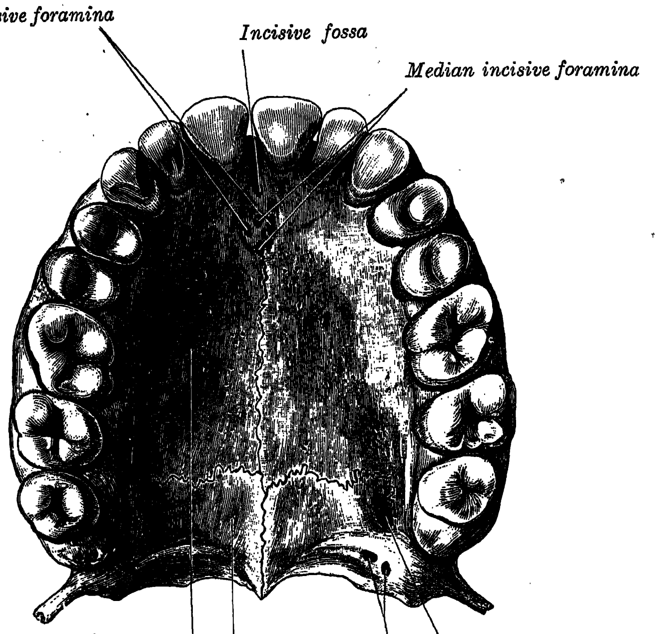
The *medial surface* of the frontal process (fig. 382) forms a portion of the lateral wall of the nasal cavity. A rough, uneven area at its upper part articulates with the ethmoid bone and closes the anterior ethmoidal sinuses. Below this rough area there is an oblique ridge, termed the *ethmoidal crest*, the posterior part of which articulates with the middle nasal concha, while the anterior part is termed the *agger nasi*; the ethmoidal crest forms the upper limit of the atrium of the middle meatus of the nose. The *upper end* of the frontal process articulates with the nasal notch of the frontal bone, the *anterior border* with the nasal bone, and the *posterior border* with the lacrimal bone.

The **alveolar process** of the maxilla is thick and arched, broader behind than in front, and excavated to form sockets (alveoli) for the reception of the roots of the teeth. These cavities are eight in number and vary in size and depth according to the teeth they contain. That for the canine tooth is the deepest; those for the molars are the widest, and are subdivided into three minor sockets by septa; those for the incisors and the second premolar are single; that for the first premolar is sometimes divided into two. The buccinator muscle arises from the outer surface of this process, as far forward as the first molar tooth. When the maxillæ are articulated with each other, their alveolar processes together form the *alveolar arch*.

The **palatine process** of the maxilla, which is thick and strong, is horizontal and projects medially from the lowest part of the nasal surface of the bone. It forms a considerable part of the floor of the nasal cavity and the roof of the mouth, and is much thicker in front than

behind. Its *inferior surface* (fig. 384) is concave, rough and uneven, and forms, with the palatine process of the opposite bone, the anterior three-fourths of the bony palate. It is marked by numerous foramina for the passage of the nutrient vessels and presents depressions for the lodgement of the palatine glands; it is channelled at the posterior part of its lateral border by two grooves, which lodge the greater palatine vessels and nerve (descending palatine vessels and the anterior palatine nerve). When the two maxillæ are articulated, a funnel-shape depression, termed the *incisive fossa* (incisive foramen), is seen in the median plane, immediately behind the incisor teeth. In this opening the orifices of two lateral canals are visible: they are named the *incisive canals*; each leads upwards into the corresponding half of the nasal cavity and transmits the terminal branch of the greater palatine artery and the long sphenopalatine nerve. Occasionally there are two additional apertures in the median plane; they are termed the *anterior* and *posterior incisive foramina*, and, when present, transmit the long sphenopalatine nerves, the left passing through the anterior, and the right through the posterior foramen. On the under surface of the palatine process, a delicate

FIG. 384.—The bony palate and the alveolar arch. Inferior aspect.



suture, well seen in young skulls, may sometimes be noticed extending laterally and forwards from the incisive fossa to the interval between the lateral incisor and the canine teeth. The small part in front of this suture constitutes the *os incisivum* (premaxilla), which in most vertebrates forms an independent bone: it includes the whole thickness of the alveolus, the corresponding part of the floor of the nose and the anterior nasal spine, and contains the sockets of the incisor teeth. The *upper surface* of the palatine process is concave from side to side, smooth, and forms the greater part of the floor of the nasal cavity; close to the anterior part of its medial margin the bone is pierced by the upper orifice of the incisive canal. The *lateral border* of the process is fused with the rest of the bone. The *medial border*, thicker in front than behind, is raised into a ridge, termed the *nasal crest*, which, with the corresponding ridge of the opposite bone, forms a groove for the reception of the vomer. The front part of this ridge rises to a considerable height and is sometimes named the *incisor crest* (fig. 382); it is prolonged forwards into a sharp process, which, with the similar process of the opposite bone, forms the *anterior nasal spine*. The *posterior border* is serrated for articulation with the horizontal plate of the palatine bone.

Ossification.—The maxilla is developed mainly in membrane. Mall * and Fawcett † have

* *American Journal of Anatomy*, vol. v. 1906.

† *Journal of Anatomy and Physiology*, vol. xlv. 1911.

shown that it is ossified from two principal centres, one for the maxilla proper and one for the os incisivum (premaxilla). These centres appear about the end of the sixth week of intrauterine life, that for the maxilla proper above the canine tooth-germ, and that for the os incisivum above the incisor tooth-germs; the latter centre grows upwards and forms the anterior part of the frontal process. These two centres unite at the end of the second or early in the third month, but the suture between them (fig. 386) may persist on the palate until nearly middle life. At a later stage an additional centre (*prevomerine* or *paraseptal centre*) appears for the os incisivum on the medial side of the corresponding paraseptal cartilage. The maxillary sinus appears as a shallow groove (fig. 387) on the nasal surface

Fig. 385.—The right maxilla at birth. Lateral aspect.

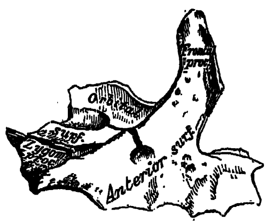


Fig. 386.—The right maxilla at birth. Inferior aspect.

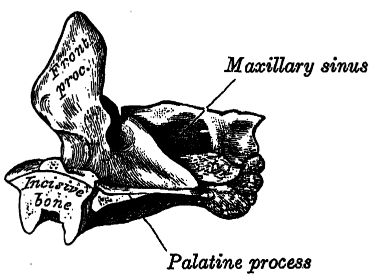
Fig. 387.—The right maxilla at birth. Medial aspect.



of the bone about the fourth month of intrauterine life, but does not reach its full size until after the second dentition. The infra-orbital vessels and nerve lie for a time in an open groove in the floor of the orbit; the anterior part of this groove is converted into the infra-orbital canal by a lamina of bone which grows from the lateral side of the groove.

Changes produced in the Maxilla by Age

At birth the transverse and anteroposterior diameters of the maxilla are each greater than the vertical. The frontal process is well-marked, but the body of the bone consists of little more than the alveolar process, the tooth-sockets reaching almost to the floor of the orbit. The maxillary sinus is seen as a furrow on the lateral wall of the nose. In the adult the vertical diameter is the greatest, owing to the development of the alveolar process and the increase in size of the sinus. In old age the bone reverts in some measure to the infantile condition: its height is diminished and, after the loss of the teeth, the alveolar process is absorbed (p. 282), and the lower part of the bone contracted and reduced in thickness.*

The Palatine Bones (Ossa Palatina)

The **palatine bones** are situated at the posterior part of the nasal cavity, between the maxillæ and the pterygoid processes of the sphenoid bone (fig. 368). Each assists in forming the floor and lateral wall of the nasal cavity, the roof of the mouth, and the floor of the orbit, and enters into the formation of the pterygopalatine and pterygoid fossæ and the inferior orbital fissure.

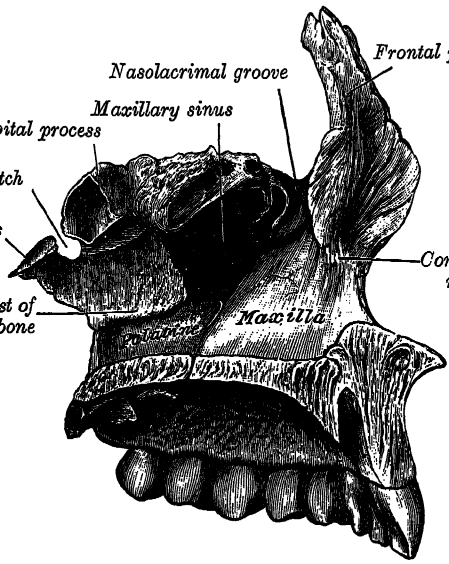
The palatine bone bears some resemblance to the letter L, and consists of a horizontal and a perpendicular plate, and three processes—viz. the tubercle (pyramidal process), which

* See references in footnote on p. 282.

is directed backwards, laterally and downwards from the junction of the horizontal and perpendicular plate, and the orbital and sphenoidal processes, which surmount the perpendicular plate and are separated by a deep notch, named the sphenopalatine notch.

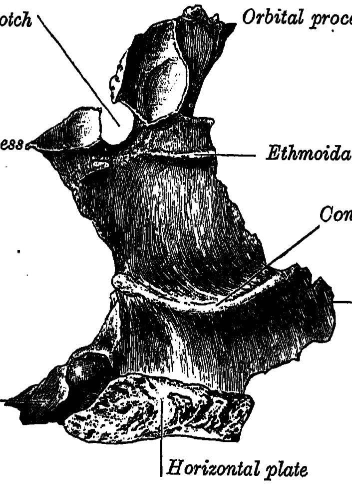
The **horizontal plate** of the palatine bone (figs. 384, 389) is quadrilateral and has two surfaces and four borders. The *nasal surface*, concave from side to side, forms the posterior

FIG. 388.—The articulation of the left palatine bone with the left maxilla.



part of the floor of the nasal cavity. The *palatine surface* forms, with the corresponding surface of the opposite bone, the posterior one-fourth of the bony palate; near its posterior margin there is a curved ridge, termed the *palatine crest*. The *posterior border* is thin and concave; to it, and to the palatine surface as far forwards as the palatine crest, the expanded

FIG. 389.—The left palatine bone. Medial aspect. (Enlarged.)



tendon of the tensor palati is attached. The medial end of the posterior border is pointed and, when united with that of the opposite bone, forms a projecting process, which gives attachment to the musculus uvulæ, and is named the *posterior nasal spine*. The *anterior border* is serrated and articulates with the palatine process of the maxilla. The *lateral border* is united with the inferior border of the perpendicular plate and is grooved by the lower end

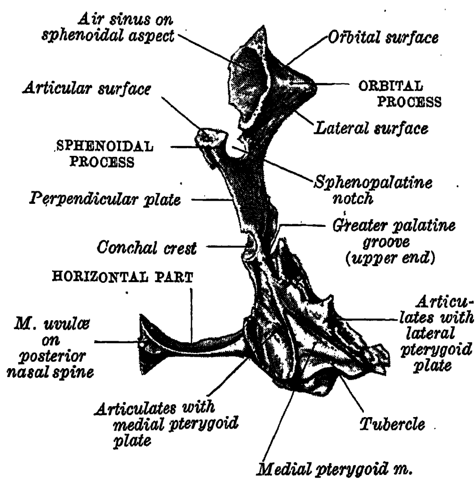
of the greater palatine groove (pterygopalatine sulcus). The *medial border*, which is thick and serrated, articulates with the corresponding border of the opposite bone, and the opposed borders form the *nasal crest*. This crest articulates with the posterior part of the lower edge of the vomer and is continuous anteriorly with the nasal crest of the maxillæ.

The **perpendicular plate** of the palatine bone (figs. 389, 390) is thin and of an oblong form, and has two surfaces and four borders.

The *nasal surface* exhibits at its lower part a broad, shallow depression which forms part of the inferior meatus of the nasal cavity. Immediately above this the *conchal crest* forms a horizontal ridge for articulation with the inferior nasal concha; still higher there is a second broad, shallow depression, which forms part of the middle meatus and is limited above by the *ethmoidal crest* for articulation with the middle nasal concha. Above the ethmoidal crest there is a narrow, horizontal groove, which forms part of the superior meatus.

The *maxillary surface* is rough and irregular throughout the greater part of its extent, for articulation with the nasal surface of the maxilla; its upper and posterior part is smooth and forms the medial wall of the pterygopalatine fossa; its front portion, which is also smooth, projects beyond the posterior border of the maxillary hiatus and forms the posterior part of the medial wall of the maxillary sinus (fig. 383). On the posterior part of the maxillary surface there is a deep vertical groove, named the *greater palatine groove* (*pterygopalatine sulcus*), which in the articulated skull is converted into the *greater palatine canal* (*pterygopalatine canal*) by the maxilla; this canal transmits the greater palatine (descending palatine) vessels and nerves.

Fig. 390.—The right palatine bone. Posterior aspect.



The *anterior border* is thin and irregular; at the level of the conchal crest a pointed, projecting lamina is directed forwards below and behind the maxillary process of the inferior nasal concha. It articulates with the latter and assists in forming the medial wall of the maxillary sinus (fig. 383). The *posterior border* (fig. 390) is serrated for articulation with the medial pterygoid plate of the sphenoid bone. This border is continuous above with the sphenoidal process; it expands below into the tubercle (pyramidal process) of the palatine bone. The *superior border* supports the orbital process in front and the sphenoidal process behind. These processes are separated by the *sphenopalatine notch*, which is converted into the *sphenopalatine foramen* by the under surface of the body of the sphenoid. In the articulated skull this foramen leads from the pterygopalatine fossa into the posterior part of the superior meatus of the nose, and transmits the sphenopalatine vessels and nerves. The *inferior border* is fused with the lateral border of the horizontal plate and, in front of the tubercle (pyramidal process), is marked by the lower end of the greater palatine groove.

The **tubercle (pyramidal process)** of the palatine bone projects backwards, laterally, and downwards from the junction of the horizontal and perpendicular plates of the bone, and fits into the angular interval between the lower ends of the pterygoid plates. On its *posterior surface* there is a smooth, grooved, triangular area, limited on each side by a rough articular furrow. The furrows articulate with the pterygoid plates, while the grooved triangular area completes the lower part of the pterygoid fossa and gives origin to some fibres of the medial pterygoid muscle. The anterior part of the *lateral surface* is rough for articulation with the maxillary tuberosity; the posterior part consists of a smooth triangular area, which appears, in the articulated skull, at the lower part of the infratemporal fossa between the maxillary tuberosity and the lateral pterygoid plate (fig. 317). The *inferior surface* of the tubercle, close to its union with the horizontal plate of the bone, presents the *lesser palatine foramina* for the transmission of the lesser (middle and posterior) palatine nerves (fig. 384).

The **orbital process** of the palatine bone (figs. 389, 390) is directed upwards and laterally from the front of the perpendicular plate, to which it is joined by a constricted neck. It encloses an air-sinus, and presents three articular and two non-articular surfaces. Of the articular surfaces: (1) the *anterior* or *maxillary*, of an oblong form, is directed forwards, laterally, and downwards, and articulates with the maxilla; (2) the *posterior* or *sphenoidal*,

directed backwards, upwards, and medially, presents the opening of the air-sinus, which usually communicates with the sphenoidal sinus; the margins of the opening articulate with the sphenoidal concha; (3) the *medial* or *ethmoidal* is directed medially and forwards, and articulates with the labyrinth of the ethmoid bone. In some cases, the air-sinus opens on this surface and then communicates with the posterior ethmoidal sinuses; more rarely it opens on the ethmoidal and sphenoidal surfaces, and then communicates with the posterior ethmoidal sinuses and the sphenoidal sinus. Of the non-articular surfaces: (1) the *superior* or *orbital*, triangular in shape, is directed upwards and laterally, and forms the posterior part of the floor of the orbit; and (2) the *lateral*, of an oblong form, is directed towards the pterygopalatine fossa and is separated from the orbital surface by a rounded border, which forms the medial part of the lower margin of the inferior orbital fissure; the lower part of this surface may present a groove, directed laterally and upwards, which lodges the maxillary nerve and is continuous with the groove on the upper part of the posterior surface of the maxilla (p. 317). The border between the lateral and posterior surfaces is prolonged downwards as the anterior boundary of the sphenopalatine notch.

The **sphenoidal process** of the palatine bone (figs. 389, 390) is a thin, compressed plate, smaller and on a lower level than the orbital process; it is directed upwards and medially. Its *superior surface* articulates with the under surface of the sphenoidal concha and the root of the medial pterygoid plate; it presents a groove which contributes to the formation of the palatinovaginal (pharyngeal) canal. The *inferomedial surface* is concave and forms a small part of the roof and lateral wall of the nasal cavity. The posterior part of the *lateral surface* articulates with the medial pterygoid plate; the anterior part is smooth and forms a portion of the medial wall of the pterygopalatine fossa. The *posterior border* is rough and articulates with the vaginal process of the medial pterygoid plate. The *anterior border* forms the posterior boundary of the sphenopalatine notch. The *medial border* articulates with the ala of the vomer.

The orbital and sphenoidal processes are separated from each other by the *sphenopalatine notch*, which is converted into the sphenopalatine foramen by the under surface of the body of the sphenoid; sometimes the two processes are united by a spicule of bone which converts the notch into a foramen.

Ossification.—The palatine bone is ossified in membrane from one centre, which appears during the eighth week of intrauterine life in the perpendicular plate of the bone. From this point ossification spreads upwards into the orbital and sphenoidal processes, medially into the horizontal plate, and downwards into the tubercle.

At the time of birth the height of the perpendicular plate is about equal to the transverse width of the horizontal plate, whereas in the adult it measures nearly twice as much.

The Zygomatic Bones [Ossa Zygomatica]

The **zygomatic bones** are situated in the upper and lateral parts of the face. Each forms the prominence of the cheek, and contributes to the formation of the lateral wall and floor of the orbit and to the walls of the temporal and infratemporal fossæ (fig. 391).

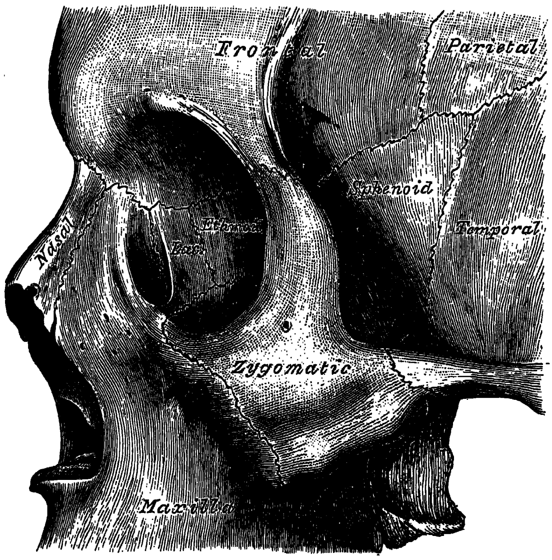
The zygomatic bone is quadrangular in shape, but has a flange-like projection from the anterior part of its medial aspect. It has three surfaces, five borders and two processes.

The *lateral surface* (figs. 391, 392), directed laterally and forwards, is convex and is pierced near its orbital border by the *zygomaticofacial foramen* (which is often double), for the passage of the zygomaticofacial nerve and vessels; below this foramen a slight elevation gives origin to the zygomaticus minor (zygomatic head of quadratus labii superioris), and more posteriorly the zygomaticus major (zygomaticus) takes origin. The *temporal surface* (fig. 393), which is directed medially and backwards, is concave. It presents anteriorly a roughened area for articulation with the maxilla, and posteriorly a smooth, concave area, which extends upwards on the posterior aspect of the frontal process to form the anterior boundary of the temporal fossa. It also extends backwards on the medial aspect of the temporal process to form an incomplete lateral wall for the infratemporal fossa. The *zygomaticotemporal foramen*, for the transmission of the nerve of the same name, pierces this surface near the base of the frontal process. The *orbital surface* (fig. 393), smooth and concave, forms the anterolateral part of the floor and the adjoining part of the lateral wall of the orbit, extending upwards on to the medial aspect of the frontal process. It usually presents the orifices of two canals, termed the *zygomatico-orbital foramina*, one of which leads to the zygomaticofacial and the other to the zygomaticotemporal foramen.

The *anterosuperior* or *orbital border* is smooth and concave, and forms a considerable part of the circumference of the orbital opening, below and on the lateral side. It separates the orbital from the lateral surface. The *antero-inferior* or *maxillary border* is rough and articulates with the maxilla; its medial extremity is pointed and lies above the infraorbital foramen: near the orbital margin it gives origin to a part of the levator labii

superioris. The *posterosuperior* or *temporal border* is curved like the italic letter *f*, and is continuous above with the posterior border of the frontal process and below with the upper border of the zygomatic arch; it gives attachment to the temporal fascia. A little below the frontozygomatic suture this border presents a small, rounded projection, termed the

FIG. 391.—The left zygomatic bone *in situ*.



marginal tubercle, which can be felt easily through the skin. The *postero-inferior* or *zygomatic border* affords attachment by its rough edge to the masseter muscle. The *posteromedial border* is serrated for articulation with the greater wing of the sphenoid above, and the orbital surface of the maxilla below. Between these two serrated portions there is usually a short, concave, nonarticular part, which forms the lateral boundary of the inferior orbital

FIG. 392.—The left zygomatic bone. Lateral aspect.

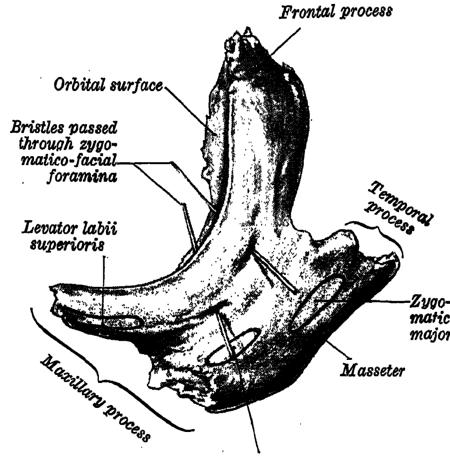


FIG. 393.—The left zygomatic bone. Medial aspect.

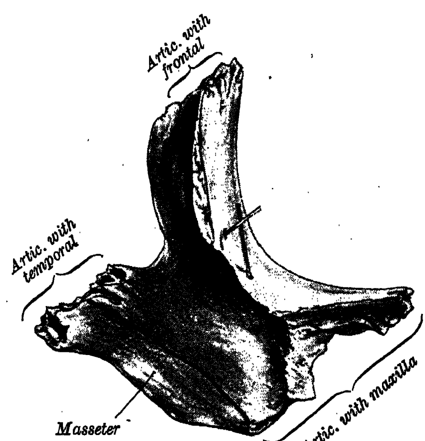


fissure. This non-articular part is sometimes absent, and the fissure is then completed by the junction of the maxilla and the sphenoid bone, or by the interposition of a small sutural bone in the angular interval between them.

The *frontal process* is thick and serrated; it articulates above with the zygomatic process of the frontal bone and behind with the greater wing of the sphenoid. On its orbital aspect, just within the orbital opening and about 11 mm. below the frontozygomatic suture, there

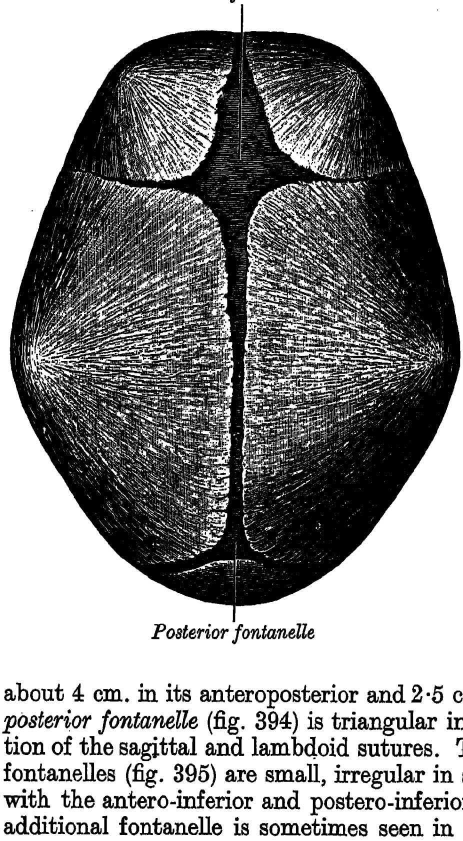
is a tubercle of varying size and form, but present in 95 per cent. of skulls (Whitnall).* The *temporal process* is directed backwards and ends in an oblique, serrated margin which articulates with the zygomatic process of the temporal bone, and helps to form the zygomatic arch.

Ossification.—The zygomatic bone is ossified from one centre, which appears about the eighth week of intrauterine life. The bone is sometimes divided by a horizontal suture into an upper larger, and a lower smaller division.

The Differences in the Skull due to Age

At birth the skull is large in proportion to the other parts of the skeleton, but the base is short and narrow in proportion to the vault; the facial portion is small and equals only about one-eighth of the size of the cranium as compared with one-half in the adult. The frontal and parietal eminences are prominent, and when the skull is viewed from above it presents a pentagonal outline with its greatest width at the parietal eminences (fig. 394); on the other hand, the glabella, superciliary arches, and mastoid processes are not developed. Ossification of the skull bones is not completed, and many of them—e.g. the occipital, temporals, sphenoid, frontal, and mandible—consist of more than one piece. Unossified membranous intervals, termed fontanelles (fonticuli), are seen at the angles of the parietal bones; these fontanelles are six in number; two, the anterior and posterior, are situated in the median plane, and two, the anterolateral and posterolateral, on each side.

Fig. 394.—The skull at birth, showing the anterior and posterior fontanelles. Superior aspect.



The *anterior fontanelle* (fig. 394) is the largest, and is placed at the junction of the sagittal, coronal, and frontal sutures; it is lozenge-shaped, and measures about 4 cm. in its anteroposterior and 2·5 cm. in its transverse diameter. The *posterior fontanelle* (fig. 394) is triangular in form and is situated at the junction of the sagittal and lambdoid sutures. The anterolateral and posterolateral fontanelles (fig. 395) are small, irregular in shape, and correspond respectively with the antero-inferior and postero-inferior angles of the parietal bones. An additional fontanelle is sometimes seen in the sagittal suture at the region of the obelion (p. 328).

The fontanelles are usually closed by the growth and extension of the bones which surround them, but sometimes they are the sites of separate centres of ossification which develop into sutural bones. The posterior and anterolateral fontanelles are obliterated within two or three months after birth; the posterolateral fontanelle is usually closed about the end of the first year, and the anterior fontanelle about the middle of the second year.

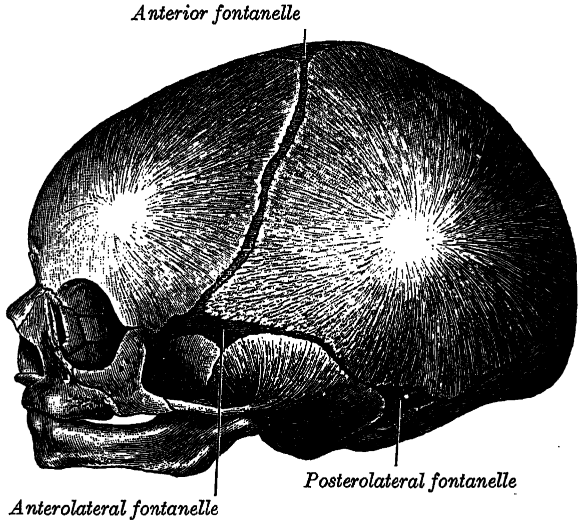
The smallness of the face at birth is mainly accounted for by the rudimentary condition of the mandible and maxillæ, the non-eruption of the teeth, and the

* S. E. Whitnall, *The Anatomy of the Human Orbit*, 1921.—The structures attached to this tubercle are: (1) the 'check ligament' of the rectus lateralis; (2) part of the aponeurosis of the levator palpebræ superioris; (3) the suspensory ligament of the eyeball; and (4) the lateral palpebral ligament.

small size of the maxillary sinuses and nasal cavity. At birth the nasal cavity lies almost entirely between the orbits, and the lower border of the anterior nasal aperture is only a little below the level of the orbital floor. With the eruption of the deciduous teeth there is an enlargement of the face and jaws, and these changes are still more marked after the second dentition.

The skull grows rapidly from birth to the seventh year, but the greater part of the increase of its cranial part occurs during the first year owing to the rapidity of the growth of the brain in that period (p. 123). Growth in length occurs at the coronal suture and at the other sutures which are parallel with it; growth in breadth, at the sagittal and parallel sutures; growth in height, at the parietotemporal and at the other sutures which lie in a transverse plane. Towards the end of the second year the mastoid process makes its appearance, and the tympanic ring lengthens to form the bony part of the external auditory meatus (p. 302). As a result the styloid process and the stylomastoid foramen, which are relatively superficial in the newly-born child, become more deeply

FIG. 395.—The skull at birth, showing the anterolateral and posterolateral fontanelles. Left lateral aspect.



situated. At the seventh year the cribriform plate of the ethmoid bone, the foramen magnum, and the petrous parts of the temporal bones have reached their full size, and the orbits are only a little smaller than those of the adult. Growth is slow from the seventh year until the approach of puberty, when a second period of increased activity occurs: this results in an enlargement in all directions, but especially in the frontal and facial regions, where it is associated with the development of the air-sinuses. The enlargement of the cranium is effected, in its latter stages, by absorption from the inner surface and by bone deposition on the outer surface. This process chiefly affects the bones of the vault and of the lateral aspects of the skull.

Obliteration of the sutures of the vault of the skull takes place as age advances. It may commence between the ages of thirty and forty on the inner surface, and about ten years later on the outer surface of the skull, but the times at which the sutures are closed are subject to great variations. Obliteration usually occurs first in the lower part of the coronal suture, next in the posterior part of the sagittal suture, and then in the lambdoid suture.

In old age the skull generally becomes thinner and lighter, but in a small proportion of cases it increases in thickness and weight. The most striking feature of the senile skull is the diminution in the size of the mandible and maxillæ consequent on the loss of the teeth and the absorption of the alveolar processes. This is associated with a marked reduction in the vertical measurement of the face and with an alteration in the angles of the mandible (p. 282).

The Sex Differences in the Skull

Until the age of puberty there is little difference between the skull of the female and that of the male. The skull of an adult female is as a rule lighter and smaller, and its capacity is about 10 per cent. less, than that of the male. Its walls are thinner and its muscular ridges less marked; the glabella, superciliary arches, and mastoid processes are less prominent, and the corresponding air-sinuses are small or rudimentary. The upper margin of the orbit is sharp, the forehead vertical, the frontal and parietal eminences prominent, and the vault somewhat flattened. The contour of the face is rounder, the facial bones are smoother, and the mandible and maxillæ and their contained teeth smaller. Speaking generally, more of the infantile characteristics are retained in the skull of the adult female than in that of the adult male. A well-marked male or female skull can easily be recognised as such, but in some skulls the respective characteristics are so indistinct that the determination of the sex may be difficult or impossible.*

Craniology

Skulls vary in size and shape, and the term craniology is applied to the study of these variations.

The *capacity* of the cranial cavity constitutes a good index of the size of the brain which it contained, and is most conveniently arrived at by filling the cavity with shot and measuring the contents in a graduated vessel. Skulls may be classified according to their capacities as follows:

1. *Microcephalic*, with a capacity of less than 1350 c.cm.—e.g. those of native Australians and Andaman Islanders.
2. *Mesocephalic*, with a capacity of from 1350 c.cm. to 1450 c.cm.—e.g. those of African negroes and Chinese.
3. *Megacephalic*, with a capacity of over 1450 c.cm.—e.g. those of Europeans, Japanese and Eskimos.

In comparing the shape of one skull with that of another it is necessary to adopt some definite position in which the skulls should be placed during the process of examination. They should be so placed that a line carried through the lower margin of the orbit and upper margin of the opening of the external auditory meatus is in the horizontal plane. The normæ of one skull can then be compared with those of another, and the differences in contour and surface-form noted. Further, it is necessary that the various linear measurements used to determine the shape of the skull should be made between definite and easily localised points on its surface. The principal points may be divided into two groups: (1) those in the median plane, and (2) those on either side of it (fig. 396).

The **points in the median plane** are the:

Pogonion. The most prominent point of the chin.

Alveolar point or *prosthion.* The central point of the anterior margin of the upper alveolar arch.

Akanthion. The tip of the anterior nasal spine.

Subnasal point. The middle of the lower border of the anterior nasal aperture, at the base of the anterior nasal spine.

Rhinion. The most prominent point of the internasal suture.

Nasion. The central point of the frontonasal suture.

Glabella. The point in the median plane at the level of the superciliary arches.

Ophryon. The point in the median plane of the forehead at the level where the temporal lines most nearly approach each other.

Bregma. The meeting point of the coronal and sagittal sutures.

Obelion. A point on the sagittal suture on a level with the parietal foramina.

Lambda. The point of junction of the sagittal and lambdoid sutures.

Occipital point. The point in the median plane of the occipital bone farthest from the glabella.

Inion. The most prominent point on the external occipital protuberance in the median plane.

Opisthion. The mid-point of the posterior margin of the foramen magnum.

Basion. The mid-point of the anterior margin of the foramen magnum.

* Some additional differences between the male and female skull are given by F. G. Parsons and Lucas Keene, *Journal of Anatomy*, vol. liv. 1919.

FIG. 1.—Radiograph of skull. Lateral view. Crosses are placed on the frontal, the maxillary and the sphenoidal sinuses. Behind the last-named, the hypophyseal fossa can be identified. The dense white area below and behind the fossa is due to the petrous part of the temporal bone.

FIG. 2.—Radiograph of adult skull. Frontal view. 1 =maxillary sinus ; 2 =frontal sinus. The arrow is directed towards the mastoid air-cells.

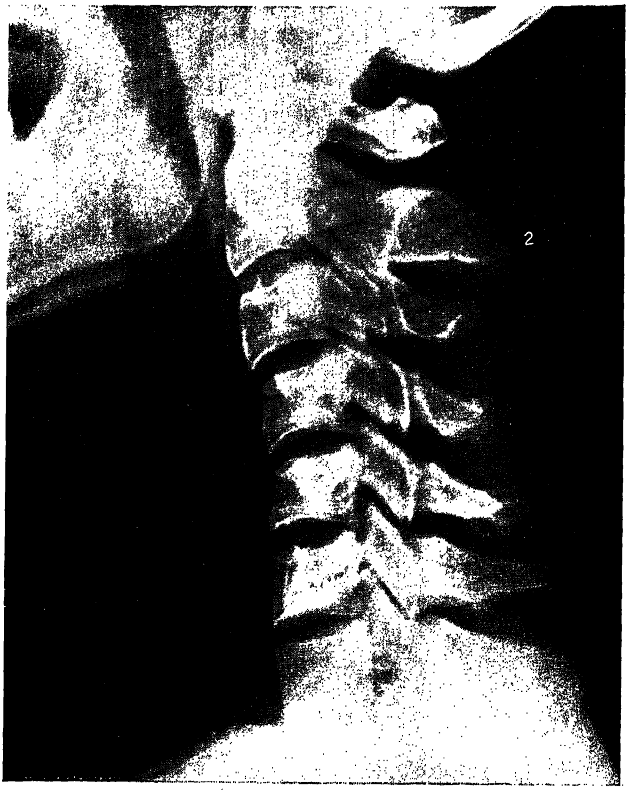


FIG. 1.—Radiograph of the cervical vertebræ. Lateral view. 1 = anterior arch of atlas; 2 = spine of axis. The curvature is abnormal.

FIG. 2.—Radiograph of the lumbar vertebræ, after intravenous injection of uroselectan, B. Anterior view. The ureters and their pelves, and the major and minor calyces are well shown. Note the cupping at the extremities of the minor calyces. Note also the relation of the ureter to the transverse processes and that the lateral edge of the left Psoas major muscle can be recognised. The arrow points to the shadow of the right kidney.

The points on each side of the median plane are the:

Gonion. The outer margin of the angle of the mandible.

Jugal point. The angle between the temporal border of the zygomatic bone and the upper border of the zygomatic arch.

Dacryon. The point of union of the anterosuperior angle of the lacrimal with the frontal bone and the frontal process of the maxilla.

Pterion. This point is the centre of the circular area of the same name (p. 251).

Stephanion. The point where the temporal line intersects the coronal suture.

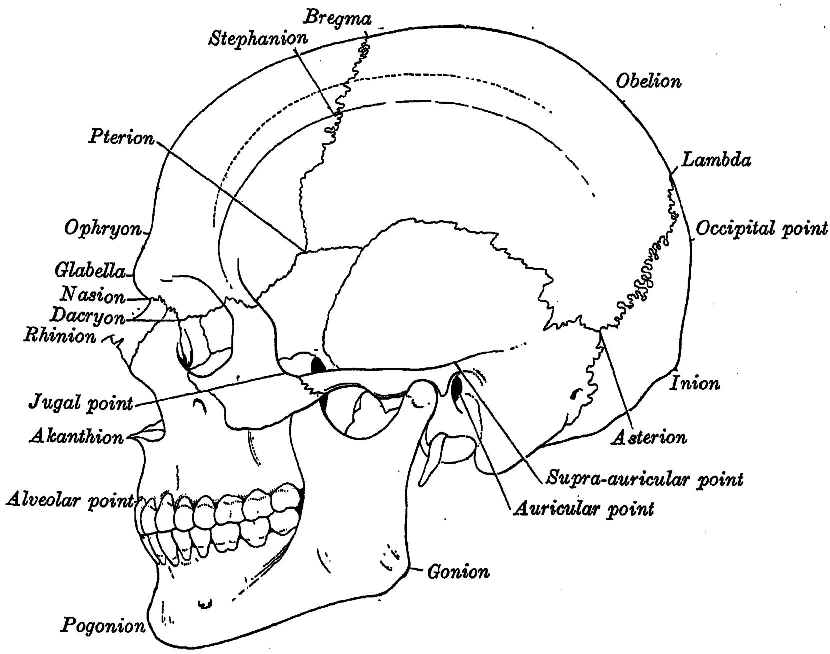
Auricular point. The centre of the orifice of the external auditory meatus.

Supra-auricular point. A point on the posterior root of the zygomatic arch, above the middle of the orifice of the external auditory meatus.

Asterion. The point of meeting of the lambdoid, occipitomastoid, and parietomastoid sutures.

The *horizontal circumference* of the cranium is measured in a plane passing through the glabella in front, and the occipital point behind; it averages about 50 cm. in the female and 52·5 cm. in the male.

FIG. 396.—An outline of the left side of the skull.



The *occipitofrontal* or *longitudinal arc* is measured from the nasion over the median plane of the vertex to the opisthion, while the basinasal length is the distance between the basion and the nasion. These two measurements, plus the anteroposterior diameter of the foramen magnum, represent the *vertical circumference* of the cranium.

The *length* is measured from the glabella to the occipital point, while the *breadth* or greatest transverse diameter is usually found a little above and behind the opening of the external auditory meatus. The proportion of breadth to length $\frac{\text{breadth} \times 100}{\text{length}}$ is termed the *cephalic index* or *index of breadth.*

The *height* is measured from the basion to the bregma, and the proportion of height to length $\frac{\text{height} \times 100}{\text{length}}$ constitutes the *vertical* or *height index.*

In studying the face the principal points to be noticed are the proportion of its length to its breadth, the shape of the orbits and of the anterior nasal aperture, and the degree of projection of the jaws.

The *length of the face* is measured from the nasion to the lower margin of the mandible, or, if the mandible be wanting, to the alveolar point; its *width* is the distance between the zygomatic arches. By comparing the length with the width of the face, skulls may be divided into two groups; *dolichofacial* (long-faced) and *brachyfacial* (short-faced).

The *orbital index* signifies the proportion which the orbital height bears to the orbital width, thus:

$$\frac{\text{orbital height} \times 100}{\text{orbital width}}$$

The *nasal index* expresses the proportion which the width of the anterior nasal aperture bears to the height of the nose, the latter being measured from the nasion to the subnasal point, thus:

$$\frac{\text{nasal width} \times 100}{\text{nasal height}}.$$

The degree of projection of the jaws is determined by the *gnathic* or *alveolar index*, which represents the proportion between the basi-alveolar and basinasal lengths, thus:

$$\frac{\text{basi-alveolar length} \times 100}{\text{basinasal length}}.$$

The *dental index* is arrived at by comparing the *dental length* (i.e. the distance between the anterior surface of the first premolar and the posterior surface of the third molar tooth of the maxilla) with the basinasal length, thus:

$$\frac{\text{dental length} \times 100}{\text{basinasal length}}.$$

The following table, modified from that given by Duckworth,* illustrates how some of these indices may be utilised in the classification of skulls:

INDEX.	CLASSIFICATION.	NOMENCLATURE.	EXAMPLES.
1. Cephalic .	Below 75 . . .	Dolichocephalic .	Kaffirs and Native Australians
	Between 75 and 80 .	Mesaticephalic .	Europeans and Chinese
	Above 80 . . .	Brachycephalic .	Mongolians and Andamans
2. Orbital .	Below 84 . . .	Microseme . .	Tasmanians and Native Australians
	Between 84 and 89 .	Mesoseme . .	Europeans
	Above 89 . . .	Megaseme . .	Chinese and Polynesians
3. Nasal .	Below 48 . . .	Leptorhine . .	Europeans
	Between 48 and 53 .	Mesorhine . .	Japanese and Chinese
	Above 53 . . .	Platyrhine . .	Negroes and Native Australians
4. Gnathic .	Below 98 . . .	Orthognathous .	Europeans
	Between 98 and 103 .	Mesognathous .	Chinese and Japanese
	Above 103 . . .	Prognathous .	Native Australians

Applied Anatomy.—The chief function of the skull is to protect the brain, and therefore those portions of the skull which are most exposed to external violence are thicker than those which are shielded from injury by overlying muscles. Thus, the skull-cap is thick and dense, whereas the squamous temporal, being protected by the temporal muscles, and the inferior occipital fossæ, being shielded by the muscles at the back of the neck, are thin and fragile. Additional features which tend to prevent fracture of the skull are its elasticity, its rounded shape, and its construction of a number of secondary elastic arches, each made up of a single bone. The manner in which vibrations are transmitted through the bones of the skull is also of importance as regards its protective mechanism, at all events as far as the base is concerned. In the vault, the bones being of a fairly equal thickness and density, vibrations are transmitted in a uniform manner in all directions, but in the base, owing to the varying thickness and density of the bones, this is not so; and therefore in this situation there are special buttresses which serve to carry the vibrations in certain definite directions. At the front of the skull, on each side, is the ridge which separates the anterior from the middle fossa of the base; and behind, the ridge or buttress which separates the middle from the posterior fossa; and if any violence is applied to the vault, the vibrations would be carried along these buttresses to the sella turcica, where they meet. This part has been termed the 'centre of resistance,' and here there is a special protective mechanism to guard the brain. The subarachnoid cavity at the base of the brain is dilated, and the cerebrospinal fluid which fills it acts as a water-cushion to shield the brain from injury. In like manner, when violence is applied to the base of the skull, as in falls upon the feet, the vibrations are carried backwards through the occipital crest, and forwards through the basilar part of the occipital and body of the sphenoid bone to the vault of the skull.

* W. L. H. Duckworth, *Morphology and Anthropology*, Cambridge University Press.

Fractures of the vault of the skull generally involve the whole thickness of the bone; but sometimes the inner table alone is fractured, and portions of it driven inwards. In fractures of the skull, and especially in punctured fractures, the inner table is more splintered and comminuted than the outer, and this is due to several causes. It is thinner and more brittle; the force of the violence as it passes inwards becomes broken up and is more diffused by the time it reaches the inner table; the bone being in the form of an arch bends as a whole and spreads out, and thus presses the particles together on the convex surface of the arch, i.e. the outer table, and forces them asunder on the concave surface or inner table; and, lastly, there is nothing firm under the inner table to support it and oppose the force.

The most common place for fracture of the base to occur is through the middle fossa, and here the fissure usually takes a fairly definite course. Starting from the point struck, which is generally somewhere in the neighbourhood of the parietal eminence, it runs downwards through the parietal and the squamous temporal and across the petrous portion, frequently traversing and implicating the internal auditory meatus, to the foramen lacerum. From this it may pass across the body of the sphenoid, through the sella turcica, to the foramen lacerum of the other side, and may indeed travel round the whole cranium so as to separate completely the anterior from the posterior part. The course of the fracture explains the symptoms to which fracture in this region may give rise: thus if the fissure passes across the internal auditory meatus injury to the facial and auditory nerves may result, with consequent facial paralysis and deafness; if the fissure extends through the semicircular ducts giddiness will be complained of, especially on turning the head sideways; or the tubular prolongation of the arachnoid around the nerves in the meatus may be torn and thus permit of the escape of the cerebrospinal fluid, should there be a communication between the internal ear and the tympanic cavity together with rupture of the tympanic membrane, as is frequently the case: again, if the fissure passes across the sella turcica, and the mucoperiosteum covering the under surface of the body of the sphenoid bone is torn, blood will find its way into the pharynx and be swallowed, and after a time vomiting of blood will result. Fractures of the anterior fossa, involving the bones forming the roof of the orbit and nasal cavity, are generally the result of blows on the forehead; but fracture of the cribriform plate of the ethmoid may be a complication of fracture of the nasal bone. When the fracture implicates the roof of the orbit, the blood finds its way into this cavity, and travelling forwards, appears as a subconjunctival ecchymosis. If the roof of the nasal cavity be fractured, the blood escapes from the nose. In rare cases there may be also escape of cerebrospinal fluid from the nose, should the dura mater and arachnoid have been torn.

The bones of the face are sometimes fractured as the result of direct violence. Those most commonly broken are the nasal bones and the mandible; the latter is by far the most frequently fractured of all the facial bones. Fracture of the *nasal bone* is for the most part transverse, and takes place about 1·25 cm. from the free margin. The broken portion may be displaced backwards or more generally to one side by the force which produced the lesion. The most common situation for a fracture of the *mandible* is in the neighbourhood of the canine tooth, as at this spot the bone is weakened by the deep socket for the root of this tooth; it is next most frequently fractured at the angle; then at the symphysis; and finally the neck of the mandible or the coronoid process may be broken. Occasionally a double fracture may occur, one in either half of the bone. The fractures are usually compound, from laceration of the mucous membrane covering the gums.

THE LIMBS

The upper and lower limbs are constructed after a common type, but the different functions for which they have become adapted in man have led to structural differences of a very definite kind. Each limb has a girdle, which connects it to the trunk, and three segments. The terminal segment in the upper limb is the hand and is specially adapted for prehension. In the lower limb the terminal segment is the foot and is primarly adapted to constitute an efficient supporting base for the body in the erect attitude, but it is, at the same time, constructed in such a manner as to facilitate locomotion (p. 516). In order that the full benefit of the prehensile character of the hand may be obtained, the living upper limb is characterised by the wide range of movement which it enjoys—in some situations, e.g. the shoulder-joint, actually at the expense of stability. In the living lower limb, on the other hand, the demand for stability is the prime factor, and stability is assured, even although some degree of mobility may be sacrificed for the purpose.

The bones by which the upper and lower limbs are attached to the trunk constitute, respectively, the shoulder and pelvic girdles. The *shoulder girdle*,

which is formed by the scapulæ and the clavicles, is deficient both in front and behind. In front, however, it is completed by the upper end of the sternum, with which the medial ends of the clavicles articulate. Behind, the scapulæ are separated from each other by a wide gap and are connected to the trunk by muscles only. The *pelvic girdle* is formed by the hip bones, which articulate with each other in front at the pubic symphysis so that the girdle is complete anteriorly. Posteriorly the girdle is incomplete, but the gap is filled by the upper part of the sacrum, with which the hip bones articulate. The pelvic girdle, with the sacrum, forms a complete ring, massive and comparatively rigid, in marked contrast with the lightness and mobility of the shoulder girdle.

THE BONES OF THE UPPER LIMB

THE SCAPULA (figs. 397, 398, 399)

General features.—The **scapula** is a large, flattened, triangular bone which lies on the posterolateral aspect of the chest wall, covering parts of the second to the seventh ribs. It presents for examination costal and dorsal surfaces, upper, lateral and medial borders, inferior, superior and lateral angles and three bony processes, viz., the spine, its continuation the acromion, and the coracoid process. The *lateral* angle is truncated and bears the glenoid cavity for articulation with the head of the humerus. This part of the bone may be regarded as the head, and it is connected to the plate-like body by an inconspicuous neck. The long axis of the scapula is nearly vertical and the relatively featureless *costal* surface can easily be distinguished from the *dorsal* surface, which is interrupted by the shelf-like projection of the spine (fig. 399). The bone is very much thickened in the immediate neighbourhood of the lateral border, which runs from the inferior angle *below*, to the glenoid cavity *above*. The student now possesses sufficient information to enable him to assign a given scapula correctly to its appropriate side of the body.

The *costal surface* (fig. 397), which is directed medially and forwards when the arm is by the side, is slightly hollowed out, especially in its upper part. Near the lateral border it presents a longitudinal, rounded ridge, stout and salient in the neighbourhood of the neck, but becoming less prominent below, which is separated from the lateral border by a narrow, grooved area. The *dorsal surface* (fig. 398) is divided into a smaller, upper area and a larger, lower area by a shelf-like projection, termed the *spine of the scapula.* These two areas communicate with each other through the *spinoglenoid notch,* which lies between the free, lateral border of the spine and the dorsal aspect of the neck of the bone. A flattened strip, for muscular attachments, marks the dorsal surface along the lateral border.

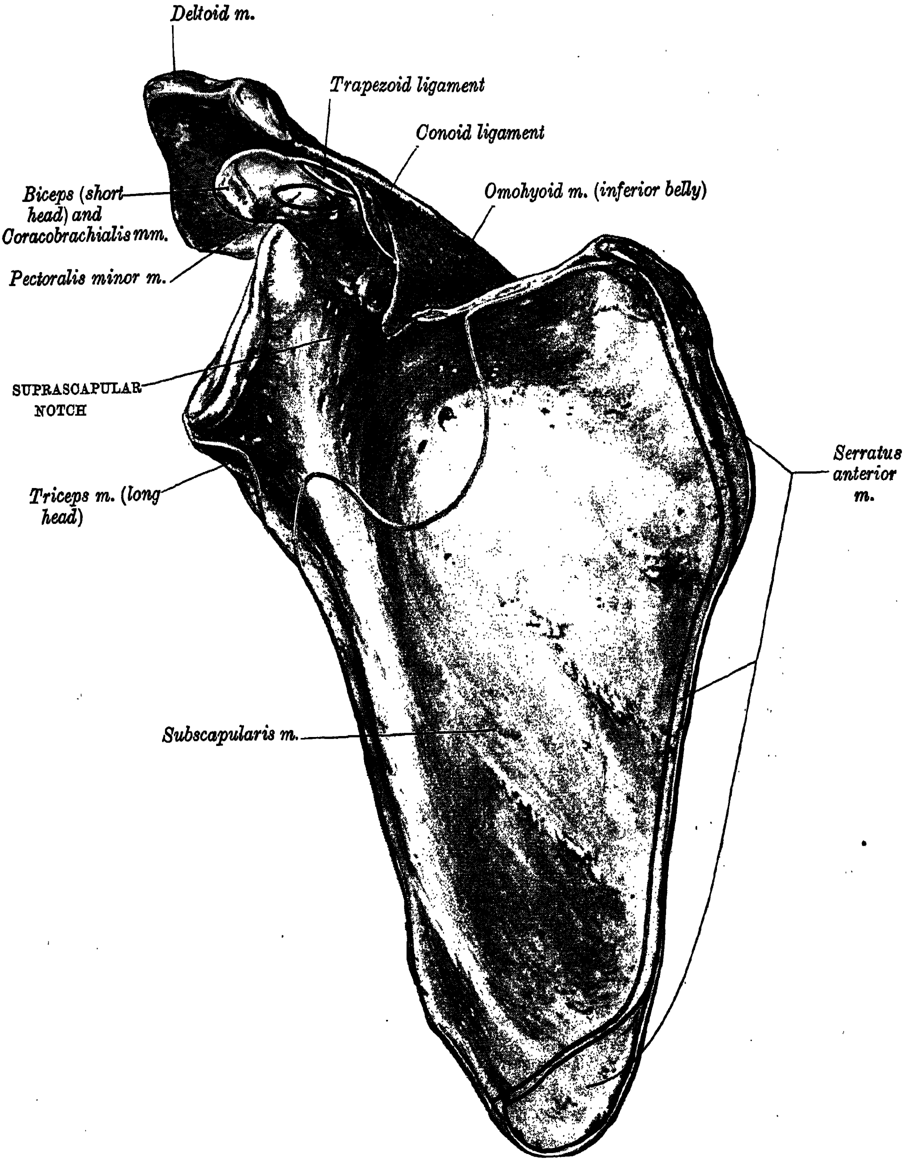
The *lateral border* (axillary border) of the scapula forms a sharp, roughened ridge,* which runs sinuously from the inferior angle to the glenoid cavity. At its upper end it widens into a rough, somewhat triangular, area, which is termed the *infraglenoid tubercle* (fig. 399). Throughout its whole length the lateral border is thickly covered with muscles and cannot be felt satisfactorily in the living subject. The *medial border* (vertebral border) of the scapula extends from the inferior to the superior angle. In its lower two-thirds this border can easily be felt through the skin, but its upper third is more deeply placed and cannot be palpated in the normal subject. The *superior border,* thin and sharp, is the shortest of the three borders. At its anterolateral end it is separated from the root of the coracoid process by the *suprascapular notch,* which is converted into a foramen by the suprascapular ligament.

The *inferior angle* lies over the seventh rib, or over the seventh intercostal space. It can be felt through the skin and the muscles which cover it and, when the arm is raised above the head, it can be seen to pass forwards round the chest wall. The *superior angle* is placed at the junction of the superior and medial

* The lateral border is often described as a thick border, but such a description includes in the border the grooved, lateral part of the costal surface and, frequently, the flattened strip along the lateral part of the dorsal surface. The actual border, however, is clearly defined on the bone as a narrow, roughened ridge (fig. 399).

borders, and is obscured by the muscles which cover it. The *lateral angle* is truncated and broadened. It constitutes the head of the bone. On its free surface it bears the *glenoid cavity* for articulation with the head of the humerus in the shoulder-joint. When the arm is by the side the glenoid cavity is directed forwards and laterally and slightly upwards. Very gently hollowed out, it forms a poor socket for the humeral head. It is narrow above and wider below, and is therefore

FIG. 397.—The right scapula. Costal aspect.



pear-shaped in outline. Immediately above the glenoid cavity a small roughened area encroaches on the root of the coracoid process and is termed the *supraglenoid tubercle*. The *neck* of the scapula is the constriction immediately adjoining the head. It can be identified most easily on its inferior and dorsal aspects. Ventrally, it can be regarded as extending between the infraglenoid tubercle and the anterior margin of the suprascapular notch.

The *spine of the scapula* (fig. 398) forms a shelf-like elevation on the upper part of the dorsal surface of the bone, and is triangular in shape. Its lateral border is

free, thick and rounded and helps to bound the *spinoglenoid notch*, which lies between it and the dorsal surface of the neck of the bone. Its anterior border joins the dorsal surface of the scapula along a line which runs laterally and slightly upwards from the junction of the upper and middle thirds of the medial border. It should be noted that the plate-like body of the bone is bent along this line, and this fact accounts for the concavity of the upper part of the costal surface. The third border is termed the *crest of the spine*, and is *subcutaneous throughout nearly its whole extent*. At its medial end the crest expands into a smooth, triangular area. Elsewhere the upper and lower edges and the surface of the crest are roughened for muscular attachments. The upper surface of the spine widens as it is traced laterally, and is slightly hollowed out. Together with the upper area of the dorsal surface of the bone, the upper surface of the spine forms the *supraspinous fossa*. The lower surface is overhung by the crest at its medial, narrow end, but is gently convex in its wider, lateral portion. Together with the lower area of the dorsal surface of the bone, the lower surface of the spine forms the *infraspinous fossa*, which communicates freely with the supraspinous fossa through the spinoglenoid notch. Both surfaces of the spine display large vascular foramina running towards the junction of the free, lateral border with the body of the bone.

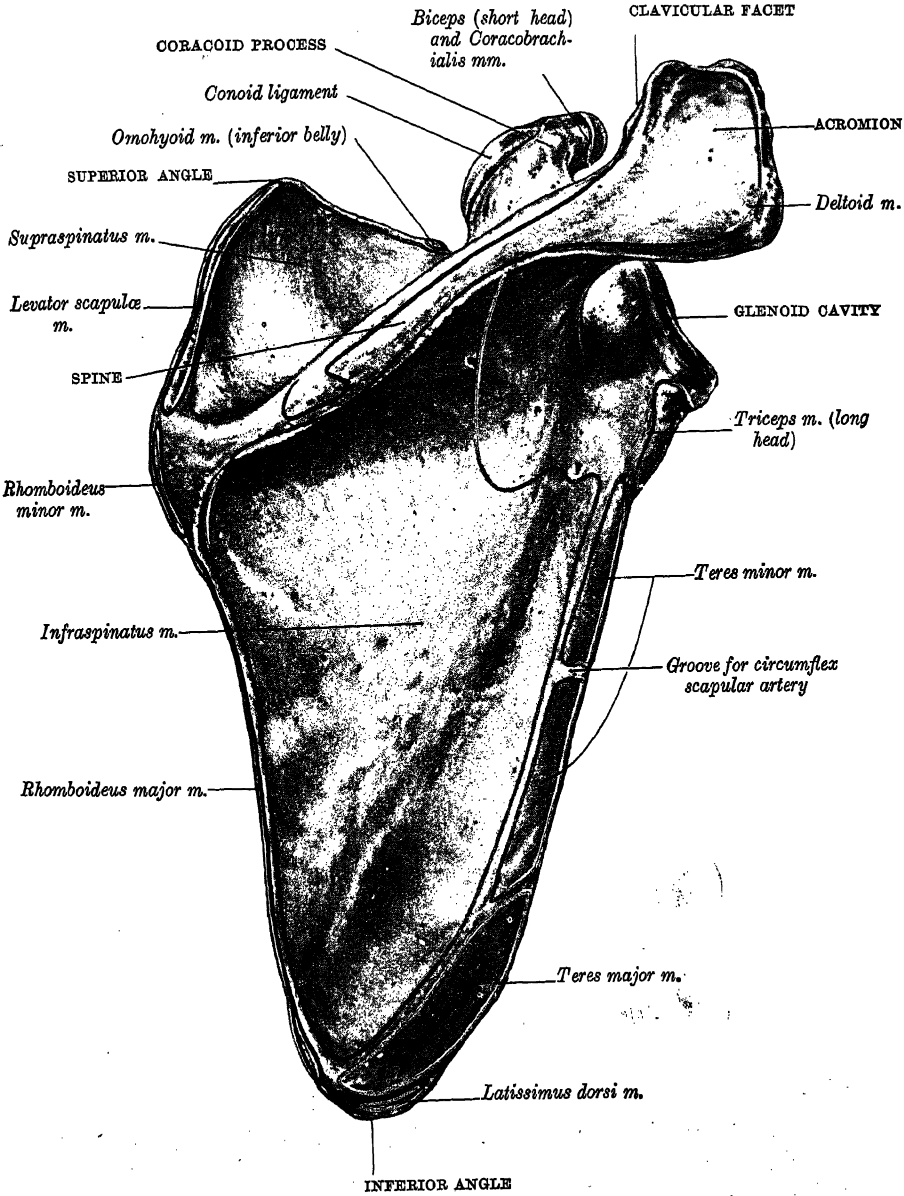
The *acromion* projects freely from the lateral end of the spine, with which it is continuous. Its long axis, however, does not coincide with that of the spine, but makes an angle with it of rather more than 90°. The lower border of the crest of the spine becomes continuous with the lateral border of the acromion at the *acromial angle*, which forms a subcutaneous, bony landmark. The medial border of the acromion is short and is marked anteriorly by a small, oval facet, directed upwards and medially, for articulation with the lateral end of the clavicle. The lateral border, tip and upper surface of the acromion can all be felt through the skin without difficulty. The *coracoid process* (fig. 397) springs from the upper border of the head of the scapula and is bent sharply so as to project forwards and slightly laterally. *When the arm is by the side, the coracoid process points almost straight forwards* and its slightly enlarged tip can be felt through the skin, although it is covered by the anterior fibres of the deltoid muscle. The supraglenoid tubercle marks the root of the coracoid process where it adjoins the upper part of the glenoid cavity. Another impression is placed on the dorsal aspect of the coracoid process at the point where it changes direction. This gives attachment to the conoid part of the coracoclavicular ligament, which will be mentioned again in connexion with the clavicle.

Particular features.—The *costal surface* gives origin to the subscapularis muscle (fig. 397), which arises from nearly the whole of this aspect including the grooved area immediately adjoining the lateral border and excluding the area adjoining the neck of the bone. Small intramuscular tendons are attached to the roughened ridges which subdivide this surface incompletely into a number of smooth areas. The anterior aspect of the neck is separated from the subscapularis muscle by a bursal protrusion of the synovial membrane of the shoulder-joint. Near the inferior angle a somewhat oval area gives insertion to the lower five or six digitations of the serratus anterior (fig. 397). The remainder of the muscle is inserted into a narrow strip along the ventral aspect of the medial border, which is wider above, where it receives the large first digitation. The rounded, longitudinal ridge near the lateral border corresponds to a localised thickening of the bone and provides a lever of the necessary strength to enable the serratus anterior to rotate the scapula forwards. In this movement the upper limb is raised from the side and carried above the head against the action of gravity, and it is this latter factor which calls for the provision of a substantial lever.

On the *dorsal surface*, the supraspinous fossa in its medial two-thirds gives origin to the supraspinatus, and its margins give attachment to the fascia which covers the muscle. The flattened strip adjoining the lateral border gives origin in its upper two-thirds to the teres minor muscle and is grooved, near its upper end, by the circumflex scapular vessels, which pass between the muscle and the bone as they enter the infraspinous fossa (fig. 398). The lower limit of the origin of the teres minor is indicated by an oblique ridge, which runs from the lateral border to the neighbourhood of the inferior angle and cuts off a somewhat oval area for the origin of the teres major muscle. The dorsal aspect of the inferior angle may give origin to a small slip which joins the deep surface of the latissimus dorsi. With the exception of an area near the neck of the bone, the rest of the infraspinous fossa, which is hollowed out laterally but convex medially, gives origin to the infraspinatus muscle. The strong infraspinatus fascia passes on to the teres minor and the teres major and sends fascial partitions between them to reach the bone along the ridges which mark the limits of their attachments.

The *lateral* (*axillary*) *border* separates the origin of the subscapularis from the origins of the teres minor and the teres major. These muscles project laterally beyond it, and together with the latissimus dorsi cover it so completely that it cannot be felt through the skin. The infraglenoid tubercle gives origin to the long head of the triceps muscle. The *medial* (*vertebral*) *border* is thin and often angled opposite the root of the spine. A narrow strip, extending from the superior angle to the root of the spine, gives insertion to the levator scapulæ muscle. Below this, and opposite the root of the spine, the rhomboideus minor

FIG. 398.—The right scapula. Dorsal aspect.



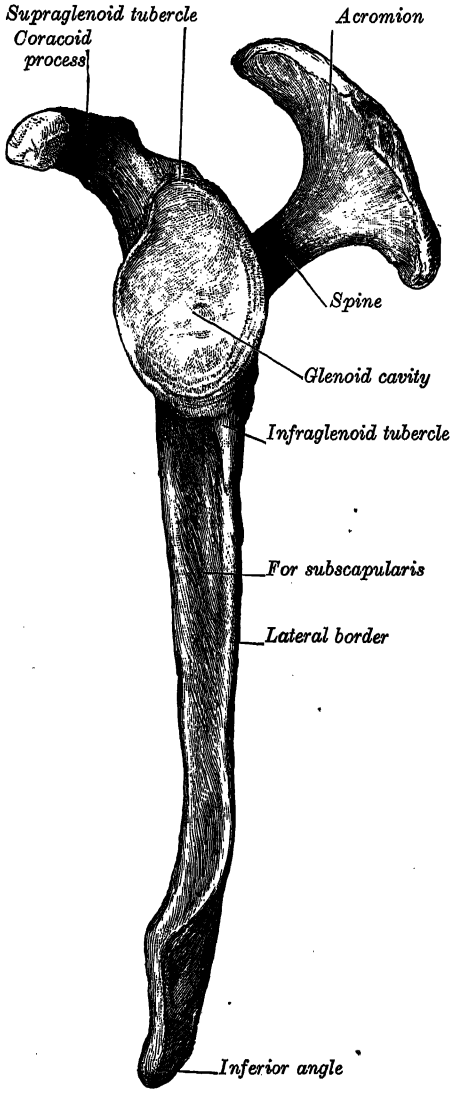
gains insertion. The remainder of the border provides insertion for the rhomboideus major, but the precise character of the insertion is unusual (p. 585). The attachment of the serratus anterior has been noted already (p. 334).

The *upper border* of the scapula is thin and sharp. Near the suprascapular notch it gives origin to the inferior belly of the omohyoid muscle, and the posterior limit of the notch gives attachment to the suprascapular ligament, which is sometimes ossified. The foramen

completed by the ligament transmits the suprascapular nerve to the supraspinous fossa, whereas the suprascapular (transverse scapular) vessels pass backwards above the ligament.

The *inferior angle* of the scapula is covered on its dorsal aspect by the upper border of the latissimus dorsi muscle, which frequently receives a small slip of origin from this part of the bone. The *superior angle* of the scapula is covered by the upper part of the trapezius muscle. The truncated *lateral angle* bears the *glenoid cavity*, the margins of which give attachment to the glenoidal labrum. Its surface is covered with a layer of hyaline articular cartilage, which is thinnest at the centre of the cavity and thickest at its periphery. Its anterior margin gives attachment to the glenohumeral ligaments (p. 457). When the arm is by the side the cavity is directed forwards, laterally and slightly upwards. When the arm is raised above the head it is directed almost straight upwards

FIG. 399.—The left scapula. Lateral aspect.



The *spine of the scapula* gives attachment by its upper and lower surfaces to the supra- and infraspinatus muscles, respectively. The flattened, triangular area at its root lies opposite the spine of the third thoracic vertebra and is covered by the tendon of the trapezius, a bursa intervening to enable the tendon to play over this part of the bone. The lower border of the crest gives origin to the posterior fibres of the deltoid muscle, which often produce an elongated tubercle in this situation. The upper border of the crest receives the insertion of the lower fibres of the trapezius, which often encroach on the dorsal or subcutaneous aspect of the crest, especially near the root of the spine.

The *acromion* is subcutaneous over its dorsal surface, being covered only by the skin and superficial fascia. The lateral border, which is thick and irregular, and the tip of the process, as far round as the clavicular facet, give origin to the middle fibres of the deltoid muscle. The medial aspect of the tip gives attachment, below the deltoid, to the lateral end of the coraco-acromial ligament. The articular capsule of the acromioclavicular joint is attached around the margins of the clavicular facet. Behind the facet, the medial border of the acromion gives insertion to the horizontal fibres of the trapezius muscle. The inferior aspect of the acromion is relatively smooth, and together with the coraco-acromial ligament and the coracoid process forms a protective arch over the shoulder-joint. The tendon of the supraspinatus passes below the overhanging acromion and is separated from it and from the deltoid muscle by the subacromial bursa.

The *coracoid process* lies below the clavicle at the junction of the lateral fourth with the rest of the bone and is connected to its under surface by the coraco-clavicular ligament. The attachment of the conoid part of the ligament has already been considered: the trapezoid part is attached to the upper aspect of the horizontal part of the process (fig. 397). The superior aspect of the process receives also the insertion of the pectoralis minor muscle. Its lateral border gives attachment to the wider, medial end of the coraco-acromial ligament and, below that, to the coracohumeral ligament. The enlarged tip of the process gives origin to the coracobrachialis, medially, and to the short head of the biceps, laterally. It is covered, in life, by the anterior fibres of the deltoid muscle and can be identified only on deep pressure through the lateral border of the infraclavicular fossa. It lies 2·5 cm. below the clavicle. The inferior aspect of the process is smooth and helps to complete the

coraco-acromial arch. The anterior aspect of the root is crossed by the tendon of the subscapularis, and its posterior aspect by the tendon of the supraspinatus muscle.

Structure.—The head, processes, and thickened parts of the scapula contain spongy substance; the rest consists of a thin layer of compact bone. The central part of the supraspinous fossa and the greater part of the infraspinous fossa are thin; occasionally the bone is wanting in these situations, the gaps being filled by fibrous tissue.

Ossification (fig. 400).—The scapula is ossified from eight or more centres: one for the body, two for the coracoid process, two for the acromion, one for the vertebral border, one for the inferior angle and one for the lower part of the rim of the glenoid cavity.

The centre for the body appears in the eighth week of intrauterine life, and spreads to form an irregular quadrilateral plate of bone, immediately behind the glenoid cavity. This

Fig. 400.—A plan of the ossification of the scapula.

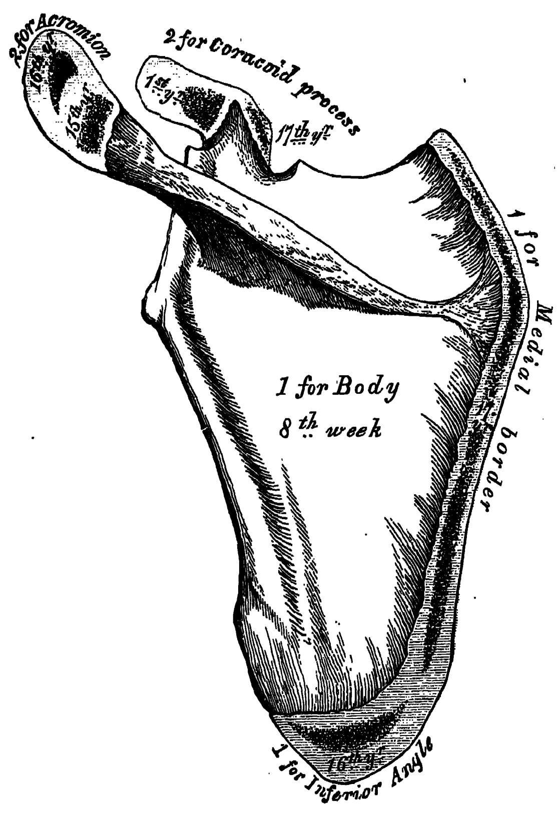


plate forms the chief part of the bone, and the spine grows backwards from it about the third month. At birth, the glenoid cavity, coracoid process, acromion, medial border, and inferior angle are cartilaginous. In the first year of life, ossification begins in the middle of the coracoid process, and this process joins the rest of the bone about the fifteenth year. Between the tenth and twentieth years ossification of the remaining parts takes place, usually in the following order: first, in the root of the coracoid process (subcoracoid centre); second, near the base of the acromion; third, in the inferior angle and contiguous part of the medial border; fourth, near the extremity of the acromion; fifth, in the medial border. The base of the acromion is formed by an extension from the spine; the rest of the acromion is ossified from two centres which unite, and then join the extension from the spine. The upper one-third of the glenoid cavity is ossified from the subcoracoid centre, which appears between the tenth and eleventh, and joins between the sixteenth and the eighteenth, years. Further, a horseshoe-shaped epiphyseal plate appears for the lower part of the glenoid cavity about puberty; thicker at its peripheral than at its central margin, it converts the flat glenoid fossa of the child into the gently concave fossa of the adult. The tip of the coracoid process frequently has a separate centre. These various epiphyses are joined to the bone by the twenty-fifth year.

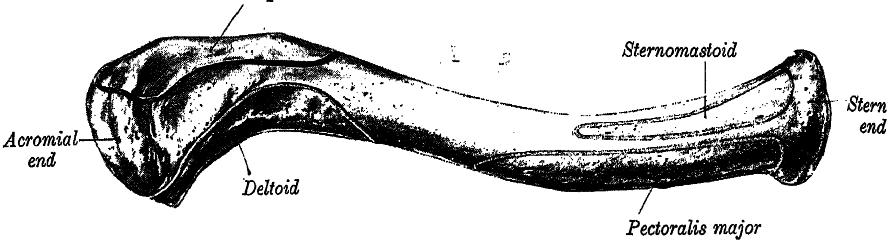
THE CLAVICLE (figs. 401, 402)

General features.—The **clavicle**, though a long bone, differs from the other long bones in the body in not possessing a medullary cavity. It lies almost horizontally at the root of the neck and is *subcutaneous throughout its whole extent*. Its most important functions are: (1) to act as a prop which braces back the shoulder and enables the limb to swing clear of the trunk: and (2) to transmit a part of the weight of the limb to the axial skeleton, in this way diminishing the muscular effort required for that purpose. The lateral or *acromial end* of the bone is flattened and articulates with the medial side of the acromion, whereas the medial or *sternal end* is enlarged and articulates with the clavicular notch of the manubrium sterni. The *shaft* is gently curved and in shape resembles the italic letter *f*, being convex *forwards* in its medial portion and concave forwards in its lateral portion. The *inferior* aspect of the intermediate third is grooved in its long axis. The student is now in a position to refer a given clavicle correctly to its appropriate side of the body.

For purposes of description it is convenient to divide the shaft into its lateral one-third, which is flattened, and its medial two-thirds, which are cylindrical or prismoid in form.

FIG. 401.—The right clavicle. Viewed from above.



The **lateral one-third** of the shaft of the clavicle has a superior and an inferior surface, limited by an anterior and a posterior border. The *anterior border* is concave, thin and roughened and may be marked by a small tubercle termed the *deltoid tubercle*. The *posterior border*, also roughened for muscular attachments, is convex backwards. The *superior surface* is flattened; it is roughened near its margins but is smooth centrally, where it can be felt through the skin. The *lower surface* presents two obvious markings. Close to the posterior border, at the junction of the lateral one-fourth with the rest of the bone, a prominent tubercle gives attachment to the conoid part of the coracoclavicular ligament and is termed the *conoid tubercle*. From the lateral side of this tubercle a narrow, roughened strip runs forwards and laterally, reaching almost as far as the acromial end. This strip is termed the *trapezoid ridge* and gives attachment to the trapezoid part of the coracoclavicular ligament.

The **medial two-thirds** of the shaft of the clavicle usually possess four surfaces, but the inferior surface is often reduced to a mere ridge. The *anterior surface* is roughened over most of its extent but it is smooth and rounded at its lateral end, where it forms the upper boundary of the infraclavicular fossa. The *upper surface*, also, is roughened in its medial part and smooth at its lateral end. The *posterior surface* is smooth and featureless. The *inferior surface* is marked, near the sternal end, by a roughened impression, which is often depressed below the surface. This gives attachment to the costoclavicular ligament, which connects the clavicle to the upper surface of the first rib and helps to limit its range of movement. The lateral half of this surface shows a groove in the long axis of the bone.

The flattened *acromial end* of the clavicle presents a small oval articular facet, which articulates with the medial aspect of the acromion at the acromioclavicular joint. The facet is directed laterally and slightly downwards.

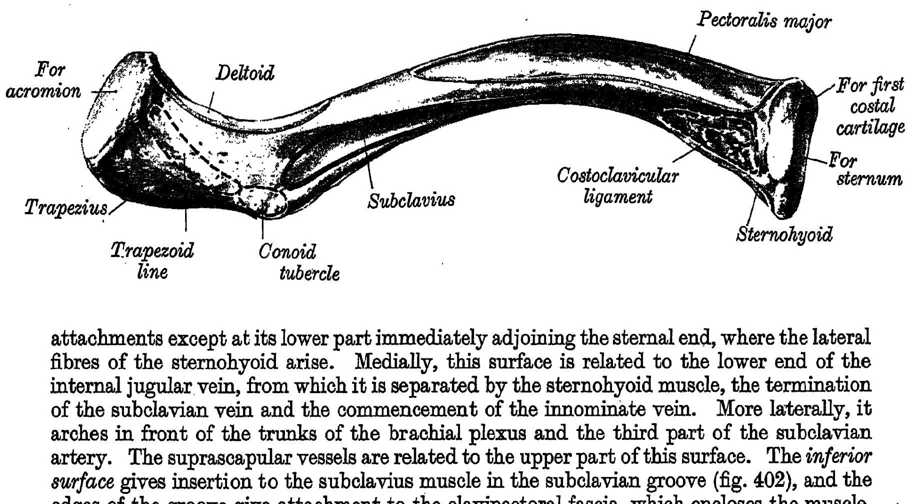
The *sternal end* of the clavicle is directed medially, and a little downwards and

forwards, to articulate with the clavicular notch of the manubrium sterni. The sternal surface is quadrangular (sometimes triangular) in form, and its uppermost part is slightly roughened for ligamentous attachments. Elsewhere, in a normal bone, the surface is smooth and articular and it is carried round on to the inferior surface for a short distance, where it articulates with the first costal cartilage. The sternal end of the clavicle projects upwards beyond the manubrium sterni and can be felt without difficulty in the lateral wall of the suprasternal fossa.

Particular features.—The *lateral one-third* of the shaft gives attachment to the deltoid muscle by its anterior border, and to the trapezius muscle by its posterior border. Both muscles encroach on the upper surface. The coracoclavicular ligament, attached to the conoid tubercle and the trapezoid ridge (fig. 402), transmits a large part of the weight of the upper limb to the clavicle. This weight is counteracted by the tonus of the trapezius muscle, which supports the lateral part of the bone. From the conoid tubercle the weight is transmitted through the medial two-thirds of the shaft to reach the axial skeleton. Fracture of the clavicle medial to the conoid tubercle interrupts the line of weight transmission, so that practically the whole weight of the limb has to be supported by the trapezius. The muscle is unable to meet the demand and the limb therefore drops on the affected side.

The *medial two-thirds* give attachment anteriorly to the clavicular head of the pectoralis major muscle, and, as a rule, the area is clearly indicated on the bone. The clavicular head of the sternomastoid arises from the medial half of the upper surface, but the marking on the bone is not very conspicuous. The smooth, posterior surface is devoid of muscular

FIG. 402.—The right clavicle. Viewed from below.



attachments except at its lower part immediately adjoining the sternal end, where the lateral fibres of the sternohyoid arise. Medially, this surface is related to the lower end of the internal jugular vein, from which it is separated by the sternohyoid muscle, the termination of the subclavian vein and the commencement of the innominate vein. More laterally, it arches in front of the trunks of the brachial plexus and the third part of the subclavian artery. The suprascapular vessels are related to the upper part of this surface. The *inferior surface* gives insertion to the subclavius muscle in the subclavian groove (fig. 402), and the edges of the groove give attachment to the clavipectoral fascia, which encloses the muscle. The posterior lip of the groove runs into the conoid tubercle and carries the fascia into continuity with the conoid ligament. A nutrient foramen is found in the lateral end of the groove, running in a lateral direction. The nutrient artery concerned is derived from the suprascapular (transverse scapular) artery. The impression for the costoclavicular ligament, which is very variable in its character, is separated from the sternal end by a short interval.

The margins of the articular facet at the *acromial end* give attachment to the articular capsule of the acromioclavicular joint.

The roughened, upper part of the *sternal end* provides attachment for the interclavicular ligament, the articular capsule and the articular disc of the sternoclavicular joint. The sternal surface, denuded of its articular cartilage, is rarely smooth and is usually irregular and somewhat pitted.

In a woman, the clavicle is shorter,* thinner, less curved and smoother than in a man. In women the acromial end is a little below the level of the sternal end; in men it is on a level with, or slightly higher than, the sternal end. In those who perform hard manual labour the clavicle is thicker and more curved, and its ridges for muscular attachment are better marked.

* F. G. Parsons (*Journal of Anatomy and Physiology*, vol. li.) gives the following as the average lengths of the clavicle in the male and female: male, left, 154 mm., right, 152 mm.; female, left, 139 mm., right, 138 mm.

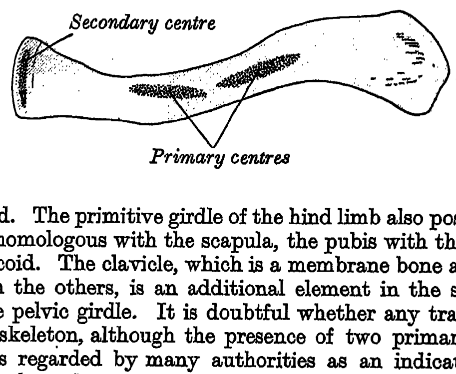
Structure.—The clavicle consists of spongy substance, enveloped by a layer of compact bone which is much thicker in the intermediate part of the bone than at the ends.

Ossification.—The clavicle begins to ossify before any other bone in the body, and is ossified from three centres. The shaft of the bone is ossified in membrane from two primary centres *—a medial and a lateral—which appear between the fifth and sixth weeks of intrauterine life, and fuse about the forty-fifth day ; a secondary centre for the sternal end appears about the eighteenth or twentieth year, and unites with the body of the bone about the twenty-fifth year. A secondary centre of ossification sometimes develops in the cartilage at the acromial end at about eighteen to twenty. The epiphysis so formed is always small and rudimentary and rapidly joins the rest of the bone.†

In a 14 mm. embryo the future clavicle is represented by a band of mesenchyme which extends from the acromion of the scapula to the tip of the first rib, and is continuous with the rudiment of the sternum. In this band a medial and a lateral mass of 'precartilage' is developed, and in the mesenchyme intervening between them the two centres for the body of the bone appear and soon fuse with each other. The sternal and acromial parts of the precartilaginous masses are converted into cartilage, and into this the ossification of the body of the bone extends.

The primitive reptilian shoulder girdle comprises a dorsal element—the scapula—and two ventral elements, of which the anterior (headward) is the precoracoid and the posterior

FIG. 403.—Diagram showing the three centres of ossification of the clavicle.



(caudal) is the coracoid. The primitive girdle of the hind limb also possesses three elements, of which the ilium is homologous with the scapula, the pubis with the precoracoid and the ischium with the coracoid. The clavicle, which is a membrane bone and therefore morphologically distinct from the others, is an additional element in the shoulder girdle but is not represented in the pelvic girdle. It is doubtful whether any trace of the precoracoid persists in the human skeleton, although the presence of two primary centres of ossification for the clavicle is regarded by many authorities as an indication that the human clavicle corresponds both to the precoracoid and to the clavicle in the reptilian shoulder-girdle.

The clavicle is absent in animals in which the forelimbs are used principally or entirely for progression, e.g. the ungulates and carnivores, but it is present and well developed in animals which use the limb for prehension, e.g. many rodents, the primates and man.

Applied Anatomy.—The clavicle is very frequently fractured. The most common cause is indirect violence, as the result of force applied to the hand or shoulder, and the bone then gives way at the junction of its lateral with its intermediate third, that is to say, at the junction of the two curves, for this is its weakest part. The deformity is mainly due to the weight of the arm acting upon the fragment when the prop-like action of the bone is gone, assisted by the muscles which pass from the thorax to the upper limb. The medial fragment, as a rule, is little displaced.

THE HUMERUS (figs. 404–409)

General features.—The **humerus** is the longest and largest bone of the upper limb. It comprises expanded upper and lower extremities and a more or less cylindrical shaft. The rounded head occupies the upper and medial part of the

* Mall, *American Journal of Anatomy*, vol. v., 1906 ; Fawcett, *Journal of Anatomy and Physiology*, vol. xlvii. ; Hanson, *Anatomical Record*, vol. xix. (number 6), 1920.

† T. Wingate Todd and J. D'Errico, jr., *American Journal of Anatomy*, vol. 41, 1928.

upper end of the bone. The lesser tuberosity projects from the front of the shaft, close to the head, and is limited on its lateral side by a well-marked groove. By examination of the head and the lesser tuberosity the student should be able to assign a given humerus correctly to its appropriate side of the body.

The **upper end** of the humerus consists of the head, and the greater and lesser tuberosities (tubercles).

The *head* of the humerus (figs. 404, 408) forms rather less than half a sphere, and its smooth surface is covered with hyaline articular cartilage in life and in the unmacerated specimen. When the arm is at rest by the side, it is directed medially, backwards and upwards to articulate with the glenoid cavity of the scapula. The humeral articular surface is much more extensive than the glenoid cavity, and only a portion of it is in contact with the cavity in any one position of the arm. The margin of the head is most distinct in its medial and lower part.

The *anatomical neck* of the humerus immediately adjoins the margin of the head and forms a slight constriction, which is least apparent in the neighbourhood of the tuberosities.

The *lesser tuberosity* (*tubercle*) is placed on the anterior aspect of the bone immediately beyond the anatomical neck, and shows a smooth, muscular impression on its upper part. Although thickly covered by muscle it can be felt through the skin. The lateral edge of the lesser tuberosity is sharp and forms the medial border of the bicipital groove.

The *greater tuberosity* occupies the lateral part of the upper end of the humerus and is *the most lateral bony point in the shoulder region.* It projects beyond the lateral border of the acromion and, covered by the thick, fleshy deltoid muscle, is responsible for the normal rounded contour of the shoulder. The portion of the tuberosity which adjoins the anatomical neck shows three flattened impressions for muscular attachments.

The *bicipital groove* (*intertubercular sulcus*) separates the two tuberosities and lodges the tendon of the long head of the biceps muscle.

The **shaft** of the humerus is almost cylindrical in its upper half but is triangular on section in its lower half, which is compressed in an anteroposterior direction. It presents three surfaces and three borders—which are not everywhere equally obvious.

The *anterior border* commences above on the front of the greater tuberosity and runs downwards almost to the lower end of the bone. Its upper third forms the lateral lip of the bicipital groove and is roughened for muscular attachments. The succeeding portion is also roughened and forms the anterior limit of the deltoid tuberosity, but the lower half of the border is smooth and rounded.

The *lateral border* is conspicuous at the lower end of the bone, where its sharp edge is roughened along its anterior aspect. In the middle and upper thirds of the bone the border is barely discernible to the inexperienced eye, but in a well-marked bone it can be traced upwards to the posterior surface of the greater tuberosity. About its middle the border is interrupted by a wide, shallow groove which crosses the bone obliquely, passing downwards and forwards from its posterior to its anterior surface. It is termed the *spiral groove* (radial groove).

The *medial border*, although rounded, can be identified without difficulty in the lower half of the shaft. A little below the middle of the bone it presents a roughened strip, and superiorly it becomes indistinct until it reappears as the medial lip of the bicipital groove. In this situation the border is again roughened and can be traced into the lesser tuberosity.

The *anterolateral surface* of the humerus lies between the anterior and the lateral borders. A little above its middle it is marked by a V-shaped roughened area which is termed the *deltoid tuberosity*. The limbs of the V are broad and behind the posterior limb the spiral groove runs downwards and fades away on the lower part of the surface.

The *anteromedial surface* is bounded by the anterior and the medial borders of the bone. Rather less than its upper third forms the rough floor of the bicipital groove, but the rest of the surface is smooth. A little below its middle the nutrient foramen, which is directed downwards, opens close to the medial border.

The *posterior surface* lies between the medial and the lateral borders and is the most extensive surface of the three. Its upper third is crossed by a faint ridge, sometimes roughened, which runs obliquely downwards and laterally. The middle

Fig. 404.—The left humerus. Anterior aspect.

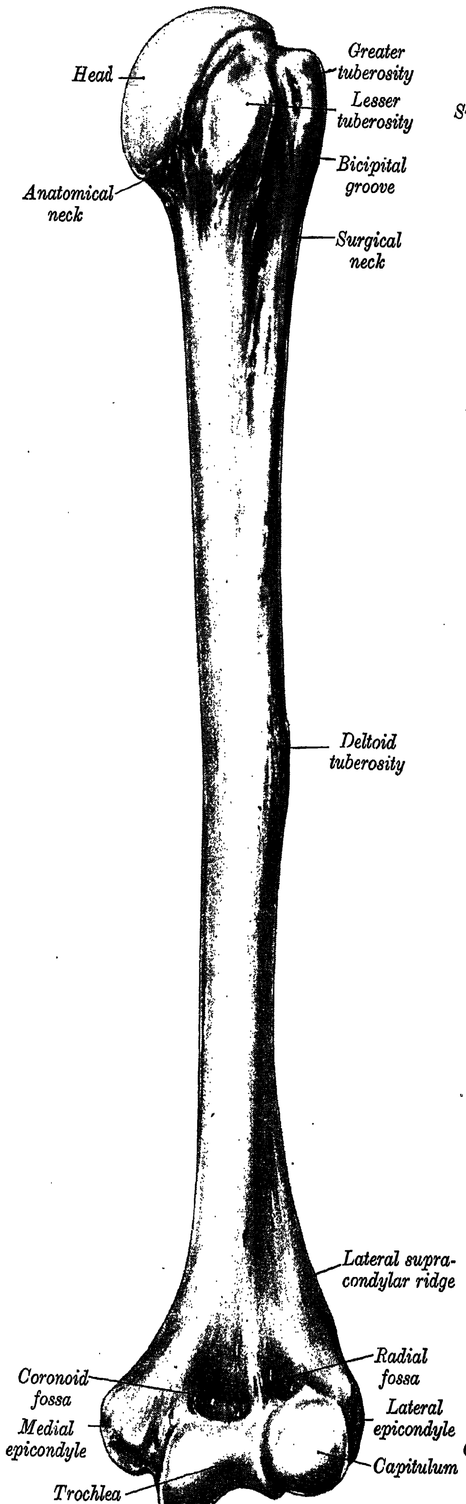


Fig. 405.—Key to fig. 404.

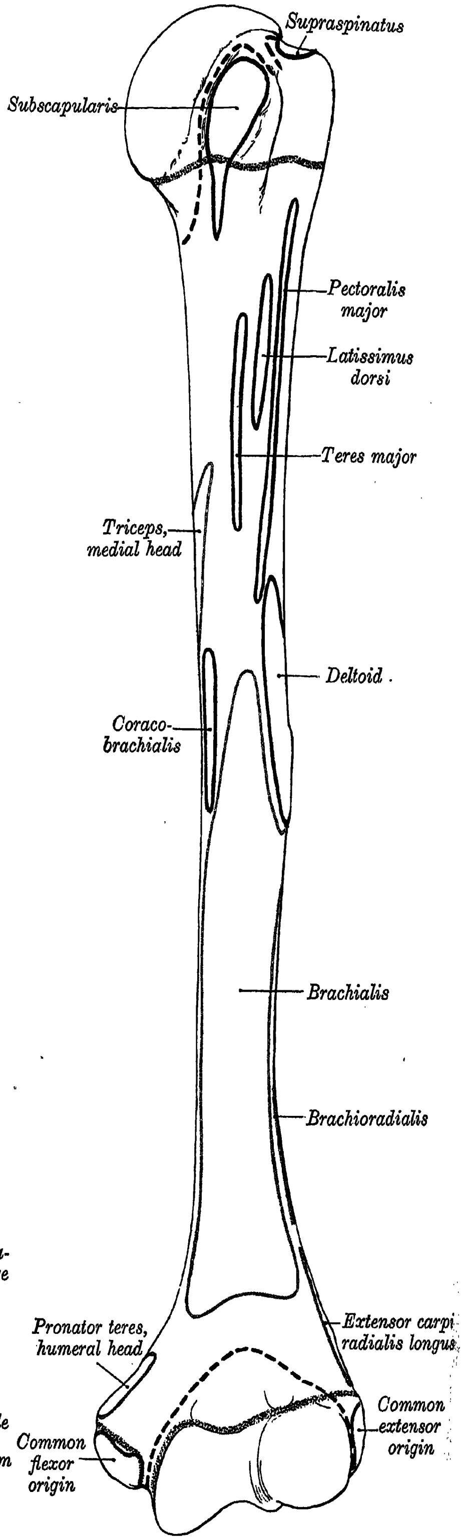

The interrupted lines indicate the attachment of the capsular ligaments; the stippled lines mark the position of the epiphyseal lines.

third is crossed by the commencement of the spiral groove. Rather more than the lower third forms an extensive, flattened surface, which widens considerably below.

The **lower end** of the humerus (figs. 404, 409) is expanded transversely, and presents articular and non-articular portions.

The *articular portion* takes part with the radius and the ulna in the formation of the elbow-joint. It is divided by a faint groove into a lateral, convex surface, termed the capitulum, and a medial, pulley-shaped surface, termed the trochlea.

The *capitulum* is a rounded, convex projection, considerably less than half a sphere, which covers the anterior and inferior surfaces of the lower end of the humerus but does not extend on to its posterior surface. It articulates with the disc-like head of the radius, which lies in contact with its inferior surface in full extension of the elbow but moves on to its anterior surface when the joint is flexed.

The *trochlea* is a pulley-shaped surface, which covers the anterior, inferior and posterior surfaces of the lower end of the humerus. On its lateral side it is separated from the capitulum by a faint groove, but its medial margin is salient and projects downwards beyond the rest of the bone. The trochlea articulates with the trochlear (semilunar) notch of the ulna. When the elbow is extended the inferior and posterior aspects of the trochlea are in contact with the ulna, but, as the joint is flexed, the trochlear notch rolls forwards on to the anterior aspect and the posterior aspect is then left uncovered. The downward projection of the medial edge of the trochlea is the principal factor in determining the angulation which is present between the long axis of the humerus and the long axis of the supinated forearm when the elbow is extended. The angle, which is of approximately 170°, is open to the lateral side and is termed the 'carrying angle' (p. 467). Owing to the existence of this angulation, the ulnar or medial border of the supinated and extended forearm cannot be brought into contact with the lateral surface of the thigh, when the arm is by the side.

The *non-articular part* of the lower end of the humerus includes the medial and lateral epicondyles together with the olecranon, coronoid and radial fossæ.

The *medial epicondyle* forms a conspicuous, blunt projection on the medial side of the lower end of the humerus. It is subcutaneous and can easily be identified through the skin. Its posterior surface is smooth and is crossed by the ulnar nerve, as it runs down into the forearm. In this situation the nerve can be felt and rolled against the bone. If the pressure exerted is sufficient, sensations are aroused identical with those produced by a knock on the 'funny bone,' when the nerve is jarred against the epicondyle. The lower part of the anterior surface of the medial epicondyle shows an impression which gives attachment to the superficial group of the flexor muscles of the forearm.

The *lateral epicondyle* occupies the lateral part of the non-articular portion of the lower end of the humerus; but does not project laterally beyond the lateral border. Its lateral and anterior surfaces show a well-marked impression, which gives origin to the superficial group of the extensor muscles of the forearm. Its posterior surface, which is very slightly convex, can easily be felt through the skin at the back of the elbow (p. 348). The lateral border of the humerus terminates at the lateral epicondyle, and its lower portion is termed the *lateral supracondylar ridge*. The medial border of the humerus terminates below at the medial epicondyle, and its lower portion is termed the *medial supracondylar ridge*.

A deep hollow is situated on the posterior surface of the lower end of the humerus, immediately above the trochlea. It is termed the *olecranon fossa*, on account of the fact that it lodges the tip of the olecranon of the ulna when the elbow is extended. The floor of the fossa is always thin and may be partially deficient. A similar but smaller hollow lies immediately above the trochlea on the anterior surface of the lower end of the humerus and is termed the *coronoid fossa*. It provides room for the anterior margin of the coronoid process of the ulna during flexion of the elbow. A very slight depression lies above the capitulum on the lateral side of the coronoid fossa. It is termed the *radial fossa*, since it is related to the margin of the head of the radius in full flexion of the elbow.

In lower mammals the long axes of the upper and lower articular surfaces of the humerus make an angle with each other of little more than 90°. In man, however,

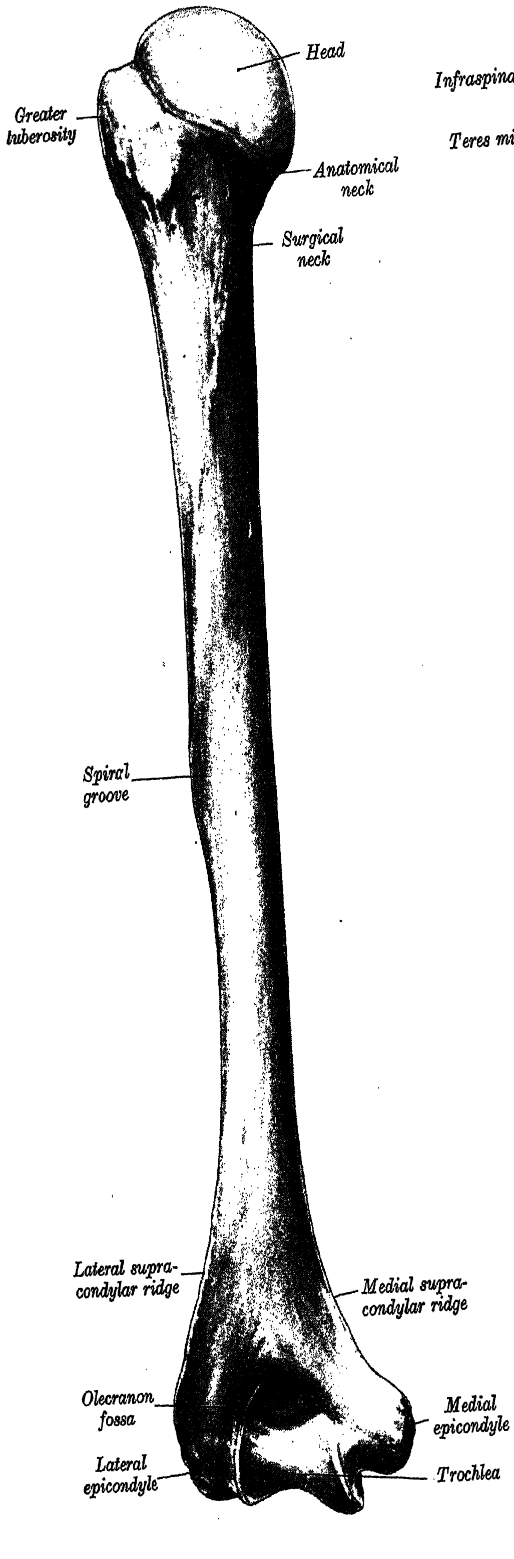

FIG. 406.—The left humerus. Posterior aspect.

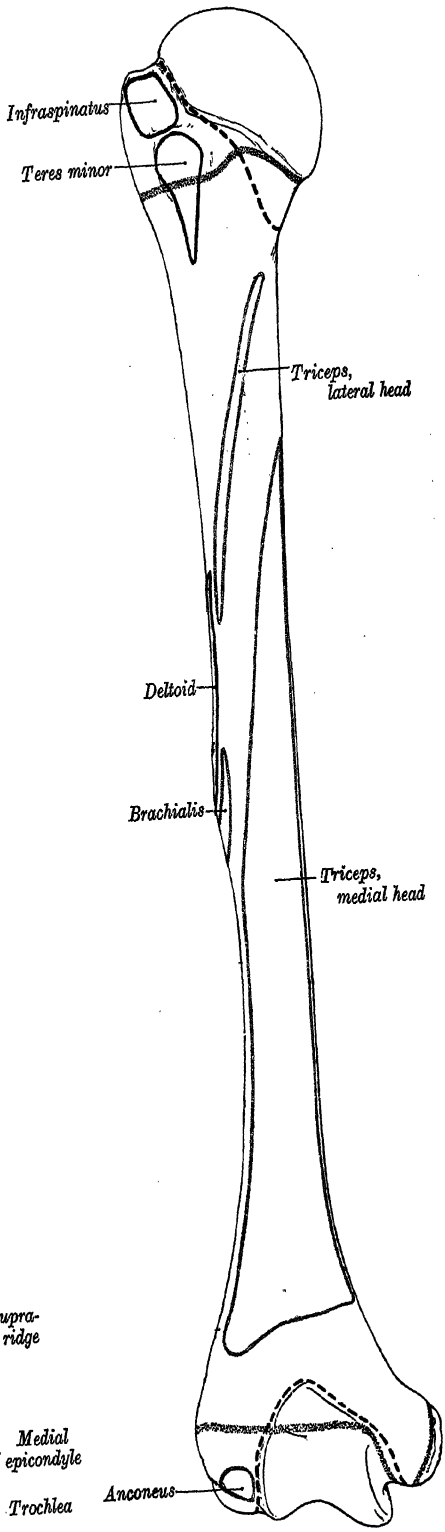

FIG. 407.—Key to fig. 406.

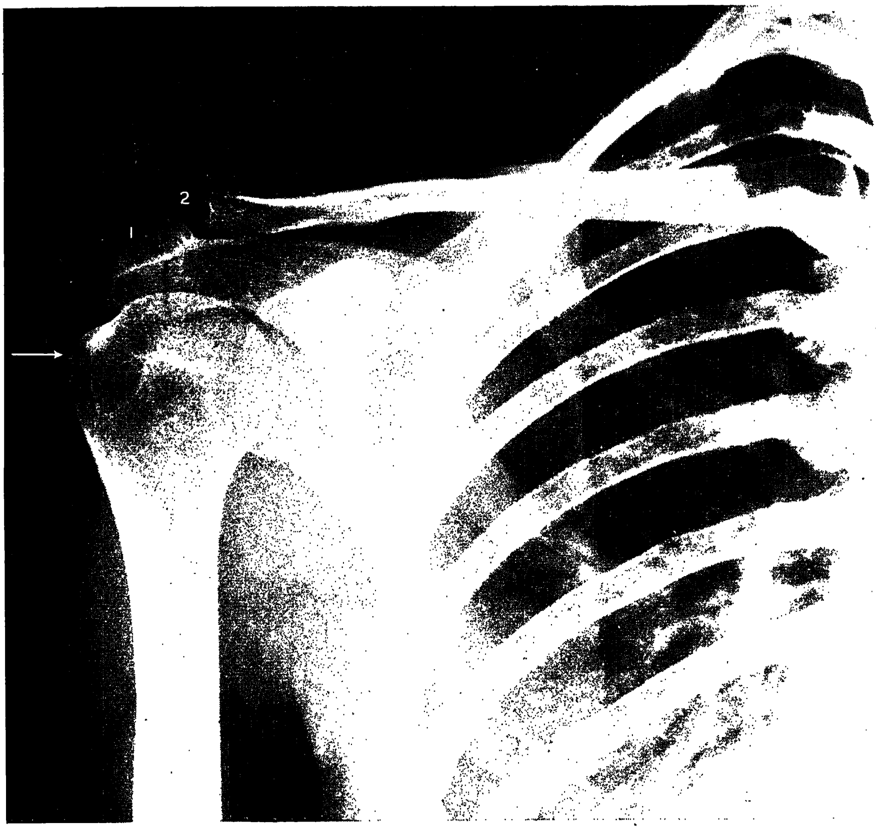
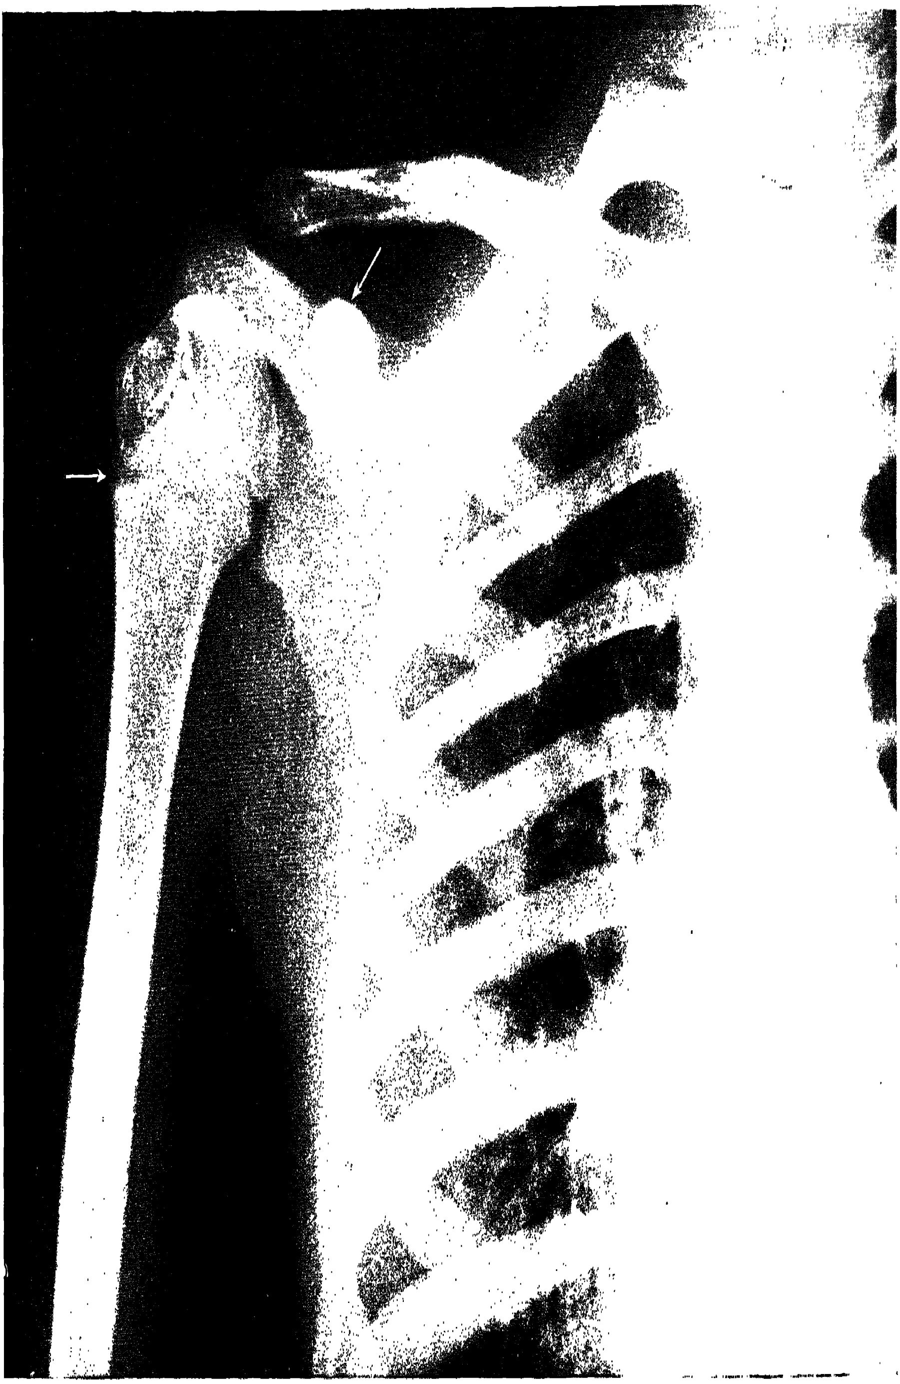
The interrupted lines indicate the attachment of the capsular ligaments; the stippled lines mark the position of the epiphyseal lines.

PLATE III



Radiograph of an adult shoulder. 1 = acromion ; 2 = acromio-clavicular joint. The lower arrow indicates the inferior angle of the scapula, the upper arrow the greater tuberosity. Note that the shadow of the head of the humerus overlaps the shadow of the acromial angle and a part of the glenoid cavity.

PLATE IV



Radiograph of the shoulder region of a child aged 6 years. The upper arrow indicates the coracoid process; the lower arrow indicates the epiphyseal line. Note that the upper end of the diaphysis is conical and projects into the centre of the epiphysis. The centres for the head of the humerus and the tuberosities have fused to form a single epiphysis.

the upper end of the humerus appears to have been rotated laterally, so that the angle between the two axes has been increased to about 164°. This angulation is referred to as the angle of 'humeral torsion.' It is greater in men than women, in adults than children, and in higher races than in lower races and anthropoids. The significance of the torsion of the humerus has not yet been explained in a satisfactory manner.

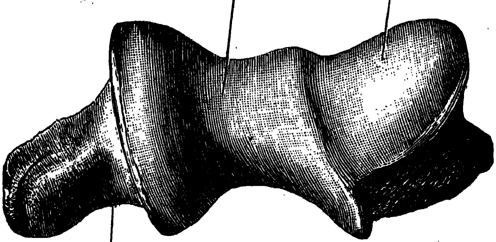
Particular features.—The cartilage which covers the *head* of the humerus is thickest at its centre and becomes thinner towards the circumference.

The *anatomical neck* gives attachment to the capsular ligament of the shoulder-joint (figs. 405, 407), except at the upper end of the bicipital groove, where a deficiency exists to allow the long tendon of the biceps to emerge from the joint. On the medial side, however, the attachment extends downwards for 1 cm. or more on to the shaft of the bone.

The *lesser tuberosity* gives insertion to the subscapularis muscle (fig. 405) and its sharp lateral margin gives attachment to the medial end of the transverse ligament of the shoulder-joint.

The *greater tuberosity* presents three muscular impressions. The uppermost receives the insertion of supraspinatus; the middle impression gives insertion to the infraspinatus; while the lowermost, which is placed on the posterior surface of the tuberosity, gives insertion to the teres minor muscle (fig. 407). The projecting lateral surface of the tuberosity presents numerous vascular foramina and is covered by the deltoid muscle. A part of the subacromial bursa may cover the upper part of this area and separate it from the muscle.

FIG. 408.—The lower end of the left humerus. Inferior aspect.



The *bicipital groove* lodges the long tendon of the biceps, its accompanying synovial sheath, and an ascending branch from the anterior circumflex humeral artery. The rough, lateral lip of the groove gives insertion to the bilaminar tendon of the pectoralis major; its floor receives the tendon of the latissimus dorsi; and its medial lip, the tendon of the teres major. The insertion of the pectoralis major extends to a lower level than the insertion of the teres major, while the insertion of the latissimus dorsi is the least extensive of the three. Below the bicipital groove the anteromedial surface of the humerus is devoid of muscular attachment over a small area, but its lower half gives origin to the medial portion of the brachialis muscle (fig. 405). The roughened strip on the middle of the medial border of the bone gives insertion to the coracobrachialis muscle. Close to the lowest part of the medial supracondylar ridge this surface gives origin over a narrow area to the superficial head of the pronator teres; and the ridge itself gives attachment to the medial intermuscular septum of the arm.

The oblique ridge which crosses the upper part of the *posterior surface* gives origin to the lateral head of the triceps. Above this muscle the circumflex (axillary) nerve and the posterior circumflex humeral vessels wind round this aspect of the bone under cover of the deltoid muscle. Below and medial to the origin of the lateral head of the triceps, the spiral groove, containing the radial nerve and the profunda vessels, runs downwards and laterally to gain the anterolateral surface of the shaft. The area for the origin of the fleshy medial head of the triceps includes a very large part of the posterior surface of the bone. It covers an elongated triangular area, the apex of which is placed on the medial part of the posterior surface above the level of the lower limit of the insertion of teres major. The area widens below and covers the whole surface almost down to the lower end of the bone (fig. 407).

The *anterolateral surface* of the humerus is smooth and featureless in its upper part, which is covered by the deltoid muscle. About, or a little above, the middle of this surface the deltoid muscle is inserted into the deltoid tuberosity, and below that level the surface

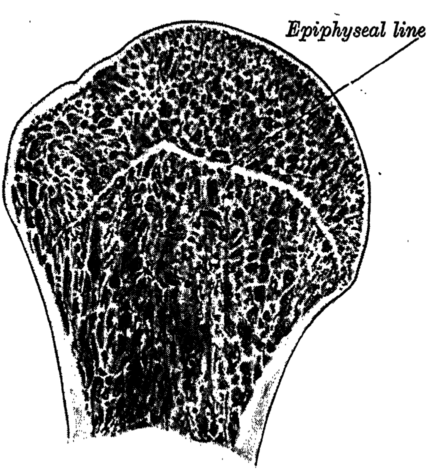
gives origin to the lateral fibres of the brachialis, which extend upwards into the floor of the lower end of the spiral groove (fig. 407). The roughened anterior aspect of the lateral supracondylar ridge gives origin by its upper two-thirds to the brachioradialis and by its lower third to the extensor carpi radialis longus. Behind these muscles the ridge gives attachment to the lateral intermuscular septum of the arm.

The *articular portion of the lower end* of the humerus is curved forwards, so that its anterior and posterior surfaces lie in front of the corresponding surfaces of the shaft. The groove of the trochlea winds backwards and laterally, as it is traced from the anterior to the posterior surface of the bone, and it is wider, deeper and more symmetrical posteriorly. Anteriorly, the medial flange of the pulley is much longer than the lateral, and the surface adjoining its projecting medial margin is convex to accommodate itself to the medial part of the upper surface of the coronoid process of the ulna.

The *capsular ligament of the elbow-joint* extends for some distance beyond the articular surface for its attachments to the humerus. Anteriorly it passes to the upper limits of the radial and coronoid fossæ, so that both these bony depressions are intracapsular and therefore lined with synovial membrane. Medially it is attached to the medial non-articular aspect of the projecting lip of the trochlea and to the root of the medial epicondyle. Posteriorly it ascends to, or almost to, the upper margin of the olecranon fossa, which is therefore intracapsular and covered with synovial membrane. Laterally it skirts the lateral borders of the trochlea and capitulum, lying medial to the lateral epicondyle.

The muscular impression on the *medial epicondyle* gives attachment to the common origin of the superficial group of flexor muscles. They arise from the epiphysis for the epicondyle, but are entirely outside the articular capsule of the elbow-joint. The impression on the *lateral epicondyle* gives attachment to the common origin of the superficial group of extensor muscles of the forearm. These arise from the lateral side of the lower humeral epiphysis, and, like the flexors, are situated outside the articular capsule. A small area on the posterior surface of the lateral epicondyle gives origin to the anconeus. The medial epicondyle is directed backwards a little at its extremity, whereas the lateral epicondyle shows a slight trend in the opposite direction.

FIG. 409.—A longitudinal section through the head of the right humerus.



It should be observed that when the humerus is at rest by the side the medial epicondyle lies on a plane which is posterior to the plane of the lateral epicondyle, so that the bone appears to be rotated medially. In this position the head of the humerus is directed almost equally backwards and medially, and the posterior surface of the shaft looks laterally as well as backwards. This position of the bone must be kept in mind when the movements of the arm and forearm are considered (pp. 460 and 467).

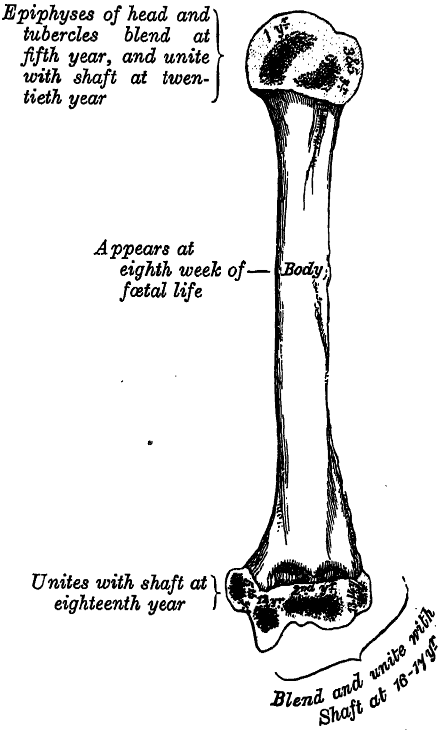
A hook-shaped process of bone, termed the *supracondylar process*, varying from 2 mm. to 20 mm. in length, is occasionally found projecting from the anteromedial surface of the shaft of the humerus, about 5 cm. above the medial epicondyle. It is curved downwards and forwards, and its pointed end is connected to the medial border, just above the epicondyle, by a fibrous band which gives origin to a portion of the pronator teres ; the foramen completed by this fibrous band usually transmits the median nerve and brachial artery. Sometimes the nerve alone is transmitted through it, or the nerve may be accompanied by the ulnar artery, in cases of high division of the brachial artery. A groove, which lodges the artery and nerve, is usually found behind the process. This foramen is the homologue of the supracondylar foramen found in many animals, and probably serves in them to protect the nerve and artery from compression during the contraction of the muscles in this region.

Structure.—The ends of the humerus consist of spongy substance, covered with a thin layer of compact bone (fig. 409) ; the shaft is a cylinder of compact bone, thicker at the centre than towards the extremities. A large medullary canal extends throughout its length.

Ossification (figs. 405, 410).—The humerus is ossified from eight centres—one for each of the following parts : the shaft, the head, the greater tuberosity, the lesser tuberosity, the capitulum and lateral part of the trochlea,

the medial part of the trochlea, and one for each epicondyle. The centre for the shaft appears near its middle in the eighth week of intrauterine life, and gradually extends towards the ends, which at birth are cartilaginous. During the first year, occasionally before birth, ossification begins in the head, during the third year in the greater tuberosity, and during the fifth in the lesser tuberosity. By the sixth year the centres for the head and tuberosities have joined to form a single large epiphysis, which is hollowed out on its inferior surface (fig. 409) to adapt it to the somewhat conical upper end of the diaphysis. It fuses with the shaft of the humerus about the twentieth year. The lower end is ossified as follows. At the end of the second year ossification begins in the capitulum and extends medially to form the chief part of the articular surface; the centre for the medial part of the trochlea appears about the twelfth year. Ossification begins in the medial epicondyle about the fifth year, and in the lateral about the thirteenth or fourteenth year. The centre for the lateral epicondyle fuses with those for the trochlea and capitulum (fig. 410), and the large epiphysis thus formed unites with the shaft about the sixteenth or seventeenth year; the centre for the medial epicondyle forms a separate epiphysis, which is entirely extra-capsular (fig. 410), and unites with the shaft about the eighteenth year.

Fig. 410.—A plan of the ossification of the humerus.



Applied Anatomy.—The upper epiphysis of the humerus, though the first to ossify, is the last to join the shaft, and the length of the bone is due mainly to growth from the upper epiphyseal plate. Hence, in cases of amputation through the arm in young subjects, the humerus continues to grow considerably, and the lower end of the bone, which immediately after the operation was covered with a thick cushion of soft tissue, begins to project, thinning the soft parts and rendering the stump conical. This may necessitate the removal of more bone, and even after this operation a recurrence of the conical stump may take place.

Fractures of the humerus are common. This bone is fractured by muscular action probably more frequently than any other long bone; it is usually the shaft of the bone, just below the insertion of the deltoid, which is thus broken, and the accident has been known to happen from throwing a stone or a hand-grenade. Fracture of the surgical neck of the bone is not uncommon; impaction may occur, or the upper end of the lower fragment may be displaced into the axilla and damage the vessels or nerves. Separation of the upper epiphysis sometimes occurs in the young subject, and is marked by a characteristic deformity, the upper end of the diaphysis projecting abruptly at the front of the shoulder and a short distance below the coracoid process. In fractures of the upper end of the humerus, extension with the arm in the abducted position is necessary, in order that, should ankylosis take place, the mobility of the scapula may be brought into full use. In fractures of the shaft of the humerus the lesion may take place at any point, but appears to be more common in the lower part of the bone than the upper. The points of interest in connexion with these fractures are: (1) that the radial nerve may be injured as it lies in the spiral groove, or may become involved during the process of repair; and (2) the frequency of non-union, which is believed to be more common in the humerus than in any other bone. The non-union is in some measure due to the difficulty in fixing the bone, since the upper end articulates with the movable scapula, and the shaft lies by the chest-wall, which moves with each respiration. Again, muscle is attached to the entire circumference of the bone and is liable to get between the fragments, should there be any overlapping of the broken ends. The circumflex (axillary) nerve may be injured by fractures of the upper end of the bone and the ulnar nerve by fracture of the medial epicondyle. In fractures of the lower end it is important to distinguish between those that involve the elbow-joint and those that do not; the former are always serious, as they may lead to impairment of the mobility of the joint; they include the T-shaped fracture and

oblique fractures which involve the articular surface. Those which do not involve the joint are the transverse fracture above the epicondyles, and the so-called epitrochlear fracture, where the tip of the medial epicondyle is broken off, generally by direct violence.

THE RADIUS (figs. 411–414)

General features.—The **radius** is the lateral bone of the forearm. It is a long bone, prismoid in form and gently curved in its long axis. The upper and lower ends are both expanded, but the lower end is much the wider of the two. The shaft increases in breadth rapidly towards the lower end, is convex to the lateral side and is concave forwards in its lower part. Examination of the shaft, therefore, will enable a given radius to be assigned correctly to its appropriate side of the body.

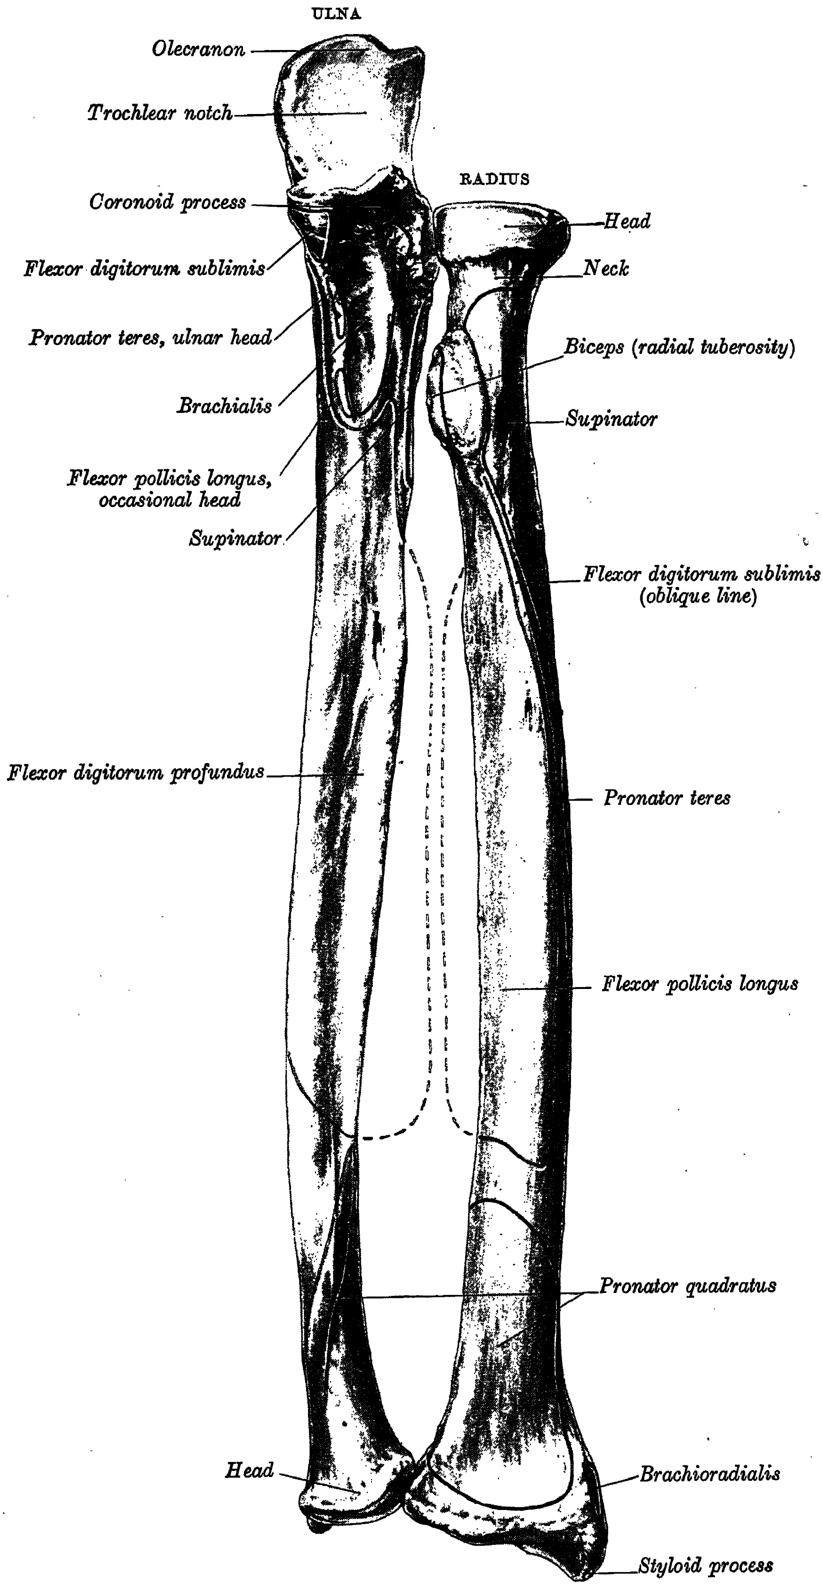
The upper end of the radius includes the head, the neck and the tuberosity. The **head** is disc-shaped and its upper surface is hollowed out to form a shallow cup for articulation with the capitulum of the humerus. The *articular circumference* of the head is smooth and is deepest on the medial side, where it articulates with the radial notch of the ulna. Its posterior surface can be felt through the skin, as it lies at the bottom of a small depression which is visible in the living subject on the lateral side of the posterior surface of the extended elbow. The *neck* of the radius is the constricted part immediately below the head, and is overhung by it, especially on the lateral side. The *tuberosity* of the radius is placed below the medial part of the neck. Its posterior part is roughened but its anterior part is usually smooth.

The **shaft** of the radius is narrow above but widens rapidly towards the lower end. As already stated, it is gently curved with the convexity directed to the lateral side. On transverse section it is triangular in outline, but only one of its three borders is sharp and easy to identify. The *interosseous border* is a salient crest, except at its upper end, where it approaches the lower part of the tuberosity. At its lower end it forms the posterior margin of a small, elongated, triangular area, which constitutes an additional—medial—surface for this end of the bone. In its lower three-fourths this border gives attachment to the interosseous membrane, which connects the opposed borders of the two bones of the forearm. The *anterior border* can be recognised without difficulty at its upper and lower ends, but it is rounded and indefinite in the intervening region. It commences just below the anterolateral part of the tuberosity and runs downwards with an inclination towards the lateral side. This part is often described as the *anterior oblique line* of the radius. The lower part of the anterior border forms a sharp crest along the lateral margin of the anterior surface, and can be recognised easily through the skin. The *posterior border* is clearly defined in its middle third only. Above, it runs obliquely upwards and medially towards the postero-inferior part of the tuberosity. Below, it forms a rounded ridge which is difficult to trace.

The *anterior surface* lies between the anterior and the interosseous borders. It is slightly concave from side to side and curves forwards at its lower end. A little above its middle it presents a nutrient foramen, which is directed upwards. The *posterior surface*, which is bounded by the interosseous and the posterior borders, is generally flat but may be slightly hollowed out in its upper part. The *lateral surface* is gently convex in all directions. Above, owing to the obliquity of the upper parts of the anterior and posterior borders, it encroaches on the anterior and posterior aspects of the bone, and this widened portion is usually slightly roughened. A finely irregular, rough surface occupies an oval area near the middle of the shaft, but below this the surface of the bone is smooth and featureless.

The **lower end** is the widest part of the radius, and is four-sided on transverse section. Its *lateral surface* is slightly rough and projects downwards beyond the rest of the bone to form the *styloid process*. This projection can be felt through the skin, when the tendons which conceal it in the living body are relaxed. The *inferior surface* of the lower end (fig. 417) is smooth and takes part in the formation of the wrist-joint. This articular surface is divided by a faint ridge into

FIG. 411.—The bones of the left forearm. Anterior aspect.



Ossification (figs. 413, 414).—The radius is ossified from three centres: one for the shaft, and one for each end. That for the shaft appears near the middle in the eighth week of intrauterine life. About the close of the second year, ossification begins in the lower end; and at the fifth year, in the upper end. The upper epiphysis fuses with the shaft at the age of seventeen or eighteen years, the lower about the age of twenty. An additional centre sometimes appears in the radial tuberosity about the fourteenth or fifteenth year.

Fig. 413.—A plan of the ossification of the radius. From three centres.

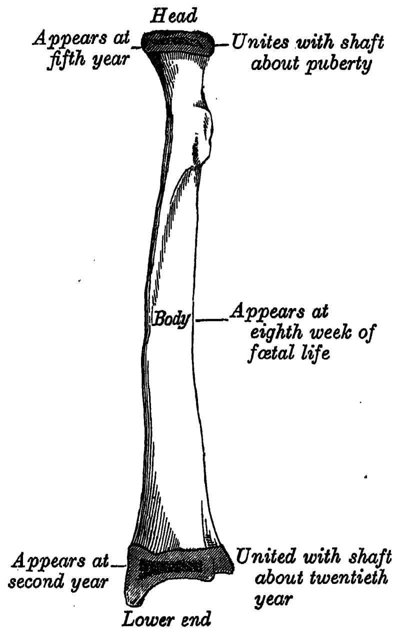


Fig. 414.—The epiphyseal lines of the left radius in a young adult. Anterior aspect.

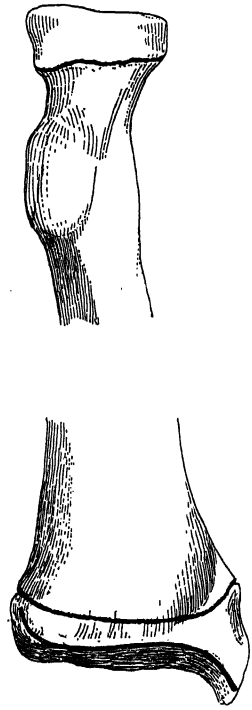

The line of attachment of the articular capsule of the wrist-joint is in blue.

THE ULNA (figs. 411, 412, 415)

General features.—The **ulna** is the medial bone of the forearm and is parallel with the radius when the forearm is supine. The upper end is thick, strong and hook-like (fig. 415), the concavity of the hook being directed forwards. The lateral border of the shaft is a thin, sharp crest. This information is sufficient to enable the student to refer a given ulna correctly to its appropriate side of the body. The bone diminishes in size from its upper to its lower end, which bears a small, rounded enlargement termed the head of the ulna. The shaft is triangular on section, and no difficulty will be experienced in determining its three surfaces and their limiting borders.

The bone is not perfectly straight, and shows a slight but appreciable double curve. Throughout its whole length it forms a gentle curve, the convexity of which is directed backwards. In addition, the upper half or more shows a slight curvature to the lateral side, and the lower half or less a similar curvature in the opposite direction.

The **upper end** of the ulna (fig. 415) displays two substantial processes, named

PLATE V

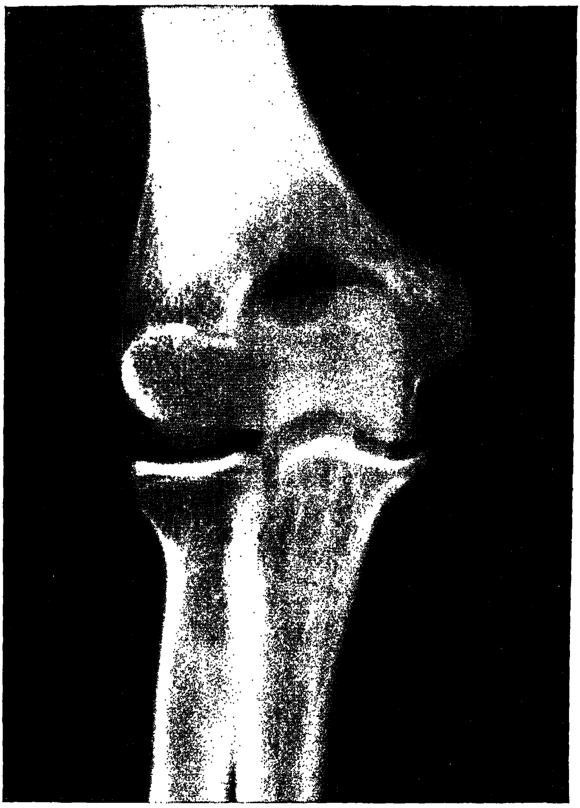

FIG. 1.—Radiograph of adult elbow. Frontal view. The shadow of the olecranon extends upwards to the olecranon fossa and obscures the outline of the trochlea. The gap between the humerus and the bones of the forearm is occupied by the articular cartilage of the bones concerned.

FIG. 2.—Radiograph of the elbow of a child aged 11 years. Frontal view. The upper epiphysis of the radius, the epiphysis for the medial epicondyle, and the centre for the capitulum and lateral part of the trochlea can be recognised without difficulty.

PLATE VI

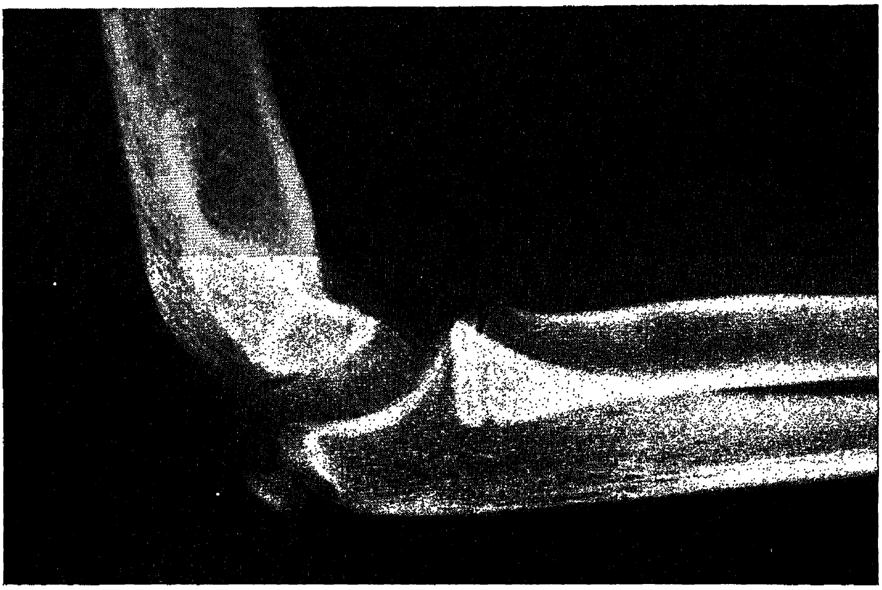

FIG. 1.—Radiograph of the elbow of a child aged 10 years. Lateral view. The upper epiphysis of the radius, the olecranon epiphysis and the centre for the capitulum and the lateral part of the trochlea can be recognised without difficulty.

FIG. 2.—Radiograph of an adult hand.

the olecranon and the coronoid process, and two articular areas, termed the trochlear (semilunar) and radial notches, which articulate, respectively, with the humerus and the radius.

The *olecranon* is the uppermost part of the bone. It is bent forwards at its summit to form a prominent beak, which is received into the olecranon fossa of the humerus when the forearm is extended. Its posterior surface, which is smooth and triangular in outline, can easily be felt through the skin, and its upper border forms the point of the elbow. The anterior surface is smooth and articular, and forms the upper part of the trochlear (semilunar) notch. The base of the olecranon is constricted where it joins the shaft, and this is the narrowest part of the upper end of the ulna.

The *coronoid process* forms a bracket-like projection from the front of the bone immediately below the olecranon. Its upper surface forms the lower part of the trochlear (semilunar) notch and is therefore smooth and articular. The upper part of the lateral surface presents the shallow *radial notch* for articulation with the side of the head of the radius, and the bone below it is hollowed out to make room for the tuberosity of the radius during the movements of pronation and supination. The anterior surface of the process is triangular in shape and bears on its lower part the rough *tuberosity of the ulna*. The medial border of the process is sharp and bears a small, but prominent, tubercle at its upper end.

The *trochlear* (*semilunar*) *notch* articulates with the trochlea of the humerus and is shaped accordingly. It is formed by the anterior surface of the olecranon and the superior surface of the coronoid process. The bone is constricted at the junction between these two areas, and they may be separated completely by a narrow, roughened strip. A smooth ridge, which corresponds to the groove of the trochlea, divides the notch into a larger, medial, and a smaller, lateral part. The medial part conforms to the large flange of the trochlea of the humerus.

The *radial notch* (fig. 415) is an oblong, articular depression on the upper part of the lateral aspect of the coronoid process. It articulates with the articular circumference of the head of the radius, and is separated from the lateral part of the trochlear notch by a smooth ridge.

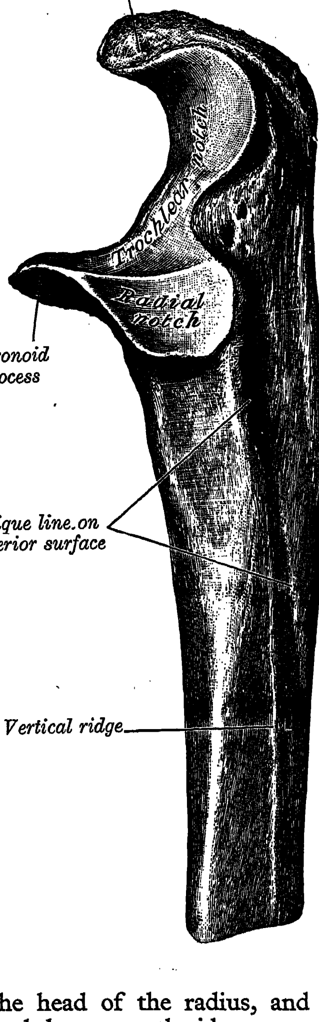

Fig. 415.—The upper part of the left ulna. Lateral aspect.

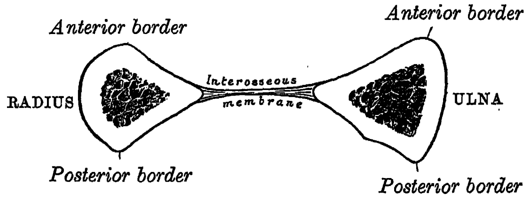
The **lower end** of the ulna is slightly expanded and comprises the rounded head and the styloid process. The *head* presents a convex articular surface on its lateral side for articulation with the ulnar notch of the radius. Its inferior surface (fig. 417) is smooth and is separated from the carpus by the articular disc of the inferior radio-ulnar joint, which is attached by its apex to the small rough area interposed between the articular surface and the styloid process. The *styloid process* is a short, rounded projection which springs from the posteromedial aspect of the lower end of the ulna. Its tip can be felt through the skin on the posteromedial aspect of the wrist, where it lies about 1 cm. above the level of the tip of the styloid process of the radius. On the dorsal surface of the lower end a shallow groove intervenes between the head of the ulna and the styloid process.

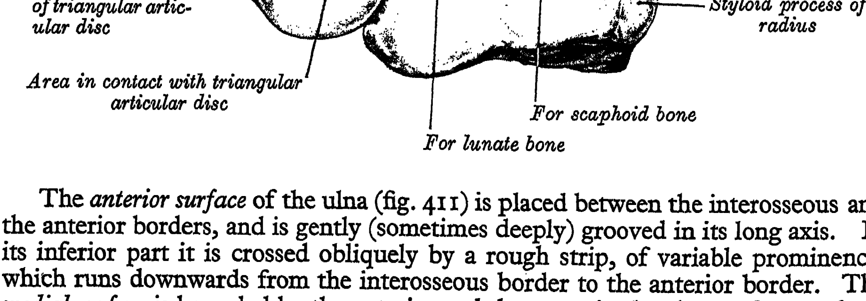
The **shaft** of the ulna is triangular in section (fig. 416) in its upper three-fourths, but is almost cylindrical in its lower fourth. The surfaces of the shaft are anterior, posterior and medial; the borders, interosseous, posterior and anterior.

FIG. 416.—A transverse section through the left radius and ulna, showing the attachment of the antebrachial interosseous membrane. Superior aspect.



The *interosseous border* is the lateral margin of the bone and forms a conspicuous crest in its middle two-fourths. The upper part becomes continuous with the posterior border of the depression which lies below the radial notch and is here termed the *supinator crest*; its lower part fades away on the cylindrical, lower portion of the shaft. The *anterior border* is thick and rounded. It commences above at the medial side of the tuberosity of the ulna and inclines backwards below where it can usually be traced to the base of the styloid process. The *posterior border*, also thick and rounded, commences at the apex of the posterior aspect of the olecranon and curves laterally as it descends. Inferiorly, it is very indistinct as it descends to the styloid process. Throughout its whole length this border can easily be felt through the skin.

FIG. 417.—The lower ends of the right radius and ulna.



The *anterior surface* of the ulna (fig. 411) is placed between the interosseous and the anterior borders, and is gently (sometimes deeply) grooved in its long axis. In its inferior part it is crossed obliquely by a rough strip, of variable prominence, which runs downwards from the interosseous border to the anterior border. The *medial surface* is bounded by the anterior and the posterior borders. Convex from side to side, it is smooth and featureless. The *posterior surface* (fig. 412) lies between the posterior and the interosseous borders. It is subdivided into three areas, of which the uppermost is limited by an oblique line—not always easily discernible—which runs upwards and medially from the junction of the middle and upper thirds of the posterior border to the posterior end of the radial notch. The region below this line is divided into a larger medial and a narrower lateral strip by a vertical ridge, usually distinct in its upper three-fourths but difficult to determine in its lower part.

Particular features.—The upper surface of the *olecranon* gives attachment, in front, to the capsular ligament of the elbow-joint; in its posterior two-thirds, which are roughened, it provides insertion for the tendon of the triceps muscle. Occasionally these two areas are separated by a smooth bursal area. The medial surface of the process is marked in its

upper part by a rough elevation, which gives attachment to the posterior and oblique bands of the medial ligament of the elbow-joint and the ulnar head of the flexor carpi ulnaris. Its lower part is smooth and gives origin to the uppermost fibres of the flexor digitorum profundus. The lateral surface of the process, and the adjoining part of the posterior surface of the shaft down to the oblique line already mentioned (p. 354), gives insertion to the anconeus muscle. Its posterior surface is separated from the skin by a bursa.

The anterior surface of the *coronoid process*, including the tuberosity of the ulna, receives the insertion of the brachialis muscle. Its medial border is sharp, and a small, rounded tubercle is situated at its upper end. This tubercle gives attachment to the oblique and anterior bands of the medial ligament of the elbow-joint and to the lowest part of the humero-ulnar head of the flexor digitorum sublimis muscle. Below the tubercle the margin gives origin to the coronoid head of the pronator teres, and below that to an occasional coronoid head of the flexor pollicis longus. The medial surface of the process is concave and gives origin to fibres of the flexor digitorum profundus. The anterior and posterior borders of the radial notch provide attachment for the annular ligament of the radius. The depressed area below the notch is limited behind by the *supinator crest*; the supinator muscle arises from the crest and from the adjoining part of the depression.

The part of the *trochlear notch* which is formed by the olecranon is, typically, divided into three areas. Of these the most medial faces forwards and slightly medially and is hollowed out to fit the medial flange of the trochlea: the intermediate area is flattened and fits the lateral flange of the trochlea; the most lateral area, which forms a narrow strip directed to the radial side, comes into contact with the trochlea only when the elbow is extended. The constriction of the articular surface is more pronounced than the constriction of the base of the olecranon. The resulting small non-articular parts of the anterior surface of the olecranon are covered in the fresh specimen and in life by tag-like processes of the synovial membrane which contain a little fat (fig. 533). The *coronoid part* of the trochlear notch is divided into medial and lateral parts, which correspond, respectively, to the medial and intermediate parts of the olecranon area. Of these the medial is hollowed out much more than the lateral, in conformity with the convexity of the medial flange of the trochlea. The medial and anterior borders of this area give attachment to the medial and anterior portions of the capsular ligament of the elbow-joint.

The carrying angle and its functional importance are described on p. 467.

The subcutaneous *posterior border* of the ulna gives attachment to the deep fascia of the forearm, which acts, in its upper three-fifths, as an additional origin for the flexor carpi ulnaris, and in its middle third as an additional origin for the extensor carpi ulnaris. Both of these muscles are therefore connected to the posterior border. The *interosseous border* is usually continuous above with the supinator crest. Except at its upper end it gives attachment to the interosseous membrane of the forearm. The rounded *anterior border* is covered in its upper three-fourths by the flexor digitorum profundus, to which it gives origin.

The *anterior surface* gives origin in its upper three-fourths to the flexor digitorum profundus. In the same extent the muscle arises also from the anterior border and the *medial surface*, extending upwards on to the medial sides of the coronoid process and the olecranon. The rough strip which crosses the lower fourth of this surface provides origin for the pronator quadratus. The anconeus is inserted into the *posterior surface* above the oblique line already mentioned, and extends upwards on to the lateral aspect of the olecranon. The narrow strip between the interosseous border and the vertical ridge gives part origin to three of the deep muscles of the forearm. The abductor pollicis longus arises from its upper fourth, and a ridge may separate this area from the succeeding fourth, which gives attachment to the extensor pollicis longus. The extensor indicis is attached to the third fourth of this area. The broad strip to the medial side of the vertical ridge is devoid of muscular attachments but is covered by the extensor carpi ulnaris, the tendon of which occupies the groove on the posterior aspect of the lower end of the bone. The medial ligament of the wrist-joint is attached to the tip of the *styloid process*. The articular disc separates the *head* of the ulna from the medial part of the lunate bone and, in ulnar deviation of the hand, from the triquetral bone.

Structure.—The structure of the ulna is similar to that of the other long bones.

Ossification (figs. 418, 419).—The ulna is ossified from three centres: one each for the shaft, the lower end, and the top of the olecranon. Ossification begins near the middle of the shaft, about the eighth week of intrauterine life, and soon extends through its greater part. About the fourth year, the centre for the lower end appears in the middle of the head, and extends into the styloid process. About the tenth year, a centre appears in the olecranon and forms a thin scale for the top of the process, the chief part of the process being formed by an upward extension of the shaft; sometimes the upper part of the olecranon

is ossified from two centres. The upper epiphysis joins the shaft about the sixteenth, the lower about the twentieth year. The former may take part in the formation of the semilunar notch although it does not usually do so.

Applied Anatomy.—When indirect force is applied to the forearm the radius as a rule gives way, though both bones may suffer. Fractures from indirect force generally take place somewhere about the middle of the bones, while those from direct violence may occur at any part, but are most frequent in the lower half of the bones. A point of interest

FIG. 418.—A plan of the ossification of the ulna. From three centres.

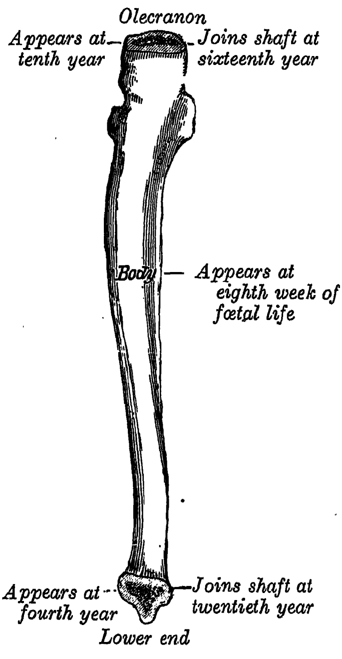


FIG. 419.—The epiphyseal lines of the left ulna in a young adult. Lateral aspect.

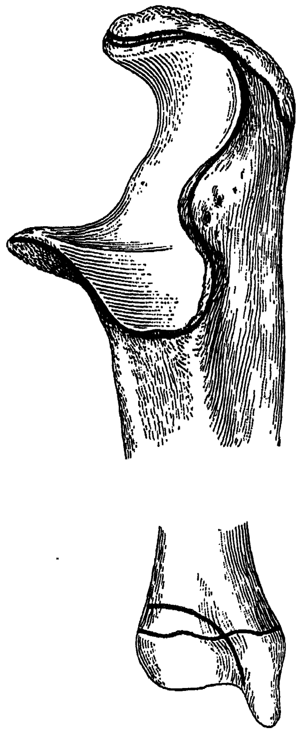

The lines of attachment of the articular capsules are in blue.

in connexion with these fractures is the tendency for the two bones to unite across the interosseous membrane; the limb should therefore be put up in a position midway between supination and pronation, which is not only the most comfortable position, but also separates the bones most widely from each other.

The special fractures of the ulna are: (1) Fracture of the olecranon: the most common fracture is at the constricted portion where the olecranon joins the shaft of the bone, and the fracture is usually transverse; but any part may be broken, and even a thin shell may be torn off. If the fibrous structures around the process are not torn, the displacement is slight, otherwise the olecranon may be drawn up for a very considerable distance. (2) Fracture of the coronoid process may occur as a complication of dislocation backwards of the bones of the forearm, but it is doubtful if it ever takes place as an uncomplicated injury. (3) Fractures of the shaft of the ulna may occur at any part, but usually take place at or a little below the middle of the bone. (4) The styloid process may be knocked off by direct violence.

Fractures of the radius may consist of: (1) Fracture of the head of the bone. (2) Fracture of the neck. (3) Fractures of the shaft of the radius are very common, and may take place at any part of the bone. In fracture of the upper one-third of the shaft—that is to say, above the insertion of the pronator teres—the displacement is very great. The upper fragment is strongly supinated by the biceps and the supinator, and flexed by the biceps; while the lower fragment is pronated and drawn towards the ulna by the two pronators. If such a fracture is put up in the ordinary position, midway between supination

and pronation, the bone will unite with the upper fragment in a position of supination, and the lower one in the mid-position, and thus considerable impairment of the movement of supination will result; the limb should therefore be put up with the forearm supinated. (4) The most important fracture of the radius is that of the lower end (Colles's fracture). The fracture is transverse, and generally takes place about 2·5 cm. from the lower end. Separation of the lower epiphysis of the radius may take place in the young. This injury and Colles's fracture may be distinguished from other injuries in this neighbourhood—especially dislocation of the wrist, with which they are liable to be confounded—by observing the relative positions of the styloid processes of the ulna and radius. In the natural conditions of parts, with the arm hanging by the side, the styloid process of the radius is on a lower level than that of the ulna. After fracture or separation of the epiphysis the styloid process of the radius is on the same level as, or on a higher level than, that of the ulna, whereas it would be unaltered in position in dislocation.

THE SKELETON OF THE HAND

The skeleton of the hand has three segments: (1) the carpal or wrist bones; (2) the metacarpal bones or bones of the palm; and (3) the phalanges or bones of the digits.

THE CARPUS (figs. 420–423)

General features.—The **carpus** is made up of eight short bones, which are arranged in a proximal and a distal row, each containing four bones. The carpal bones of the proximal row are named, from the lateral to the medial side, the *scaphoid* (*navicular*), *lunate*, *triquetral and pisiform*; those of the distal row, the *trapezium* (*os multangulum majus*), the *trapezoid* (*os multangulum minus*), the *capitate* and the *hamate*. Of these, the pisiform is placed on the anterior surface of the triquetral and is separated from the other carpal bones, all of which articulate with their immediate neighbours. The other bones of the proximal row form an arch convex upwards, which articulates with the radius and the articular disc of the inferior radio-ulnar joint. The concavity of the arch is directed downwards and forms a mortise for the upwardly projecting parts of the capitate and hamate bones. In this way the two rows are locked to each other and stability is assured.

The dorsal aspect of the whole carpus is gently convex from side to side, but the anterior surface is deeply concave, owing to the presence of certain forward projections on its lateral and medial borders. The *pisiform bone* lies at the medial part of the upper border of the muscular prominence (hypothenar eminence) which marks the medial portion of the palm, and its position on the front of the triquetral makes it easy to feel through the skin. In addition, the distal part of the *hamate bone* bears a *hook-like process* on its anterior surface. The concavity of the hook is directed towards the lateral side and its tip can be identified in the living subject. It lies 2·5 cm. distal to the pisiform and in line with the ulnar border of the ring finger. The projecting lateral border of the carpal groove is formed by the *tubercle of the scaphoid* and the *crest of the trapezium*. The tubercle is placed on the distal part of the anterior surface of the scaphoid and can be felt—and sometimes seen—as a small, rounded knob, at the medial part of the upper border of the muscular prominence (thenar eminence) which marks the lateral portion of the palm. The crest of the trapezium forms a rounded ridge which runs vertically across the anterior surface of the bone, being slightly hollowed out on its medial side. It lies immediately below and slightly lateral to the tubercle of the navicular, and can be felt only on deep pressure. The margins of the groove give attachment to a strong fibrous retinaculum, which retains the flexor tendons within an osteofibrous, carpal tunnel and so increases the efficiency of the flexor muscles. In addition, the retinaculum serves to increase the stability of the carpus. The anterior and posterior surfaces of the carpal bones—apart from the triquetral and the pisiform—are rough for the attachment of ligaments (radiocarpal, intercarpal and carpometacarpal).

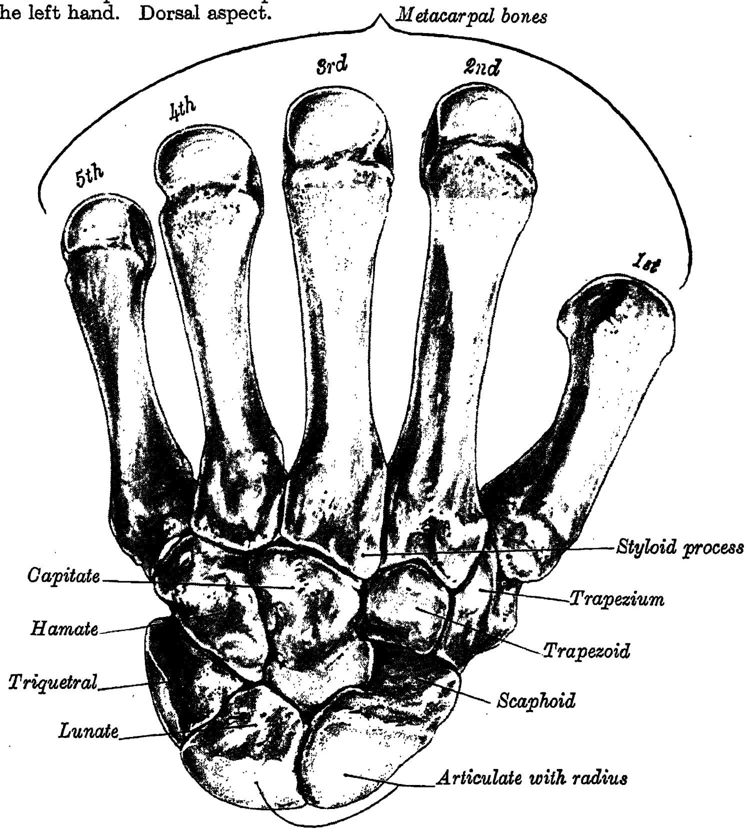

FIG. 423.—Diagram showing the muscles attached to the dorsal aspects of the carpal and metacarpal bones of the left hand.

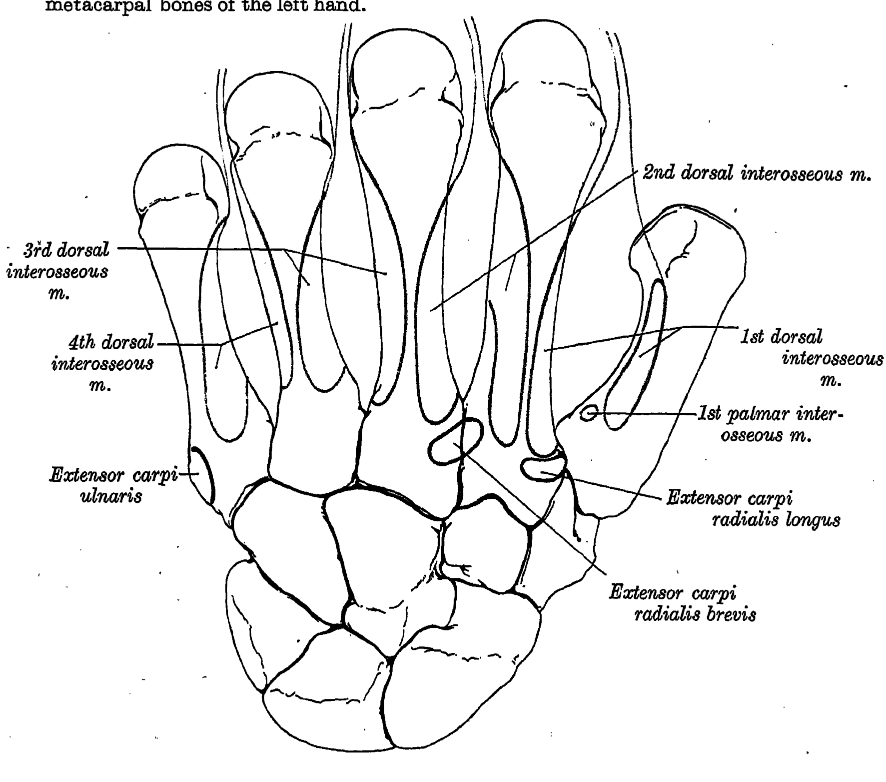


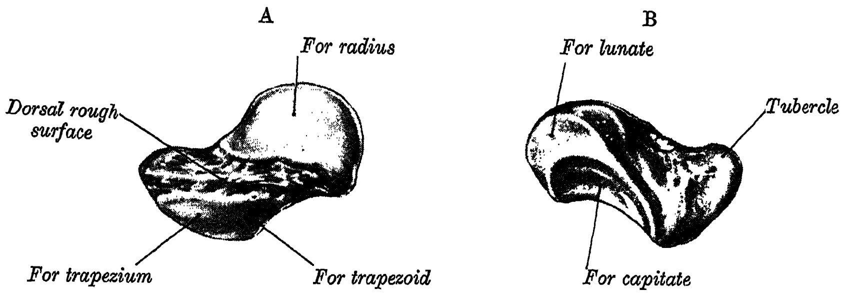
THE INDIVIDUAL CARPAL BONES

The Scaphoid Bone [Os Scaphoideum]

The **scaphoid** (B.N.A. **navicular**) **bone** (figs. 424, A and B) is named from its fancied resemblance to a boat. It is the largest bone in the proximal row and lies with its long axis directed downwards, laterally and slightly forwards. The tubercle forms a rounded elevation on the lower part of the *anterior surface* and is directed slightly to the lateral side. It gives attachment to the flexor retinaculum and a few fibres of the abductor pollicis brevis, and is crossed by the tendon of the flexor carpi radialis, which should be relaxed when the bony prominence is being examined. The *posterior surface* is rough and slightly grooved, and is narrower than the anterior surface. The *lateral surface*, also narrow and roughened, gives attachment to the lateral ligament of the wrist-joint. The remaining surfaces of the bone are articular. The *radial surface* is convex and is directed upwards and laterally. The *lunate surface* is a flattened, narrow semilune, directed medially. The *capitate surface*, large and concave, is directed medially and downwards. The *surface for the trapezium and the trapezoid bones* forms a continuous convex area, directed downwards.

Fig. 424.—The left scaphoid bone.

Viewed (A) from behind, and (B) from in front.

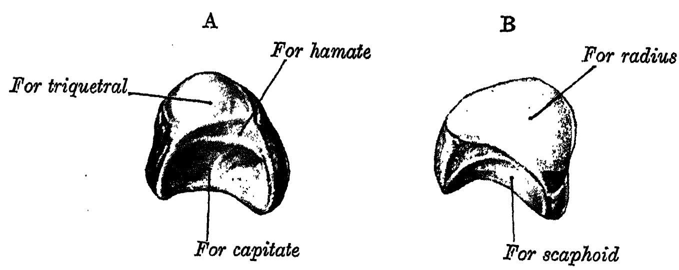


The Lunate Bone [Os Lunatum]

The **lunate bone** (figs. 425, A and B), distinguished by its crescentic outline, is placed between the scaphoid and the triquetral bones in the middle of the proximal row of the carpus. The rough, *anterior surface*, almost triangular in outline, is larger and wider than the rough, *posterior surface*. The smooth, convex, *proximal surface* articulates with the radius and the articular disc of the inferior radio-ulnar joint. The *lateral surface* is narrow and presents a flat, semilunar facet for articulation with the scaphoid. The *medial surface* articulates with the triquetral and is almost square. It is separated from the distal surface by a curved ridge, which is usually somewhat hollowed out (fig. 425, A) for articulation with the edge of the wedge-shaped hamate bone (fig. 420). The *distal surface* is deeply concave to accommodate the medial part of the head of the capitate bone

Fig. 425.—The left lunate bone.

A. Inferomedial aspect. B. Superolateral aspect.



The Triquetral Bone [Os Triquetrum]

The **triquetral bone** (fig. 426), usually pyramidal in shape, is distinguished by an oval, isolated, smooth facet for articulation with the pisiform, which marks the distal part of its rough, *anterior* surface. The *medial* and *dorsal surfaces* are confluent. Rough distally for the attachment of the medial ligament of the wrist-joint, this aspect is smooth in its proximal part, which articulates with the articular disc of the inferior radio-ulnar joint in full adduction of the hand. The *hamate surface*, directed laterally and downwards, forms a concavo-convex area, broad proximally and narrow distally. The *lunate surface*, almost square, is directed upwards and laterally.

Fig. 426.—The left triquetral bone. Palmar aspect.

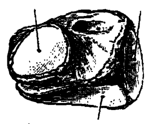


Fig. 427.—The left pisiform bone. Dorsal aspect.

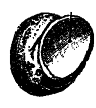


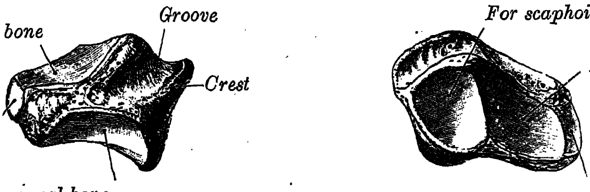
The Pisiform Bone [Os Pisiforme]

The **pisiform bone** (fig. 427), shaped like a pea with one flattened surface, can be distinguished by the fact that it possesses only one articular facet. This is on the *posterior surface* of the bone to articulate with the triquetral, and its long axis runs downwards and laterally. The non-articular part of the bone tends to project downwards beyond the articular surface, and the lateral aspect is somewhat flattened, while the medial aspect is convex. The flexor carpi ulnaris is inserted on the anterior surface and its true continuation, viz., the pisometacarpal ligament, to the distal part of the bone. The flexor retinaculum (transverse carpal ligament) is attached to the anterior part of the lateral aspect, while the abductor digiti minimi and the extensor retinaculum (dorsal carpal ligament) are attached to the medial aspect. The area surrounding the articular facet is slightly constricted and gives attachment to the capsular ligament of the pisotriquetral joint.

The Trapezium Bone [Os Trapezium]

The **trapezium (greater multangular) bone** (fig. 428) can be identified by the crest and groove which mark its rough, *anterior surface*. The groove, which is medial to the crest, lodges the tendon of the flexor carpi radialis, and its margins give attachment to the two layers of the flexor retinaculum (fig. 629 and p. 609). The *crest* is obscured to a large extent by the origin of the muscles of the thenar eminence. The opponens pollicis

Fig. 428.—The left trapezium bone. Palmar and superomedial aspects.



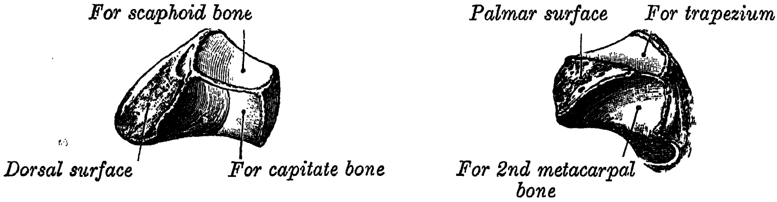
arises from its middle part, the flexor pollicis brevis from its distal part and the abductor pollicis brevis from its proximal part (fig. 421). The elongated, rough, *dorsal surface* is closely related to the radial artery, before it passes forwards into the palm to become the deep palmar (volar) arch. The *lateral surface* also is large and rough for the attachment of the lateral ligament of the wrist-joint and the capsular ligament of the carpometacarpal joint of the thumb. A large *saddle-shaped surface* is directed downwards and laterally for articulation with the base of the metacarpal bone of the thumb. The most distal part of the bone projects slightly between the bases of the first and second metacarpal bones and is covered with a small, quadrilateral facet which is directed downwards and medially to articulate with a corresponding facet on the posterior part of the lateral aspect of the base of the second

metacarpal bone. The medial surface is covered with a large, gently concave facet for articulation with the trapezoid bone. The proximal surface is occupied by a small, slightly hollowed out facet, which articulates with the scaphoid bone.

The Trapezoid Bone [Os Trapezoideum]

The **trapezoid** (lesser **multangular**) **bone** (fig. 429) is small and very irregular in shape. The *anterior surface* is rough, narrow and considerably smaller than the rough, *dorsal surface*. It is continued for a short distance on to the inferolateral aspect. The *distal surface* artic-

FIG. 429.—The left trapezoid bone. Superomedial and inferolateral aspects.

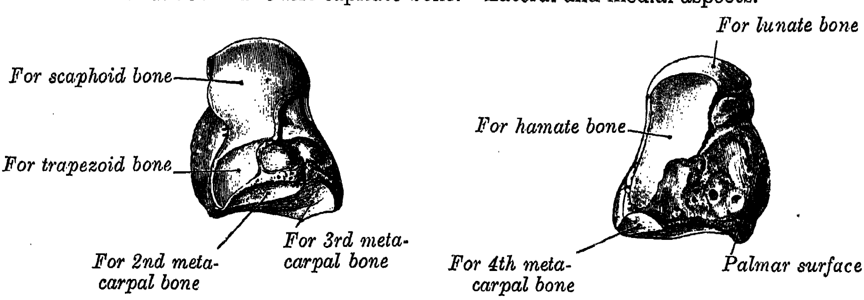


ulates with the grooved base of the second metacarpal bone. Triangular in outline, it is convex from side to side and concave from before backwards. The *medial surface* articulates with the distal part of the capitate bone, by means of a slightly concave facet. The dorsal part of this area is often rough for the attachment of an interosseous ligament. The *lateral surface* articulates with the trapezium, and the *distal surface* with the scaphoid bone.

The Capitate Bone [Os Capitatum]

The **capitate bone** (fig. 430) is the largest of the carpal bones and is placed opposite the base of the third metacarpal bone ; it is therefore more or less central in position. The *distal surface* is roughly triangular and forms a concavoconvex facet for articulation with the base of the third metacarpal bone. Its lateral border is marked by a concave strip which

FIG. 430.—The left capitate bone. Lateral and medial aspects.



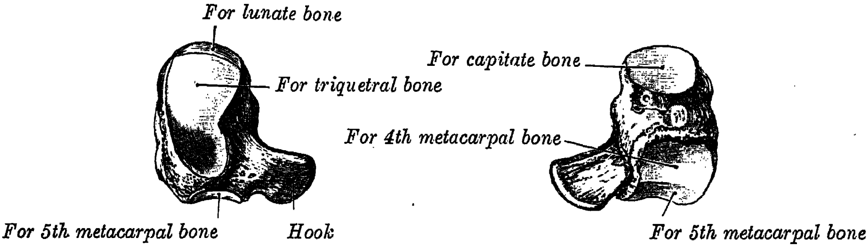
articulates with the medial side of the base of the second metacarpal bone, and its posteromedial angle usually bears a small facet for the fourth metacarpal bone. The convex *head* is received into the concavity formed by the lunate and scaphoid bones. Its *proximal surface* articulates with the lunate and its *lateral surface* with the scaphoid. The facet for the scaphoid is usually continuous with the facet for the trapezoid on the lower part of the lateral surface of the bone, but the two may be separated by a rough interval. The *medial surface* presents a large facet for the hamate bone, deeper above than below, where a part of the surface is non-articular and gives attachment to a strong interosseous ligament. The anterior and posterior surfaces are roughened ; the posterior is the larger of the two.

The Hamate Bone [Os Hamatum]

The **hamate bone** (fig. 431) can be identified easily by its wedge-shaped form and the hook-like process which projects from the distal part of its rough, *anterior surface.* The concavity of the *hook* is directed to the lateral side, and takes part in the formation of the carpal tunnel. Its tip gives attachment to the flexor retinaculum (transverse carpal

ligament), and more medially to the flexor and the opponens digiti minimi. The distal aspect of the base of the hook occasionally shows a slight transverse groove for the deep terminal branch of the ulnar nerve. The rest of the *anterior surface*, like the *posterior surface*, is rough for the attachment of ligaments. The *distal surface* is divided into two articular surfaces by a faint ridge: of these, the smaller, lateral facet articulates with the base of

FIG. 431.—The left hamate bone. Medial and inferolateral aspects.



the fourth, and the larger, medial facet with the base of the fifth metacarpal bone. The *proximal surface* is the cutting edge of the wedge and usually bears a narrow facet for the lunate bone. The *medial surface* is covered by a broad articular strip, convex above and concave below, for the triquetral bone. The *lateral surface* articulates with the capitate bone by means of a facet which covers all but the antero-inferior part of the surface.

THE METACARPUS

General features.—The **metacarpus** (figs. 420-423) comprises five metacarpal bones, which are numbered from the lateral to the medial side. They are miniature long bones, and each possesses a rounded head, a shaft and an expanded base. The *head* is at the distal end of the bone and articulates with the proximal phalanx. Its oblong, articular surface is convex, the degree of convexity being less in the transverse than in the anteroposterior direction, and extends farther upwards on the palmar surface than on the dorsal surface. The prominence of the knuckles is produced by the heads of the metacarpal bones. The *bases* of the metacarpal bones are formed by their expanded proximal ends, which articulate with the distal row of the carpus and with one another—save that the first metacarpal bone is isolated from the rest and does *not* articulate with the metacarpal bone of the index. The *shafts* are concave longitudinally on their palmar surfaces, an arrangement which provides a hollow for the lodgment of the muscles of the palm. The dorsal surface of each presents a flattened triangular area in its distal part, continued proximally as a rounded ridge. These flattened areas can be felt on the back of the hand in the living subject immediately proximal to the knuckles.

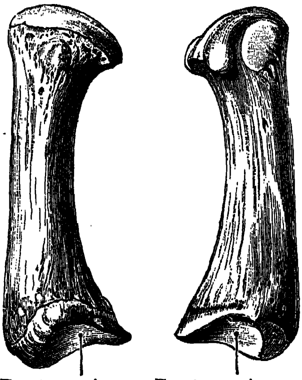
It should be observed that, whereas the medial four metacarpal bones lie side by side, the first metacarpal bone lies on a more anterior plane and that it is rotated medially round its long axis through an angle of 90°. As a result of this rotation its morphologically dorsal surface is directed to the lateral side, its radial border forwards, its palmar surface medially, and its ulnar border backwards. By virtue of its anterior position the thumb moves medially in front of the palm when it is flexed and it can be opposed to each of the fingers in turn. The ability to oppose the thumb to the fingers is rendered possible by the rotation of the bone medially. It is the most important factor in rendering the hand an efficient instrument for prehension, for, when an object is grasped in the hand, the fingers encircle it from one side and the thumb from the other, and the power of the grip is increased very greatly thereby.

THE CHARACTERS OF THE INDIVIDUAL METACARPAL BONES

The first metacarpal bone (fig. 432) is shorter and stouter than any of the others. Its dorsal surface is directed laterally, a fact which can easily be confirmed in the living hand, and its long axis passes downwards and laterally, diverging from its neighbour. The *shaft* is flattened and its dorsal surface is uniformly broad and convex from side to side. The palmar surface is concave from above downwards and is subdivided by a rounded ridge into a larger anterolateral and a smaller anteromedial surface. The opponens pollicis is inserted

into the radial border and the adjoining part of the anterolateral surface; the radial head of the first dorsal interosseous muscle arises from the ulnar border and the adjoining part of the anteromedial surface. The *base* presents a concavoconvex surface for articulation with the trapezium (greater multangular bone). On its lateral side it receives the insertion of the abductor pollicis longus; its ulnar side gives origin to the first palmar interosseous muscle (deep head of the flexor pollicis brevis). The *head* is less convex than the heads of the other metacarpal bones, and is broader from side to side than from before backwards. On its palmar surface the ulnar and radial corners are enlarged to form two articular eminences, on each of which a sesamoid bone glides.

Fig. 432.—The first left metacarpal bone. Lateral and medial aspects.



The **second metacarpal bone** (fig. 433) is the longest of all the metacarpal bones, and its base is the largest. It can be identified by its grooved *base*. This groove (fig. 629) is concave from side to side and convex anteroposteriorly: it articulates with the trapezoid (lesser multangular) bone. It is bounded on its medial side by a deep ridge, the edge of which articulates with the capitate bone. The lateral side of the base is marked, nearer the dorsal than the palmar surface, by a small, quadrangular facet for the trapezium (os multangulum majus). Immediately behind this facet, i.e. on the lateral part of the dorsal surface of the base, a small rough impression gives insertion to the extensor carpi radialis longus. The palmar surface provides a small tubercle or ridge for the insertion of the flexor carpi radialis. The medial side of the base articulates with the lateral side of the base of the third metacarpal bone by a strip-like facet which is constricted at its middle.

The *shaft* is prismoid in form and curved so as to be convex backwards in its long axis and concave forwards. It has medial, lateral and dorsal surfaces. The dorsal surface is broad near the head but narrows into a ridge as it approaches the base. This surface is covered by the extensor tendons of the index finger, and its converging borders commence

Fig. 433.—The second left metacarpal bone. Dorsilateral and medial aspects.

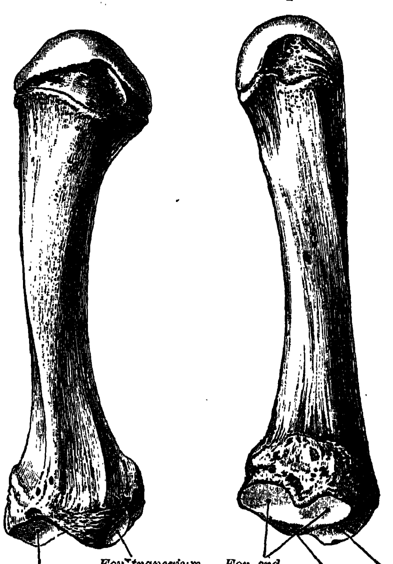


Fig. 434.—The third left metacarpal bone. Lateral and medial aspects.

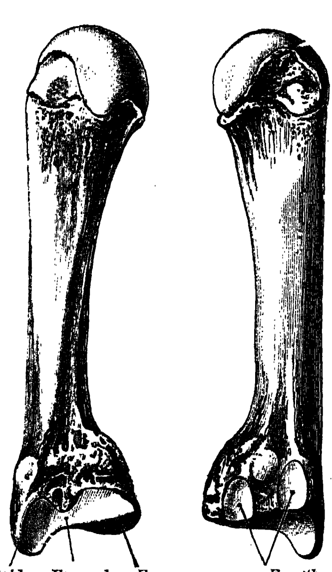

in two little tubercles, which are situated one on each side of its head. The *lateral surface* inclines dorsally at its proximal end: it gives origin to the ulnar head of the first dorsal interosseous muscle. The *medial surface* also inclines dorsally at its proximal end and is divided into two nearly parallel strips by a faint ridge. Of these, the anterior gives origin to the second palmar interosseous and the posterior to the radial head of the second dorsal interosseous muscle.

The tubercles at the side of the head provide attachment for the collateral ligaments of the metacarpophalangeal joint.

The **third metacarpal bone** (fig. 434) can be identified by means of the short *styloid process* which projects upwards from the radial side of the dorsal surface of its base. The *base* articulates, proximally, with the capitate bone by means of a facet which is convex in front but concave behind, where it covers the anteromedial aspect of the styloid process. The lateral aspect of the base is marked by a strip-like facet, constricted at its middle, for articulation with the metacarpal bone of the index. On its medial side it articulates with the base of the fourth metacarpal bone by means of two small, discrete oval facets. Sometimes the anterior facet is absent, and less frequently the two may be connected by a narrow bridge along the medial border of the base. The palmar surface of the base receives a slip from the flexor carpi radialis tendon, while its dorsal surface, immediately beyond the styloid process, gives insertion to the extensor carpi radialis brevis.

The *shaft* resembles the shaft of the metacarpal bone of the index. Its lateral surface gives origin to the ulnar head of the second dorsal interosseous and its medial surface to the radial head of the third dorsal interosseous muscle. The palmar ridge which separates these two surfaces gives origin, in its distal two-thirds, to the transverse head of the adductor pollicis. Its dorsal surface is covered by the extensor tendon of the middle finger.

Fig. 435.—The fourth left metacarpal bone. Lateral and medial aspects.

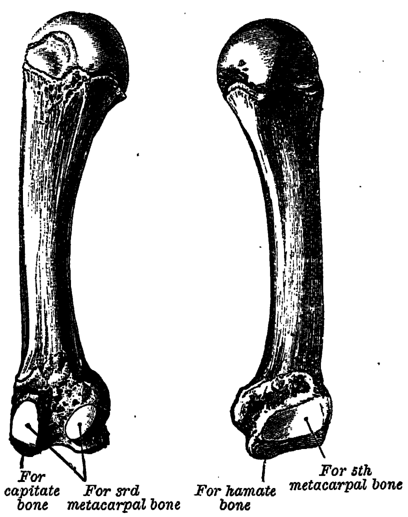

Fig. 436.—The fifth left metacarpal bone. Lateral and medial aspects.

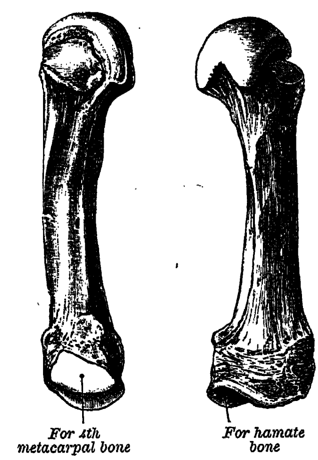


The **fourth metacarpal bone** (fig. 435) is shorter and more slender than the metacarpal bones of the index and middle fingers. It can be identified by examination of the sides of its *base*. The lateral aspect bears two small, oval, discrete facets for articulation with the third metacarpal bone. Of these the posterior is usually (but not always) the larger, and its proximal part comes into contact with the capitate bone. The medial aspect is marked by a single elongated facet for the fifth metacarpal bone. The proximal surface articulates with the hamate bone by a quadrangular facet which is convex in front and concave behind.

The *shaft* resembles the shaft of the metacarpal bone of the index finger, but its lateral surface is traversed by a faint ridge, which separates the origin of the third palmar interosseous in front, from the origin of the ulnar head of the third dorsal interosseous muscle, behind. The medial surface gives origin to the radial head of the fourth dorsal interosseous muscle.

The **fifth metacarpal bone** (fig. 436) can be identified by the fact that the medial surface of the *base* is non-articular and presents a tubercle for the insertion of the extensor carpi ulnaris. The proximal surface of the base is covered by a facet, concave from side to side and convex from before backwards, for articulation with the hamate bone. Its lateral aspect presents an elongated strip-like facet for the fourth metacarpal bone.

The *shaft* is characterised by the fact that the triangular area on its dorsal surface reaches almost to the base and that only the lateral surface inclines dorsally at its proximal end. The medial surface gives insertion to the opponens digiti minimi; the lateral surface is divided by a longitudinal ridge, sometimes quite sharp and distinct, into an anterior strip for the origin of the fourth palmar interosseous, and a posterior strip for the origin of the ulnar head of the fourth dorsal interosseous muscle.

THE PHALANGES OF THE HAND

General features.—The **phalanges** are fourteen in number, three for each finger and two for the thumb. Each has a head, a shaft and a base or proximal end. In each the *shaft* tapers to its distal end and its dorsal surface is convex. The palmar surface is flattened from side to side, but is gently concave forwards in its long axis. The *bases* of the proximal phalanges are marked by concave, oval facets for articulation with the heads of the metacarpal bones. Their *heads* are pulley-shaped and ascend farther on the palmar than on the dorsal surfaces. To conform to the shape of the head of the proximal phalanx, the base of a middle phalanx is marked by two small, concave facets separated by a smooth ridge. The head of the middle phalanx also is pulley-shaped and the base of the distal phalanx conforms to it. The head of the distal phalanx is non-articular, but is marked on its palmar surface by a rough, horseshoe-shaped *tuberosity*, which serves to support the pulp of the finger-tip.

Particular features.—In addition to providing attachment for the ligaments of the joints in which they participate, the phalanges give insertion to numerous muscles. The base of the distal phalanx gives attachment on its palmar surface to the corresponding tendon of the *flexor digitorum profundus* and on its dorsal surface to the *extensor digitorum*. The sides of the middle phalanx receive the insertion of the *flexor digitorum sublimis* tendon (p. 600) and the *fibrous flexor sheath*. Its base gives attachment on its dorsal surface to a part of the *extensor digitorum* tendon. The sides of the proximal phalanx give attachment to the *fibrous flexor sheath*. Its base receives, on its lateral side, part of the insertion of the corresponding *lumbrical muscle* and an *interosseous muscle*, and on its medial side another *interosseous muscle*.

The phalanges of the *little finger* and the *thumb* differ in certain respects from the other three. The medial side of the base of the proximal phalanx of the little finger receives the insertion of the *abductor digiti minimi* and the *flexor digiti minimi*. The base of the proximal phalanx of the thumb receives on its dorsal surface the tendon of the *extensor pollicis brevis*; on its lateral surface the *abductor pollicis brevis*, the *flexor pollicis brevis* and the lateral part of the *oblique head* of the *adductor pollicis*; and, on its medial surface, the *transverse* and the remainder of the *oblique head* of the *adductor pollicis* and the *first palmar interosseous muscle* (deep head of the *flexor pollicis brevis*). The margins of the proximal phalanx of the thumb are not sharp like those of the other digits, as the fibrous flexor sheath is not so strongly developed in the case of the thumb.

THE OSSIFICATION OF THE BONES OF THE HAND

The centre for the capitate bone, which may be present at birth in the female, is the first to appear and that for the pisiform bone is the last, but the order in which the other carpal bones ossify is subject to considerable variation. *In the male*, the capitate and the hamate ossify during the first year; the triquetral bone, during the third year; the lunate, trapezium and scaphoid bones, during the fifth and sixth years; the trapezoid bone, during the eighth year; and the pisiform bone, about the twelfth year.

Occasionally an additional bone, named the *os centrale*, is found between the scaphoid, trapezoid and capitate bones. During the second month of intra-uterine life it is represented by a small cartilaginous nodule which usually fuses with the cartilaginous scaphoid. Sometimes the styloid process of the third metacarpal bone is detached and forms an additional ossicle.

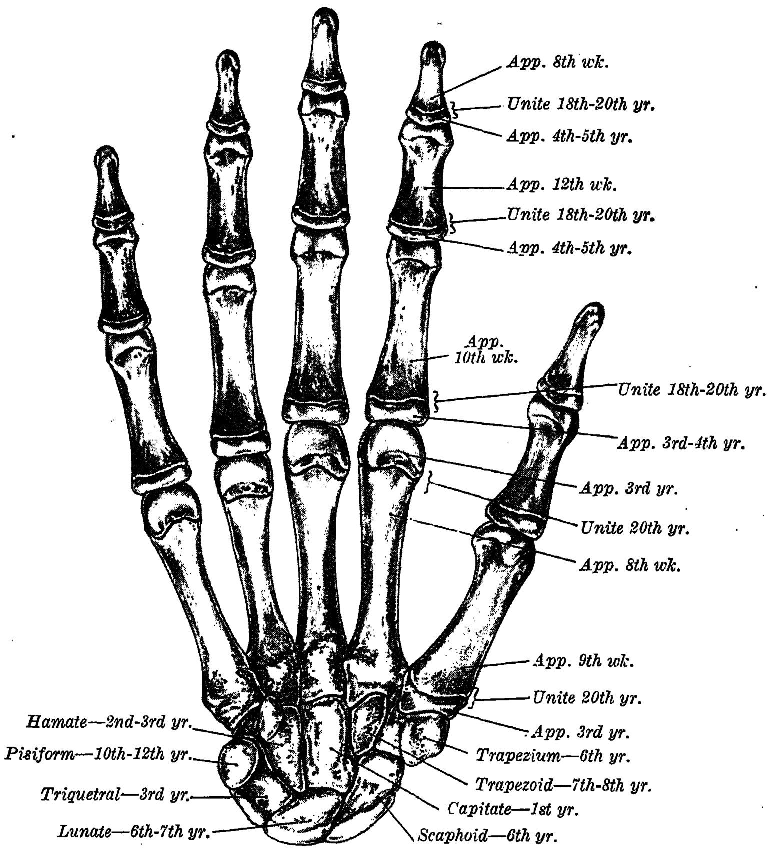
The **metacarpal bones** are each ossified from two centres: a primary centre for the shaft, and a secondary or epiphyseal centre for the base or proximal end of the first and for the head or distal end of each of the other four. The metacarpal bone of the thumb is ossified like a phalanx, and therefore some anatomists look upon the skeleton of the thumb as consisting of three phalanges, and not of a metacarpal bone and two phalanges; others believe that the distal phalanx represents fused middle and distal phalanges, a condition which has occasionally been observed in the little toe.* Ossification begins in the middle of the shaft about the eighth or ninth week of intrauterine life, the centres for the second and third metacarpal bones being the first to appear, and that for the first metacarpal bone the last. About the third year the base of the first

* See note on opposite page.

metacarpal bone, and the heads of the other metacarpal bones, begin to ossify; they unite with the shafts about the twentieth year.

It has been suggested (Parsons) that the presence of an epiphysis only at the distal end of a typical metacarpal may be associated with the greater range of movement which the metacarpophalangeal joint enjoys. In the thumb, on the other hand, it is the carpometacarpal joint which possesses the wider range of movement, and the presence of a basal epiphysis in the first metacarpal bone may be attributable to this fact.* Occasionally a distal epiphysis also is present in the first, and a basal or proximal epiphysis sometimes occurs in the second metacarpal.

FIG. 437.—The bones of the hand of a child, indicating the general plan of ossification.



The **phalanges** are each ossified from two centres; a primary centre for the shaft, and a secondary or epiphyseal centre for the proximal extremity. Ossification begins in the shaft about the eighth week of intrauterine life. The epiphyses for the bases of the proximal row of phalanges appear between the third and fourth years, and those for the middle and distal rows of phalanges a year later. All unite with the shafts between the eighteenth and twentieth years.

In the distal phalanges the centres for the shafts appear at the distal ends instead of at the middle of the shafts, as in the other phalanges. Moreover, of

* Broom (*Origin of the Human Skeleton*, Witherby, London, 1930) has put forward an ingenious explanation for the peculiar mode of ossification of the metacarpal bone of the thumb. His theory has recently been subjected to serious criticism by Nicholson ("Studies on Tumour Formation," *Guy's Hospital Reports*, vol. 87, No. 1, 1937), who has brought forward evidence to show that, when the thumb possesses an additional phalanx, the condition is always associated with the presence of a distal as well as a proximal epiphysis for its metacarpal bone. The metacarpal bone of the thumb sometimes bifurcates at its distal end. In these cases the medial branch, which has a distal epiphysis, bears a digit with three phalanges, while the lateral branch, which has no distal epiphysis, bears a digit with two phalanges.

all the bones of the hand, the distal phalanges are the first to ossify, and the middle phalanges the last.

Applied Anatomy.—The use of X-rays has shown that the carpal bones are more frequently fractured than was formerly supposed. When a single bone is broken it is usually the scaphoid or the capitate (more frequently the scaphoid) and the fracture runs at right angles to the long axis of the bone.

THE BONES OF THE LOWER LIMB

THE HIP-BONE (OS COXÆ)

General features.—The **hip-bone** (figs. 438-441) is a large, irregularly shaped bone, constricted in the middle and expanded above and below. Its *lateral surface* is marked near its middle by a deep, cup-shaped hollow, termed the **acetabulum,** which forms a secure socket for the rounded head of the femur. *Below* and *in front of* the acetabulum the bone presents a large, oval, or triangular, gap, termed the **obturator foramen.** *Above* the acetabulum the bone forms a wide, flattened plate, with a long, curved upper border termed the **iliac crest.** With this information the student should have no difficulty in assigning a given hip-bone to its appropriate side of the body.

The hip-bone articulates in front with the corresponding bone of the opposite side and the two bones form the pelvic girdle or girdles of the lower limbs (p. 331). Each consists of three parts, named the ilium, the ischium and the pubis, which are connected by cartilage in the young subject but are united by bone in the adult; the union of the three parts takes place in the walls of the acetabulum. The lines of fusion are shown as stippled bands in figs. 439 and 441. The *ilium* includes the upper part of the acetabulum and the expanded, flattened area of bone above it; the *ischium* includes the lower part of the acetabulum and the bone below and behind; the *pubis* forms the anterior part of the acetabulum and separates the ilium from the ischium in this situation; in addition, it forms the anterior part of the lower portion of the hip-bone and meets the pubis of the opposite side in the median plane.

The ilium.—General features. The ilium, so named because it supports the flank, possesses two ends and three surfaces. The lower end is the smaller and forms rather less than the upper two-fifths of the articular surface of the acetabulum; the upper end is greatly expanded and compressed to form the *iliac crest.* The surfaces are named the gluteal surface, the sacropelvic surface and the iliac fossa. The *gluteal surface* is directed backwards and laterally and forms an extensive rough area; the *iliac fossa* is smooth and gently hollowed out and occupies the anterior and upper part of the medial aspect of the ilium; the *sacropelvic surface* also is placed on the medial aspect and lies behind and below the iliac fossa, separated from it by a ridge termed the *medial border.*

The *iliac crest* is situated at the upper end of the ilium. It is convex upwards in its general outline, but is sinuously curved, being concave inwards in front and concave outwards behind. Its anterior and posterior extremities project a little beyond the bone below and are termed respectively the anterior and the posterior superior iliac spines. The *anterior superior spine* lies at the lateral end of the fold of the groin and can be felt without difficulty in the living subject; the *posterior superior spine* cannot be felt but it can be identified readily, because its position is indicated by a small dimple, which lies about 4 cm. lateral to the second spinous tubercle of the sacrum above the medial part of the buttock. Morphologically the crest consists of a long ventral and a shorter dorsal segment. The ventral segment forms rather more than the anterior two-thirds of the crest and is associated with alterations in the form of the ilium which were necessitated by the adoption of the erect attitude; the dorsal segment forms rather less than the posterior third of the crest and can be identified in all animals. The ventral segment of the crest is bounded by an *outer* and an *inner lip*, enclosing a rough *intermediate area*, which is narrowest at its middle and becomes wider both in front and behind. The *tubercle of the crest* (fig. 438) forms a prominent projection on the outer lip about 5 cm. or more behind and above the anterior superior spine. The dorsal segment presents two

sloping surfaces separated by a well-marked ridge, which terminates in the posterior superior spine. The highest point of the crest, which is a little behind its midpoint, is on the same level as the upper border of the body of the fourth lumbar vertebra.

The *lower end* of the ilium will be described with the acetabulum (p. 377).

The *anterior border* of the ilium descends to the acetabulum from the anterior superior spine. Its upper part is rounded and concave forwards; its lower part presents a roughened projection, termed the *anterior inferior iliac spine*, which lies immediately above the acetabulum.

The *posterior border* is irregularly curved (fig. 438). It commences at the posterior superior spine and runs at first downwards and forwards, with a backward concavity, forming a small notch. At the lower end of the notch the bone presents a wide, low projection, termed the *posterior inferior spine*, where the posterior border makes a sharp bend. It then runs almost horizontally forwards for about 3 cm. and finally turns downwards and backwards to become continuous with the posterior border of the ischium. As a result the posterior border shows a deep notch, termed the *greater sciatic notch*, which is bounded above by the ilium and below by the ilium and ischium.

The *medial border* is placed on the medial surface of the bone and separates the iliac fossa from the sacropelvic surface. Indistinct near the crest, it is roughened in its upper part, then sharp and clear-cut where it bounds the articular surface for the sacrum, and finally smooth and rounded. The last-named portion forms the *iliac part of the arcuate line*—the line marks the inlet of the true pelvis; at its inferior end it reaches the posterior part of the *iliopubic* (*iliopectineal*) *eminence*, which is placed at the union of the ilium with the pubis.

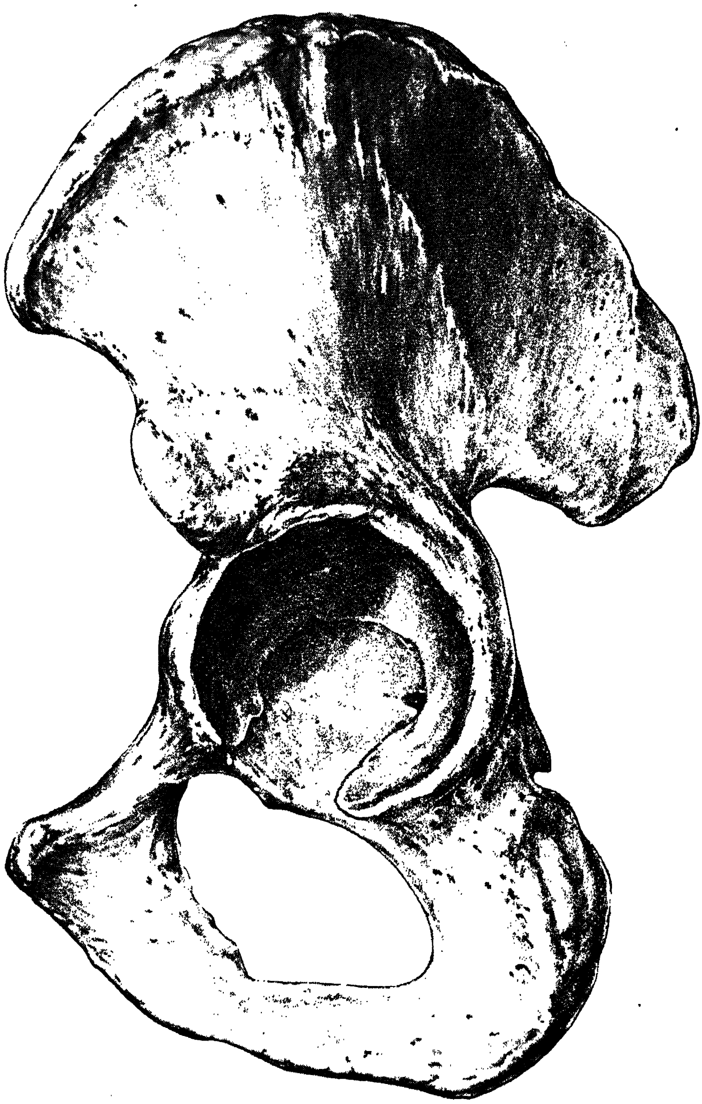
The *gluteal surface* (fig. 438) is directed backwards and laterally in its posterior part, and laterally and slightly downwards in front. It is bounded above by the iliac crest, below by the upper border of the acetabulum and in front and behind by the anterior and posterior borders. The surface, as a whole, is smooth and curved, being convex in front and concave behind, but it is marked by three roughened ridges termed the posterior, middle and inferior gluteal lines. The *posterior gluteal line*, which is the shortest of the three, begins above on the outer lip of the crest about 5 cm. in front of its posterior extremity and ends below a short distance in front of the posterior inferior spine. Its upper part is usually distinct, but its lower part is ill-defined and frequently absent. The *middle gluteal line* (anterior gluteal line), which is the longest of the three, begins about the middle of the upper margin of the greater sciatic notch and runs upwards and forwards to become confluent with the outer lip of the crest a little in front of the tubercle. The *inferior gluteal line*, which is rarely a prominent feature, begins a little above and behind the anterior inferior spine and curves backwards and downwards to end near the apex of the greater sciatic notch. Between the inferior gluteal line and the margin of the acetabulum there is a rough, shallow groove on the bone. Behind the acetabulum the lower part of the gluteal surface becomes continuous with the posterior surface of the ischium. The site of union of these two elements is marked by a low elevation.

The *iliac fossa* occupies the anterior and upper part of the medial aspect of the ilium. It is limited above by the iliac crest; in front by the anterior border, and behind by the medial border, by which it is separated from the sacropelvic surface. The surface is smooth and gently concave and forms the posterolateral wall of the false pelvis. Below it is continuous with a shallow groove (fig. 440) bounded laterally by the anterior inferior spine and medially by the iliopubic (iliopectineal) eminence.

The *sacropelvic surface* (fig. 440) occupies the posterior and lower part of the medial aspect of the ilium. It is bounded behind and below by the posterior border, in front and above by the medial border, and above and behind by the iliac crest. It is subdivided into three areas, viz., the iliac tuberosity, the auricular surface and the pelvic surface. The *iliac tuberosity* is an extensive, roughened, tuberculated and pitted area which lies immediately below the dorsal segment of the iliac crest. It gives attachment to the strong ligaments on the dorsal surface of the sacro-iliac joint. The *auricular surface* (fig. 440) is placed immediately below and in front of the tuberosity, and articulates with the lateral mass of the sacrum. It is shaped like the auricle—the wide expanded portion lying above and in front, and the

lobule below and behind, covering the medial aspect of the posterior inferior spine. The edges are sharp and clearly defined, but the surface, although articular, is finely roughened and irregular. The *pelvic surface* lies below and in front of the auricular surface and helps to form the wall of the true pelvis. It comprises an upper and a lower portion. The upper portion faces downwards and lies between the margin of the auricular surface and the upper border of the greater sciatic notch.

FIG. 438.—The left hip-bone. External surface.

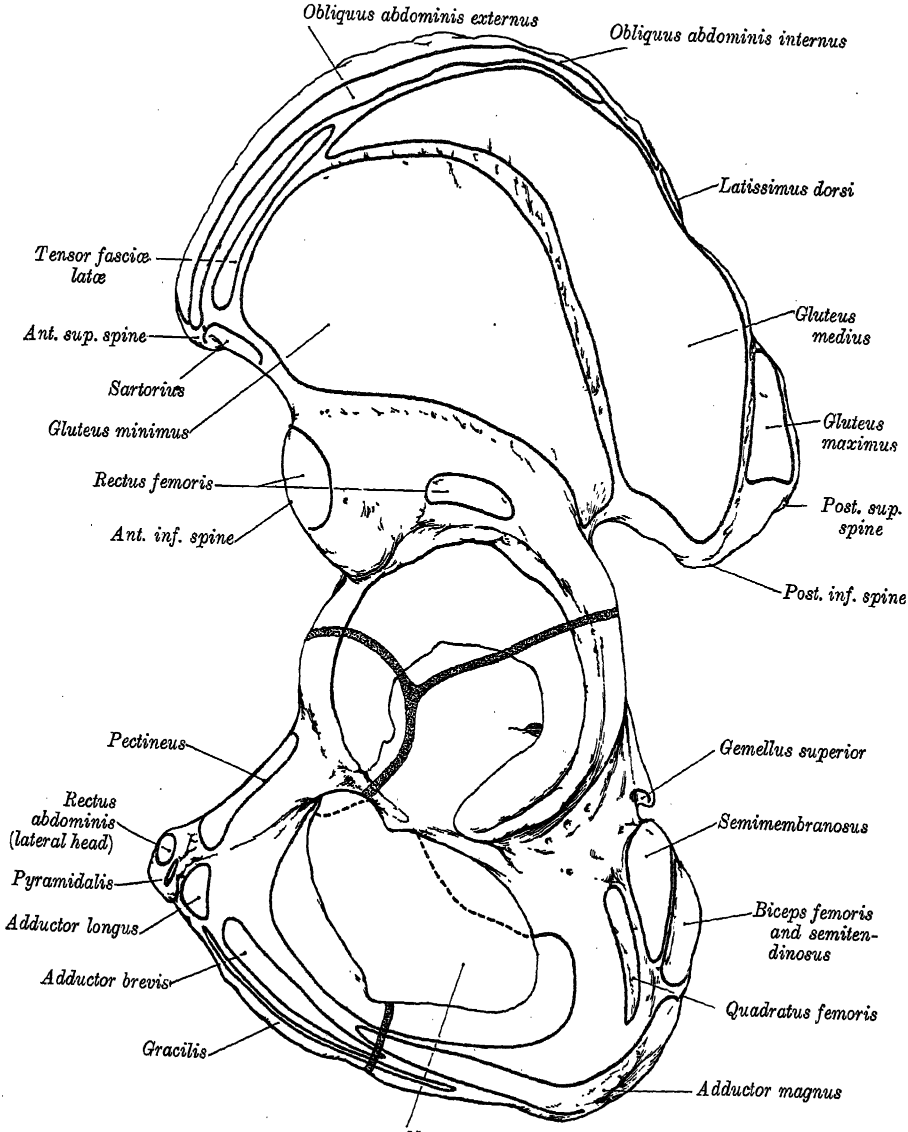


The lower portion faces inwards and is separated from the iliac fossa by the iliac part of the arcuate line. The line of union of the ilium with the ischium is completely obliterated on this surface.

Particular features.—The iliac crest forms the lower limit of the waist and gives attachment to the lateral muscles of the abdominal wall, to fasciæ and muscles of the lower limb and to muscles and fasciæ of the back (figs. 439, 441). The *outer lip* of the ventral segment (p. 368) gives attachment to the fascia lata, including the iliotibial tract; in front of the tubercle of the crest it gives origin to the tensor fasciæ latæ: in its anterior two-thirds it provides insertion for the lower fibres of the external oblique; and just behind its highest point it gives origin to the lowest fibres of the latissimus dorsi. An interval of variable size

intervenes between the posterior limit of the insertion of the external oblique and the anterior limit of the origin of the latissimus dorsi ; in this situation the crest forms the base of the lumbar triangle. The *intermediate area* gives origin to the internal oblique muscle. The *inner lip* in its anterior two-thirds gives origin to the transversus muscle ; and behind that to the lumbar fascia and the quadratus lumborum muscle. The dorsal segment (p. 368) gives origin on its lateral slope to the highest fibres of the gluteus maximus, and on its medial slope to the sacrospinalis muscle.

FIG. 439.—Key to fig. 438.



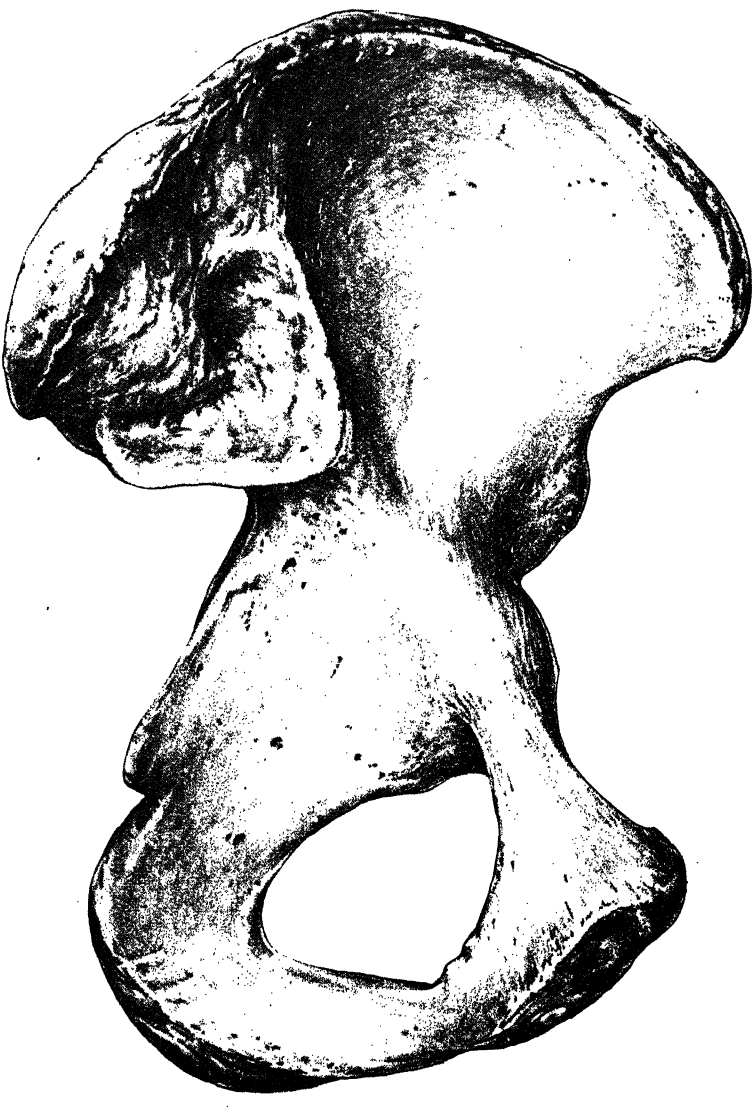
The anterior superior spine gives attachment to the lateral end of the inguinal ligament and below that to the sartorius muscle, which extends downwards for a short distance on the *anterior border*. The anterior inferior spine is divided indistinctly into two areas. The upper gives origin to the straight head of the rectus femoris and is placed on the front of the spine. The lower covers the inferior part of the spine and extends in a lateral direction along the upper margin of the acetabulum ; it is a rough impression, irregularly triangular in shape, and gives attachment to the strong iliofemoral ligament.

The upper part of the posterior border gives attachment to the upper fibres of the sacrotuberous ligament. In front of the posterior inferior spine (i.e. on the upper border of the greater sciatic notch), it gives origin to fibres of piriformis and, in front of that, is related to

the superior gluteal vessels and nerve as they emerge from the pelvis. The lower part of the posterior border (i.e. the lower margin of the greater sciatic notch) is covered by the piriformis muscle and is related to the sciatic nerve, although the nerve lies for the most part on the ischium.

The gluteal surface is divided into four areas by the three gluteal lines (fig. 438). (*a*) The area behind the posterior gluteal line gives origin in its upper roughened part to the upper

FIG. 440.—The left hip-bone. Internal surface.

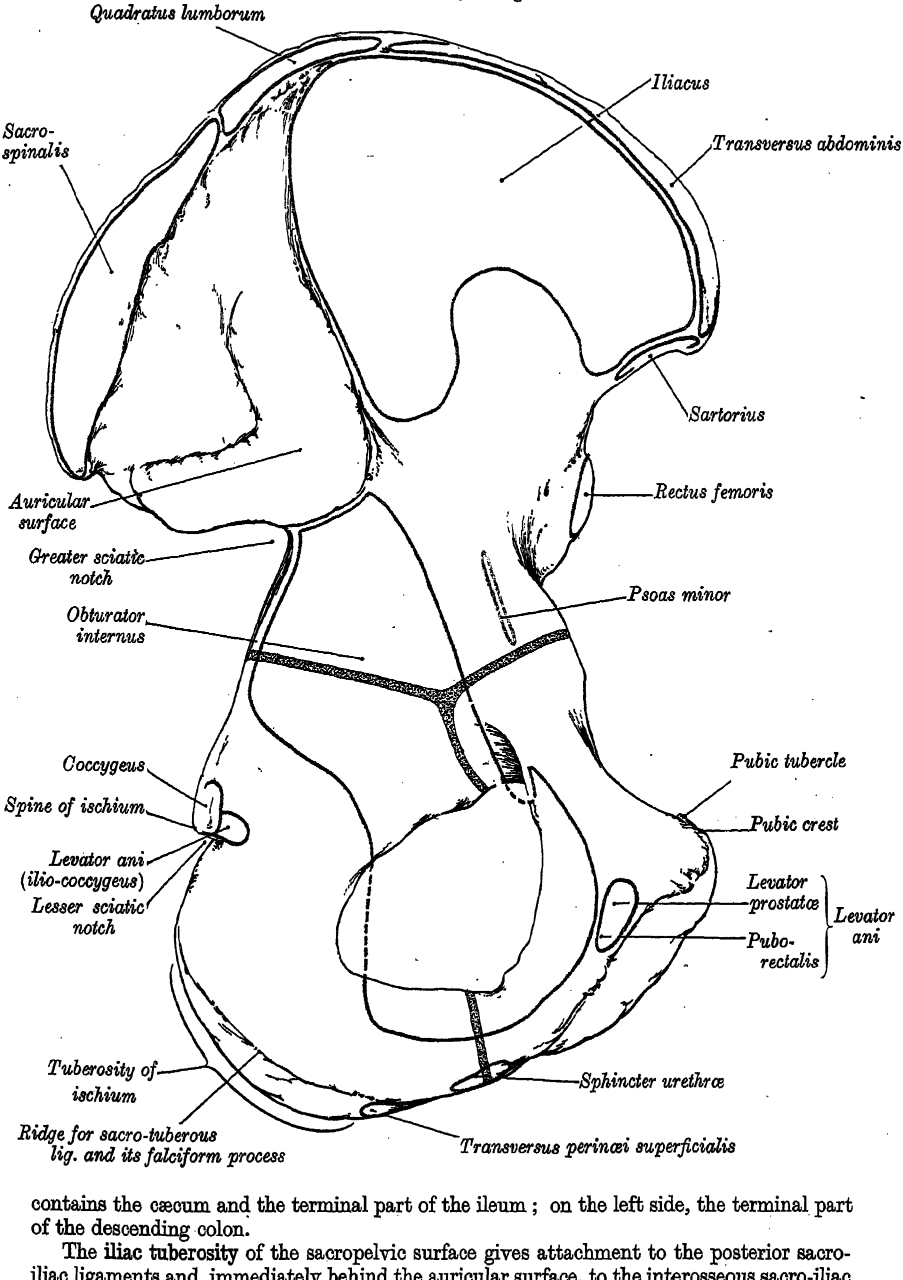


fibres of the gluteus maximus; its lower, smooth part gives attachment to some of the fibres of the sacrotuberous ligament. (*b*) The area between the posterior and middle gluteal lines, bounded above by the iliac crest, gives origin to the gluteus medius muscle. (*c*) The area between the middle and inferior gluteal lines gives origin to the gluteus minimus muscle. (*d*) The area below the inferior gluteal line is marked by numerous vascular foramina. The groove above the acetabulum gives origin to the reflected head of the rectus femoris, and the area adjoining the rim of the acetabulum affords attachment to the capsular ligament of the hip-joint. The greater part of this area is covered by the gluteus minimus muscle, but behind and below in the neighbourhood of the site of union of the ilium and ischium, the bone is related to the piriformis muscle.

The upper two-thirds of the iliac fossa provides origin for the iliacus muscle (fig. 441),

which covers the lower third but is not attached to it. Branches of the iliolumbar artery run between the muscle and the bone, and one of them enters the large nutrient foramen which is often present at the postero-inferior part of the fossa. The groove between the anterior inferior spine and the iliopubic eminence is occupied by the converging fibres of the iliacus muscle laterally and the tendon of psoas major medially; the tendon is separated from the bone near the acetabulum by its synovial bursa. On the right side the iliac fossa

FIG. 441.—Key to fig. 440.



contains the cæcum and the terminal part of the ileum; on the left side, the terminal part of the descending colon.

The **iliac tuberosity** of the sacropelvic surface gives attachment to the posterior sacro-iliac ligaments and, immediately behind the auricular surface, to the interosseous sacro-iliac ligament. The upper and anterior part of the tuberosity gives attachment to the iliolumbar ligament, and this area lies immediately below the medial part of the origin of the quadratus lumborum from the iliac crest. The **auricular surface** articulates with the upper two and a half sacral vertebræ (two only, as a rule, in the female). Its anterior and inferior borders are sharp and give attachment to the anterior sacro-iliac ligament. The upper part of the **pelvic surface**, between the inferior margin of the auricular surface and the upper

margin of the greater sciatic notch, is often marked in female subjects by a roughened groove, which is termed the *pre-auricular sulcus*; it gives attachment to the lower fibres of the anterior sacro-iliac ligament. Lateral to the sulcus the bone gives origin to fibres of the piriformis muscle. The rest of the pelvic surface gives origin to the upper half or less of the obturator internus muscle.

The pubis.—General features. The **pubis** forms the anterior part of the hip-bone and meets the pubis of the opposite side in the median plane to form a cartilaginous joint, termed the pubic symphysis. It possesses a body,* which lies anteriorly; a superior ramus, which passes upwards and backwards to the acetabulum; and an inferior ramus, which passes backwards, downwards and laterally to unite with the ramus of the ischium on the medial side of the obturator foramen.

The *body* is compressed from before backwards and presents anterior, posterior and symphyseal (or medial) surfaces and a free upper border termed the *pubic crest.* The *anterior surface* faces downwards, forwards and slightly laterally in the erect posture; rough in its upper and medial parts, it presents a smooth surface elsewhere. It is directed towards the lower limb and affords attachment for the medial group of muscles of the thigh. The *posterior surface* is smooth and faces upwards and backwards, forming the anterior wall of the true pelvis; it is related to the urinary bladder. The *symphyseal surface* is an elongated oval area, covered with cartilage in the recent state and articulating with the opposite pubis at the pubic symphysis. When denuded of cartilage it presents an irregular surface, marked by a number of small ridges and furrows or by small nodular elevations. The *pubic crest* is the rounded upper border of the body. It is projected forwards and overhangs the upper part of the anterior surface (fig. 438). Its lateral extremity forms a rounded projection termed the *pubic tubercle.* Both the crest and the tubercle can be felt through the skin in the living subject, but the latter is obscured by the spermatic cord, which crosses its upper aspect as it passes upwards from the scrotum to pierce the abdominal wall.

The *superior ramus* of the pubis springs from the upper and lateral part of the body, and passes backwards, upwards and laterally above the obturator foramen to reach the acetabulum. It is triangular on section and has three surfaces and three borders. The *pectineal surface* is directed forwards and slightly upwards. Triangular in outline, it extends from the pubic tubercle to the iliopubic eminence (fig. 438). It is bounded in front by a rounded ridge termed the *obturator crest,* and behind by a sharp edge termed the *pectineal line,* which together with the pubic crest constitutes the pubic part of the arcuate line. The *pelvic surface,* which is directed upwards, backwards and medially, is smooth and featureless; it is narrower at its lateral than at its medial extremity, where it is continuous with the posterior surface of the body. It is bounded above by the pectineal line and below by a sharp edge which forms the *inferior border.* The *obturator surface* is directed downwards and backwards, and is crossed from behind forwards and downwards by a groove termed the *obturator groove.* It is bounded in front by the obturator crest and behind by the inferior border.

The *inferior ramus* springs from the lower and lateral part of the body and passes backwards, downwards and laterally to unite with the ramus of the ischium on the medial side of the obturator foramen. The site of union may be marked by a localised thickening, but is often difficult to identify in the adult bone. The ramus has two surfaces and two borders. The *anterior* or *outer surface* is continuous above with the anterior surface of the body; it is directed towards the thigh and is roughened for muscular attachments. It is bounded laterally by the margin of the obturator foramen and medially by a rough anterior border. The *posterior* or *inner surface* is continuous above with the posterior surface of the body, and is convex from side to side. Its medial part is often prominently everted in male subjects (fig. 448) and is in contact with the crus of the penis. It is directed medially towards the perineum. Its lateral part is smooth and is directed upwards towards the pelvis.

Particular features.—The pubic tubercle gives attachment to the medial end of the inguinal ligament; it lies in the floor of the superficial inguinal ring (subcutaneous inguinal ring) and is crossed by the spermatic cord. The ascending limbs of the loops of the cre-

* The body of the pubis in the B.N.A. is the portion of the bone which takes part in the formation of the acetabulum.

master muscle are attached to the tubercle and to the anterior wall of the sheath of the rectus abdominis muscle. The lateral part of the **pubic crest** gives origin to the lateral head of the rectus abdominis, and the bone below to the pyramidalis. The medial part of the crest is crossed by the medial head of the rectus abdominis, which takes origin from an interlacement of fibres in front of the upper part of the pubis and pubic symphysis. The *anterior surface* of the body is directed towards the adductor region of the thigh. A roughened strip, usually wider in the female, marks the medial part of the surface and gives attachment to the anterior pubic ligament. In the angle between the upper end of this strip and the pubic crest the rounded tendon of the adductor longus takes origin. At a slightly lower level the gracilis arises from a linear origin close to the medial border of the body and extending downwards on to the inferior ramus. Lateral to the gracilis the adductor brevis arises from the body and the inferior ramus. The lateral part of the anterior surface, and the adjoining portions of both rami provide origin for the obturator externus muscle (fig. 439).

The **posterior surface** of the body is separated from the urinary bladder by the retropubic pad of fat. About its middle it provides origin for the anterior fibres of the levator ani muscle, and more laterally the obturator internus arises from this surface and extends on to both rami. Medial to the origin of the levator ani, the puboprostatic ligaments are attached to the bone.

The *pectineal surface* of the **superior ramus** gives origin, along its upper part, to the pectineus muscle, which covers the rest of the surface (fig. 439) but is not attached to it. The **pectineal line**, which forms the upper boundary of the pectineal surface, is a salient, sharp ridge. At its medial end it gives attachment to the conjoint tendon (falx inguinalis aponeurotica) and the pectineal part of the inguinal ligament (lacunar ligament), and throughout the rest of its extent it affords attachment to a strong fibrous band termed the pectineal ligament (p. 564). About its middle it receives the insertion of the psoas minor. The *pelvic surface* is smooth and is not covered with muscle or fascia. It is separated from the parietal peritoneum only by the intervening subperitoneal tissue, in which the lateral umbilical ligament (obliterated hypogastric artery) runs downwards and forwards across the ramus and, near its lateral end, the vas deferens passes backwards. The *obturator groove* on the obturator surface is converted into a canal by the upper borders of the obturator membrane, the obturator internus and the obturator externus muscles. It transmits the obturator vessels and nerve from the pelvis to the thigh, where they emerge under cover of the pectineus muscle. The *obturator crest* (fig. 438) at its lateral end gives attachment to some of the fibres of the pubofemoral ligament.

The *outer surface* of the **inferior ramus** gives origin to the gracilis, the adductor brevis and the obturator externus, named from the medial to the lateral side. In addition, the origin of the adductor magnus usually extends from the ramus of the ischium on to the lower part of the inferior ramus of the pubis in the interval between the adductor brevis and the obturator externus. The *inner surface* is divided into a medial, an intermediate and a lateral area, but they are not separated from one another by clear-cut markings on the bone. The medial area faces downwards and medially and is in direct contact with the crus penis; it is limited above and behind by an indistinct ridge which gives attachment to the perineal membrane (inferior fascia of the urogenital diaphragm). The intermediate area gives origin to the sphincter urethræ muscle. The lateral area gives origin to fibres of the obturator internus muscle. The *medial margin* of the ramus is strongly everted in the male and gives attachment to the fascia lata and to the membranous layer of the superficial fascia of the perineum.

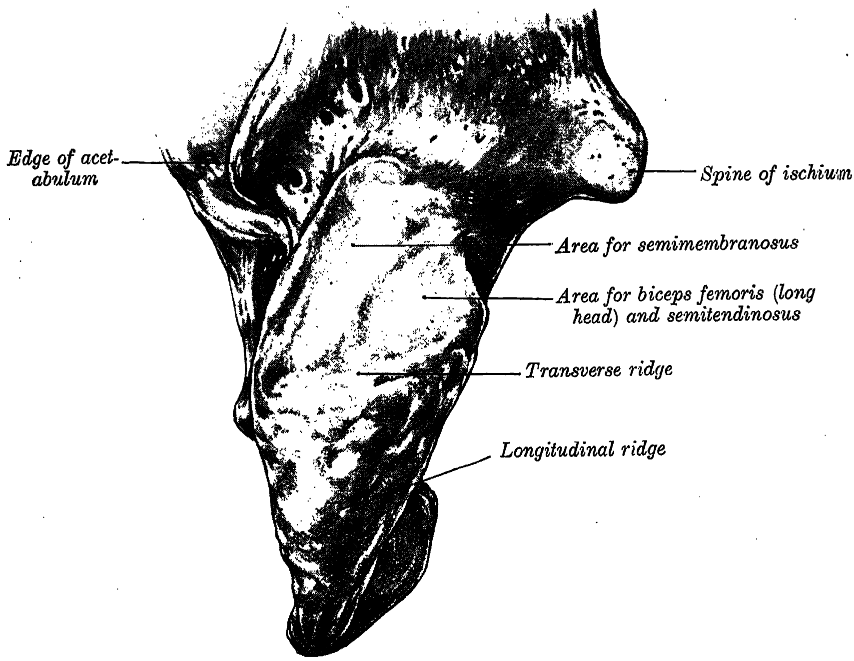
The ischium.—General features.—The **ischium** forms the lower and posterior part of the hip-bone. It comprises a body and a ramus. The body has upper and lower extremities, and femoral, dorsal and pelvic surfaces.

The *upper extremity* forms the lower part of the acetabulum and is fused with the ilium and pubis. The *lower extremity* is free and is capped by the lower part of a large bony prominence, termed the *ischial tuberosity.* The ramus springs from the front of the lower part of the body.

The *femoral surface* of the body is directed downwards, forwards and laterally towards the thigh. It is roughened and uneven, and is bounded in front by the margin of the obturator foramen, and laterally by the lateral border, which is indistinct above but clearly defined below, where it forms the lateral border of the ischial tuberosity. The *dorsal surface* is directed backwards, laterally and upwards. Above, it is continuous with the lower part of the gluteal surface of the ilium, and where the two elements meet the bone presents a low convexity, which corresponds with the curvature of the posterior part of the acetabulum. Below, the surface is marked by the upper part of the ischial tuberosity. Above the tuberosity the bone presents a wide and shallow groove both on the lateral and on the medial side. The *ischial tuberosity* is a large, roughened impression which marks the lower part

of the posterior surface and the inferior extremity of the body of the ischium. It is an elongated area, widest near its upper end and tapering away inferiorly, and provides attachment for some of the large muscles of the thigh. The posterior surface is placed between the lateral and the posterior borders of the body. The *posterior border* is continuous above with the posterior border of the ilium and helps it to complete the lower margin of the greater sciatic notch. The posterior end of that margin is marked by a conspicuous projection termed the *ischial spine*. Below the spine the border becomes rounded and indefinite, forming the floor of a rounded notch, termed the lesser sciatic notch, which lies between the ischial spine and the tuberosity. The *pelvic surface* is smooth and relatively featureless and is directed towards the pelvic cavity; its lower portion forms part of the lateral wall of the ischiorectal fossa in the perineum.

FIG. 442.—The left ischial tuberosity, viewed from behind and below.



The *transverse ridge* forms the lower boundary of the area for the hamstring muscles and separates it from the lower half of the tuberosity, which is divided into lateral and medial areas by the *longitudinal ridge*. The lateral area gives origin to the adductor magnus; the medial area is covered with fibro-fatty tissue and supports the body in the sitting posture.

The *ramus* of the ischium springs from the lower part of the front of the body and passes upwards, forwards and medially to meet the inferior ramus of the pubis, forming the lower boundary of the obturator foramen. It presents anterior (or outer) and posterior (or inner) surfaces, continuous with the corresponding surfaces of the inferior pubic ramus. The *anterior surface* is directed forwards and downwards towards the thigh and is rough for the attachment of the medial femoral muscles. The *posterior surface* is smooth, and partly subdivided into a perineal and a pelvic area, like the inferior ramus of the pubis. The *upper border* helps to complete the margin of the obturator foramen; the *lower border* is roughened and free, and together with the medial border of the inferior ramus of the pubis forms the lateral boundary of the subpubic angle and part of the pubic arch.

Particular features.—The *femoral surface* of the body of the ischium gives origin below to a part of the obturator externus muscle and along the lateral border of the upper part of the ischial tuberosity to the quadratus femoris. The upper part of this surface is pitted by numerous vascular foramina and is covered by the tendon of the obturator externus as it passes laterally and backwards in the groove between the acetabulum and the ischial tuberosity. Just below the acetabulum the lateral border gives attachment to the ischiofemoral ligament.

Immediately above the ischial tuberosity the *dorsal surface* is crossed by the tendon of the obturator internus and the gemelli muscles; the nerve to the quadratus femoris intervenes between these structures and the bone as it descends to reach its destination. At a higher level, the bone is covered with the piriformis muscle, which is partially separated from it by the sciatic nerve and the nerve to the quadratus femoris. The **ischial tuberosity** is divided by a nearly transverse ridge into an upper and a lower area. The upper area is associated with the hamstring muscles; it is divided by an oblique line into an upper and lateral part which gives origin to the semimembranosus, and a lower and medial part from which the long head of the biceps femoris arises in common with the semitendinosus muscle. The lower portion of the tuberosity narrows as it passes forwards on to the lower end of the ischium. It is divided into a lateral and a medial area; the lateral area is the larger and affords origin to part of the adductor magnus muscle; the medial area is covered by fibro-fatty tissue, which usually contains the ischial bursa of the gluteus maximus. It is the medial area on the lower part of the tuberosity which supports the body in the sitting posture. On its medial side the tuberosity is limited by a curved ridge which extends forwards on to the ramus of the ischium and gives attachment to the sacrotuberous ligament and its falciform process (fig. 441). Many of the fibres of origin of the biceps femoris can be traced into the sacrotuberous ligament, and this intimate relationship is noteworthy, for the sacrum and the posterior part of the ilium constitute the primitive mammalian origin of the biceps femoris. The origin of the muscle from the tuberosity in man is secondary and the sacrotuberous ligament represents the remains of its primitive tendon of origin.

Above and medial to the tuberosity the posterior surface presents a wide, shallow groove. In this situation the bone is usually covered with a thin layer of cartilage in the recent state and a bursa is interposed between it and the tendon of the obturator externus, which lies in the groove. The lower margin of the groove, close to the tuberosity, gives origin to the inferior gemellus; the upper margin of the groove, close to the ischial spine, gives origin to the superior gemellus.

The **ischial spine** projects downwards and medially. Its margins give attachment to the sacrospinous ligament, which separates the greater sciatic foramen from the lesser (fig. 540). Its dorsal surface is crossed by the internal pudendal vessels and the nerve to obturator internus, as they lie in the gluteal region. The pelvic surface of the spine gives origin to the coccygeus and the most posterior fibres of the levator ani muscle. The structures transmitted by the greater and lesser sciatic foramina are described on p. 481.

The *pelvic surface* of the body of the ischium is smooth. Its upper part gives origin to the obturator internus muscle, the fibres of which converge on the lesser sciatic notch and cover the remainder of this surface, with the exception of the pelvic aspect of the ischial spine. The muscle and its covering fascia separate the bone from the ischiorectal fossa.

The *anterior surface* of the **ramus of the ischium** is directed towards the adductor region of the thigh. It gives origin to the obturator externus above, the anterior fibres of the adductor magnus and, near the lower border, to the gracilis muscle. Between the adductor magnus and the gracilis the origin of the adductor brevis may extend downwards from the inferior ramus of the pubis for a short distance. The *posterior surface* is divided into pelvic and perineal areas. The pelvic area is directed upwards and backwards and gives origin to part of the obturator internus. The perineal area is directed medially; its upper part is related to the crus of the penis and gives origin to the sphincter urethræ; its lower part gives origin to the ischiocavernosus and to the superficial transversus perinei muscles. The perineal membrane is attached to the ridge which separates the perineal from the pelvic area below, and the area for the crus from the origin of the sphincter urethræ above. The *lower border* of the ramus provides attachment for the fascia lata of the thigh and the membranous layer of the superficial fascia of the perineum.

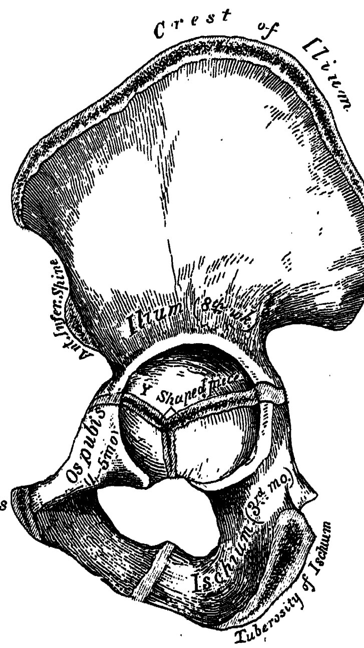
The **acetabulum** (fig. 438) is a deep cup-shaped cavity on the lateral aspect of the hip-bone about its centre, and is directed laterally, downwards and forwards. It is surrounded by an irregular projecting margin which is deficient inferiorly; this gap is termed the *acetabular notch.* The floor of the cavity is roughened and non-articular and is termed the *acetabular fossa.* The sides of the cup present a horseshoe-shaped *articular surface* which is widest superiorly; in this situation the weight of the trunk is transmitted to the femur in the erect attitude. In the recent state this strip is covered with articular cartilage and provides the surface on which the head of the femur moves within the hip-joint. All three elements of the hip-bone contribute to the formation of the acetabulum in man, but not in equal proportions. The pubis forms the upper and anterior fifth of the articular surface; the ischium, the floor of the acetabular fossa and rather more than the lower and posterior two-fifths of the articular surface; the ilium forms the remainder of the articular surface.

The **obturator foramen** is a large gap in the hip-bone, below and in front of the acetabulum and placed between the pubis and the ischium. It is bounded

above by the grooved obturator surface of the superior ramus of the pubis; medially by the body and inferior ramus of the pubis; below by the ramus of the ischium; and laterally by the anterior border of the body of the ischium, including the margin of the acetabular notch. The foramen is occupied in the recent state by a fibrous sheet, termed the obturator membrane, which is attached to its margins except above, where a communication is left between the pelvis and the thigh. The free upper edge of the membrane is attached in front to the *anterior obturator tubercle*, which marks the anterior end of the inferior border of the superior ramus of the pubis, and behind to the *posterior obturator tubercle*, which is placed on the anterior border of the acetabular notch. These tubercles are not always easy to identify. The foramen is large and oval in the male, but is smaller and nearly triangular in the female.

FIG. 443.—A plan of the ossification of the hip-bone.

By eight centres { *Three primary, for the ilium, ischium, and pubis.* / *Five secondary.* }



Symphysis pubis

The three primary centres unite through the Y-shaped piece about puberty.
Secondary centres appear about puberty, and unite about 25th year.

Structure.—The thicker parts of the hip-bone consist of spongy substance, enclosed between two layers of compact bone; the thinner parts, as at the bottom of the acetabulum and centre of the iliac fossa, are usually semitransparent, and composed entirely of compact bone. At the upper part of the acetabulum and along the arcuate line, i.e. along the line of weight transmission from the sacrum to the head of the femur, the amount of compact bone shows a considerable increase. In this situation the underlying spongy substance shows the presence of two sets of pressure lamellæ. The first arise near the upper part of the auricular surface and diverge to impinge on two stout buttresses formed by the compact bone. From there two similar sets of lamellar arches take origin and converge on the acetabulum.*

Ossification (fig. 443).—The hip-bone is ossified from eight centres: three primary, one each for the ilium, ischium, and pubis; and five secondary, one each for the iliac crest, the anterior inferior iliac spine (said to occur more frequently in the male than in the female), the tuberosity of the ischium, the pubic symphysis (more frequent in the female than in the male), and one

* C. P. G. Wakeley, *Proceedings of Anatomical Society, Journal of Anatomy*, vol. lxiv. 1929.

or more for the Y-shaped cartilage at the bottom of the acetabulum. The centres appear in the following order: in the ilium, immediately above the greater sciatic notch, about the eighth or ninth week of intrauterine life; in the body of the ischium, about the third month; in the superior ramus of the os pubis, between the fourth and fifth months. At birth, the iliac crest, the greater part of the acetabulum, the ischial tuberosity, and the inferior ramus of the pubis and the ramus of the ischium are cartilaginous. By the seventh or eighth year, the inferior ramus of the pubis and the ramus of the ischium are almost completely united by bone. The three primary centres extend their growth into the bottom of the acetabulum, where they are separated from each other by a Y-shaped portion of cartilage, which begins to ossify from two or more centres in the twelfth year. One of these centres, named the *os acetabuli*, forms a triangular scale of bone over the acetabular part of the pubis and fuses with the main parts of the bone about puberty. The ilium and ischium then become joined, and lastly the pubis and ischium, through the medium of this Y-shaped portion. At about the age of puberty, ossification takes place in each of the remaining portions, and they join with the rest of the bone between the twentieth and twenty-fifth years. Separate centres are frequently found for the pubic tubercle, crest and angle, and for the ischial spine.

Comparison of the girdles of the upper and lower limbs.—The importance of mobility in the upper limb as contrasted with the necessity for stability in the lower limb is well illustrated by the more obvious differences which exist between the two girdles.

Girdle of Upper Limb.	*Girdle of Lower Limb.*
(*a*) Consists of two separate bones, viz., the scapula and the clavicle.	(*a*) Consists of a single bone, viz., the hip-bone.
(*b*) Reaches the axial skeleton only at the sternoclavicular joint.	(*b*) Articulates with the vertebral column at the sacro-iliac joint.
(*c*) Is not directly connected to its fellow of the opposite side, except by the interclavicular ligament.	(*c*) Articulates with its fellow of the opposite side at the pubic symphysis.
(*d*) Has a shallow fossa for the head of the humerus.	(*d*) Has a deep cup for the head of the femur.

THE PELVIS

The **pelvis**, so called from its resemblance to a basin, is a massive bony ring interposed between the movable segments of the vertebral column, which it supports, and the lower limbs, upon which it rests; it is composed of the two hip-bones laterally and in front, and the sacrum and coccyx behind. It is divided into the false (greater) and the true (lesser) pelvis by an oblique plane passing through the prominence of the sacrum behind, and the arcuate line on each side and in front. These two subdivisions communicate with each other through the *pelvic inlet*.

The **false pelvis (greater pelvis)**, the expanded portion of the cavity above and in front of the pelvic inlet, is bounded on each side by the ilium and posteriorly by the base of the sacrum.

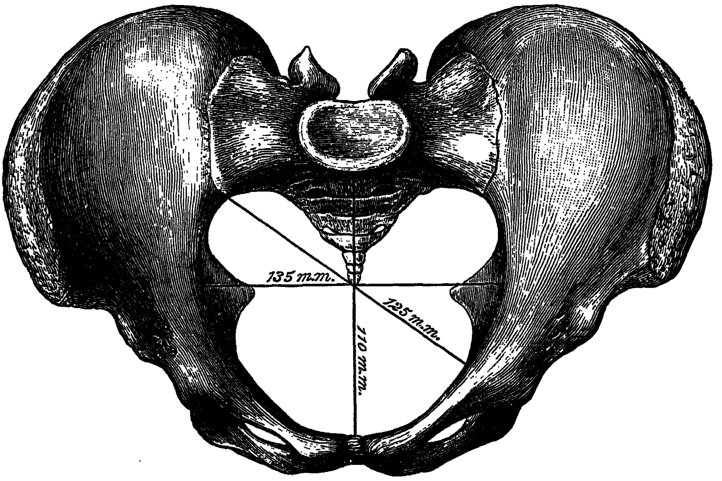
The **true pelvis (lesser pelvis)** is that part of the pelvic cavity which lies below and behind the pelvic inlet. Its bony walls are more complete than those of the false pelvis. It possesses an inlet, an outlet and a cavity.

The bony boundaries of the pelvic inlet constitute the *brim* of the pelvis (fig. 444). The inlet is somewhat heart-shaped, obtusely pointed in front, and encroached upon behind by the forward projection of the promontory of the sacrum. It has three principal diameters: anteroposterior, transverse, and oblique. The *anteroposterior* or *conjugate diameter* extends from the lumbosacral angle to the symphysis pubis; its average measurement is about 110 mm. in the female. The *transverse diameter* extends from the middle of the brim on one side to the same point of the opposite side; its average measurement is about 135 mm. in the female. The *oblique diameter* extends from the iliopubic (iliopectineal) eminence

to the opposite sacro-iliac joint; its average measurement is about 125 mm. in the female.

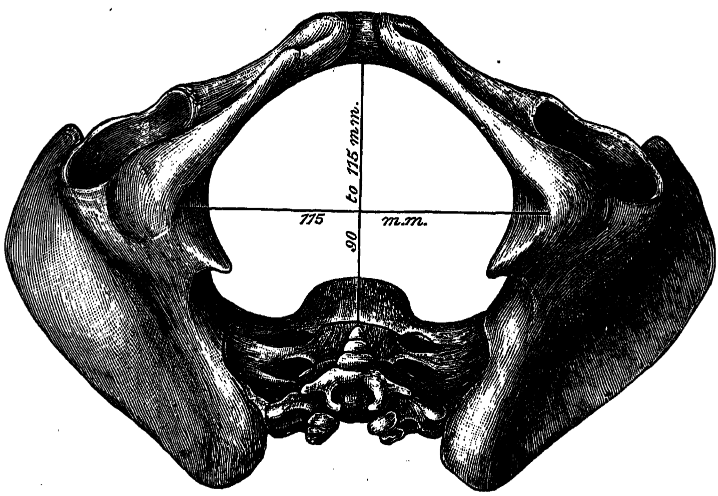
The *cavity* of the true pelvis is a short curved canal, considerably deeper behind than in front. It is bounded in front and below by the pubic rami and symphysis;

FIG. 444.—The diameters of the inlet of the true pelvis (female).



above and behind, by the pelvic surfaces of the sacrum and coccyx; laterally by a smooth, quadrangular area of bone, formed by the pelvic surfaces of the ilium and ischium. It contains, in the recent subject, the pelvic colon, rectum, urinary bladder, and some of the organs of generation. The rectum is placed at the back of the pelvis, in the curve of the sacrum and coccyx; the urinary bladder is in front,

FIG. 445.—The diameters of the outlet of the true pelvis (female).



behind the pubic symphysis. In the female, the uterus and vagina lie between the rectum and the urinary bladder.

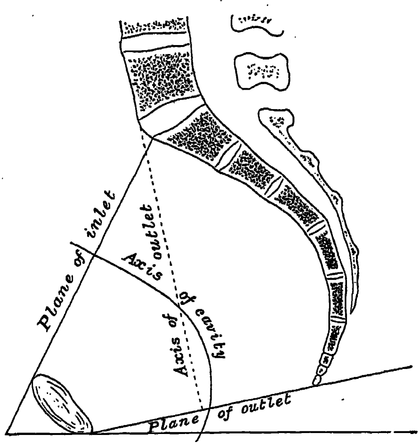
The *outlet* is very irregular in shape (fig. 445) and is bounded behind by the apex of the coccyx, and laterally by the ischial tuberosities. These eminences are separated by three notches: one in front—the *pubic arch*—formed by the convergence of the rami of the ischium and pubis on each side. The other notches, one on each side, are formed by the sacrum and coccyx behind, the ischium in front, and the ilium above: they are called the *sciatic notches*; in the natural state they are converted into foramina by the sacrotuberous and sacrospinous ligaments. When

these ligaments have been preserved, the outlet of the pelvis is lozenge-shaped, and is bounded, in front, by the inferior pubic ligament and the inferior rami of the pubic bones and the ischial rami; laterally, by the ischial tuberosities; behind, by the sacrotuberous ligaments and the tip of the coccyx.

The *anteroposterior diameter* of the outlet of the pelvis extends from the apex of the coccyx to the lower part of the pubic symphysis; its measurement is from 90 to 115 mm. in the female. It varies with the length of the coccyx, and is capable of increase or diminution, on account of the mobility of that bone. The *transverse diameter*, measured across the widest part of the outlet, is about 115 mm. in the female.*

Axes (fig. 446).—The axis of the inlet, i.e. a line at right angles to the plane of the inlet through its centre, is directed downwards and backwards, and if the line is prolonged it passes through the umbilicus above and the middle of the coccyx below. The axis of the outlet is directed downwards and slightly backwards; if prolonged upwards it touches the base of the sacrum. The axis of the cavity—i.e. an axis at right angles to a series of planes between and including those of the inlet and outlet—is curved like the cavity itself: this curve is parallel with that of the sacrum and coccyx.

Fig. 446.—A median sagittal section through the pelvis.



Position of the pelvis (fig. 446).—In the erect posture, the pelvis is placed obliquely with regard to the trunk: the plane of the inlet forms with the horizontal plane an angle of from 50° to 60°, and that of the outlet one of about 15°. The pelvic surface of the pubic symphysis looks upwards and backwards, the concavity of the sacrum and coccyx downwards and forwards. The position of the pelvis in the erect posture may be demonstrated by holding it so that the anterior superior iliac spines and the front of the top of the pubic symphysis are in the same vertical plane.

In the sitting posture the body rests on the medial and lower parts of the ischial tuberosities (p. 377), and a coronal plane drawn through the anterior superior iliac spines passes through the acetabula. The lumbosacral angle is considerably reduced and the projection of the sacral promontory is correspondingly diminished.

Differences between the male and female pelves (figs. 447, 448, 449, 450).—Sexual characters are more pronounced in the bones of the pelvis than in any other bones in the body. The female pelvis is specially adapted to facilitate the passage of the fœtal head during parturition and it must therefore provide more accommodation than is necessary in the male pelvis, while its depth must be diminished. The essential differences were well summed up by Arthur Thomson, who described the male pelvis as a long section of a short cone and the female pelvis as a short section of a long cone. There are, however, very many differences in detail, most of which can be referred to these fundamental distinctions.

As a whole, the bones of the female pelvis are more delicate and their muscular impressions are not so well marked. The ilia are more vertical and, although the distance between the iliac crests is less in the female, the anterior superior iliac spines are farther apart. As a rule, the iliac fossæ are shallower and the curves of the crest, as seen from above, are not so pronounced. The prominence of the hips in the female may be attributed, in part, to the sexual characters of the ilium.

The inlet of the true pelvis is larger in the female and is more nearly circular in outline: in the male it is typically heart-shaped.

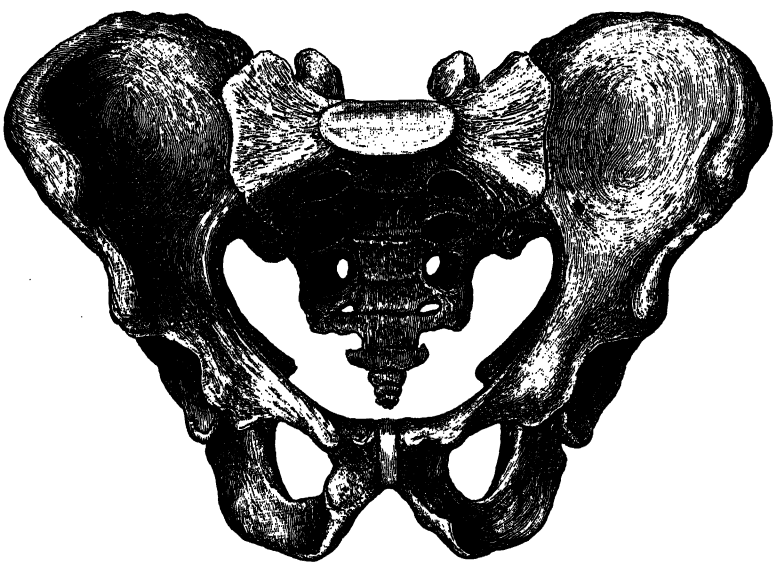
* The measurements of the pelvis given above are fairly representative, but different figures are given by various authors, no doubt mainly due to difference in the physique and stature of the population from whom the measurements have been taken.

The cavity of the female pelvis is wider and shallower, and, in the production of this general difference, the following factors are to be noted. (1) The sacrum is shorter and wider in the female and its upper part is straight (p. 223). (2) The depth of the pubic symphysis is less and the distance between the two pubic tubercles is greater in the female. (3) The sciatic notches are wider and shallower,

FIG. 447.—The female pelvis. Anterior aspect.

From a specimen in the museum of the Royal College of Surgeons of England.

FIG. 448.—The male pelvis. Anterior aspect.



and the spines of the ischia do not project inwards to the same extent as they do in the male.

The outlet is larger in the female, since (1) the pubic arch is wider and more rounded and it will always admit a set square: whereas in the male it is more pointed and definitely less than a right angle; (2) the ischial tuberosities are more everted; and (3) the coccyx is more movable.

The male pelvis possesses one positive sexual character: the margins of the pubic arch are more everted, owing to the larger size of the crura of the penis.

The following additional differences should also be mentioned. (1) The acetabula are smaller in the female: they are wider apart and look more definitely forwards.* As a result the transverse diameter of the acetabulum is distinctly less than the distance from its anterior margin to the pubic symphysis. In the male, on the other hand, the two measurements are practically equal. (2) The obturator foramen is smaller in the female and is triangular in shape. In the male it is more oval in outline, but this difference is not of great value as a sexual character. (3) The pre-auricular sulcus (p. 374) is more constantly present in the female ilium, and its presence is presumably associated with the existence of a more movable sacro-iliac joint. (4) The auricular surface of the sacrum is limited to the first and second sacral vertebræ in the female, but in the male it usually extends to the middle of the third vertebra.

The size of the pelvis varies not only in the two sexes, but also in different members of the same sex, and does not appear to be greatly influenced by the height of the individual. Women of short stature, as a rule, have broad pelves. Occasionally the pelvis is contracted in all its dimensions, and its diameters may be as much as 12·5 mm. less than the average, and this even in well-formed women of average height. The principal divergences, however, are found at the inlet, and affect the relation of the anteroposterior to the transverse diameter. Thus the inlet may be elliptical either in a transverse or an anteroposterior direction, the transverse diameter in the former, and the anteroposterior in the latter, greatly exceeding the other diameters; in some instances it is almost circular.

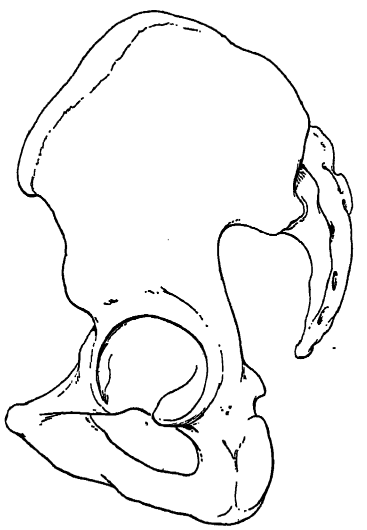


FIG. 449.—Profile view of male pelvis.

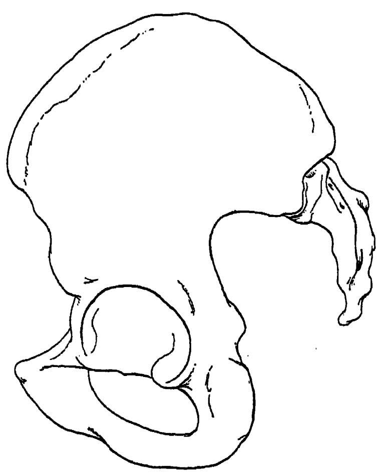

FIG. 450.—Profile view of female pelvis.

In the *fœtus*, and for several years after birth, the pelvis is small in proportion to that of the adult, and the projection of the lumbosacral angle less marked. The characteristic differences between the male and female pelves are distinctly indicated as early as the fourth month of intrauterine life.

THE FEMUR (figs. 453–456)

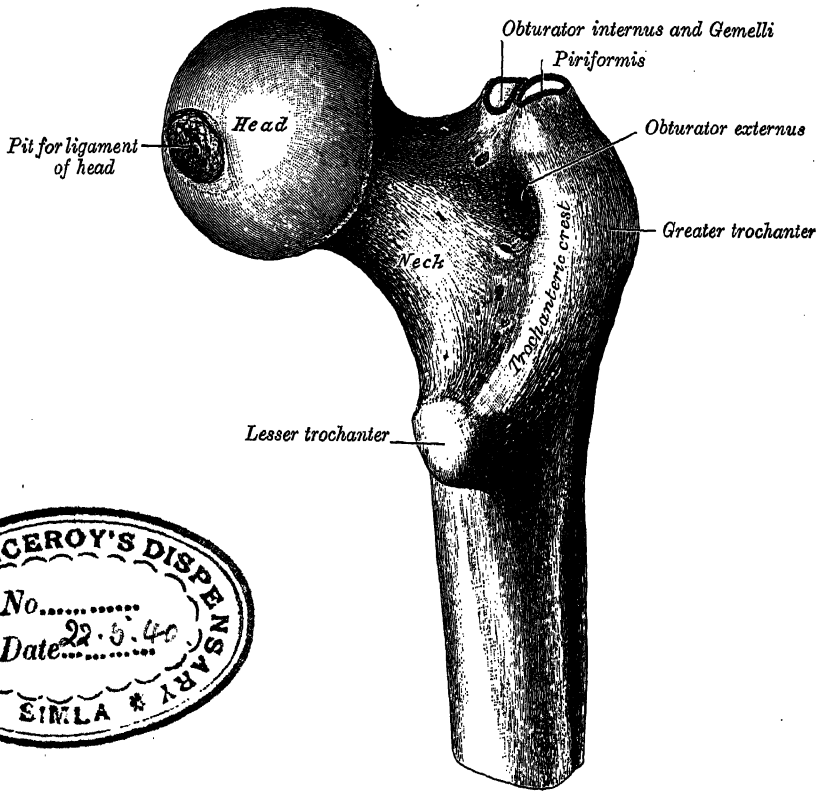
The **femur**, or thigh-bone, is the longest and strongest bone in the body. It possesses a shaft and two extremities. The shaft is almost cylindrical in most of its length, and is curved with a *forward convexity*. The head, which is rounded, can easily be distinguished from the widely expanded lower end: it projects from the *medial* side of the *upper* end of the shaft. This information is sufficient to enable the student to assign a given femur correctly to its appropriate side of the body.

In the erect posture the femora are placed obliquely (fig. 261). Their heads

* Derry, *Journal of Anatomy and Physiology*, vol. xliii.

are separated by the breadth of the true pelvis and their shafts incline downwards and medially, so that the medial sides of the two knees can just touch. As the bones of the legs descend vertically from the knees, the obliquity of the femoral shafts results in the approximation of the feet in the erect attitude and the provision of a narrow base for the support of the weight of the body. The narrowness of the base detracts from the stability of the body but greatly facilitates movements and increases the speed with which they can be executed. The degree of obliquity of the shafts varies in different individuals, but is usually greater in women on account of the greater breadth of the pelvis.

Fig. 451.—The upper part of the right femur. Viewed from behind.



The **upper end** of the femur (fig. 451) comprises a head, a neck, a greater and a lesser trochanter.

General features.—The **head** forms rather more than half a sphere; it is directed upwards, medially and slightly forwards, to articulate with the acetabulum of the hip-bone. Its surface is smooth, and is marked a little below and behind its centre by a small roughened pit.

The **neck** of the femur, which is about 5 cm. long, connects the head and the shaft, with which it forms an angle of about 125°. The arrangement facilitates the movements of the hip-joint and enables the lower limb to swing clear of the pelvis. The neck is narrowest at its middle and is wider at its lateral than at its medial end. Its two borders are rounded. The upper border is nearly horizontal and is gently concave upwards. The lower border is straight but oblique, and is directed downwards, laterally and backwards to meet the shaft near the lesser trochanter. The anterior surface of the neck is flattened and its junction with the shaft is marked by a prominent rough ridge termed the *trochanteric line*. The posterior surface is convex backwards and upwards in its transverse axis, and concave in its long axis, and its junction with the shaft is marked by a rounded ridge termed the *trochanteric crest*.

Fig. 1.—Radiograph of the hand and wrist of a child aged 2½ years. The capitate and hamate bones are in process of ossification, but the other carpal bones are still cartilaginous. The centre for the head of the ulna has not yet appeared, but the centre for the lower epiphysis of the radius is present. Note the condition of the metacarpal bones and phalanges.

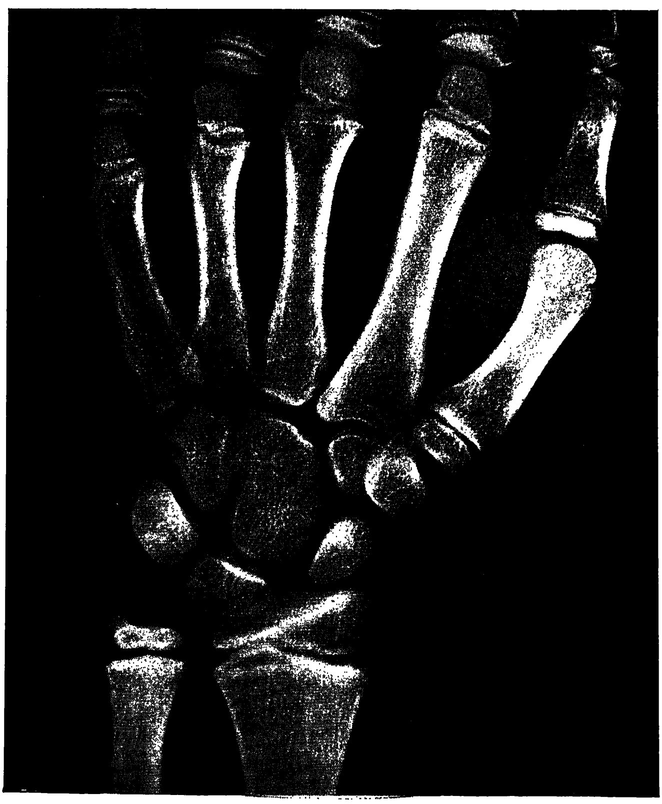


Fig. 2.—Radiograph of hand and wrist of a child aged 11 years. All the centres of ossification are present except that for the pisiform bone. Note how the first metacarpal differs from the other metacarpal bones.

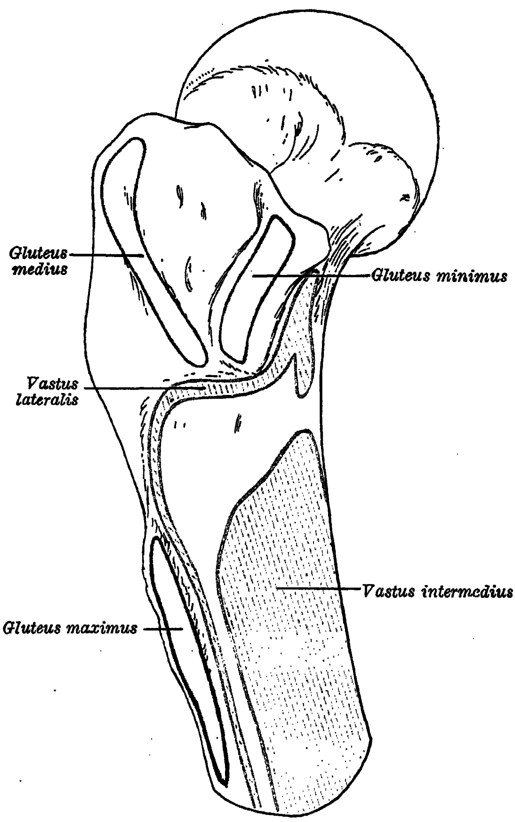
FIG. 1.—Radiograph of an adult pelvis. The upper arrow indicates the line of the sacro-iliac joint; the lower arrow points to the anterior inferior iliac spine.

FIG. 2.—Radiograph of the pelvis of a child aged $3\frac{1}{2}$ years. The epiphysis for the head of the femur is well formed, but the centre for the greater trochanter has not yet appeared. The rami of the pubis and ischium are still connected by cartilage and the triradiate cartilage in the acetabulum is wide.

The **greater trochanter** is a large, quadrangular eminence, situated at the upper part of the junction of the neck with the shaft. Its posterosuperior portion projects upwards and medially (fig. 455) so as to overhang the adjoining part of the posterior surface of the neck; in this situation its medial surface presents a roughened, depressed area, termed the *trochanteric fossa.* The upper border of the trochanter lies one hand's-breadth below the tubercle on the iliac crest, and is on a level with the centre of the head of the femur. The anterior surface of the trochanter presents a roughened impression; its lateral surface is divided into two areas by an oblique, flattened strip, wider above than below, which runs downwards and forwards across it. The lateral surface of the trochanter can be palpated in the living subject, and, when the adjoining muscles are relaxed, the trochanter can be gripped between the thumb and fingers.

Fig. 452.—The upper part of the right femur. Lateral aspect.



The **lesser trochanter** (fig. 451) is a conical eminence, which projects medially and backwards from the shaft at its junction with the lower and posterior part of the neck. Its summit and anterior surface bear a roughened impression, but its posterior surface, which lies at the lower end of the trochanteric crest, is smooth and even. It is placed too deeply to be felt in the living subject.

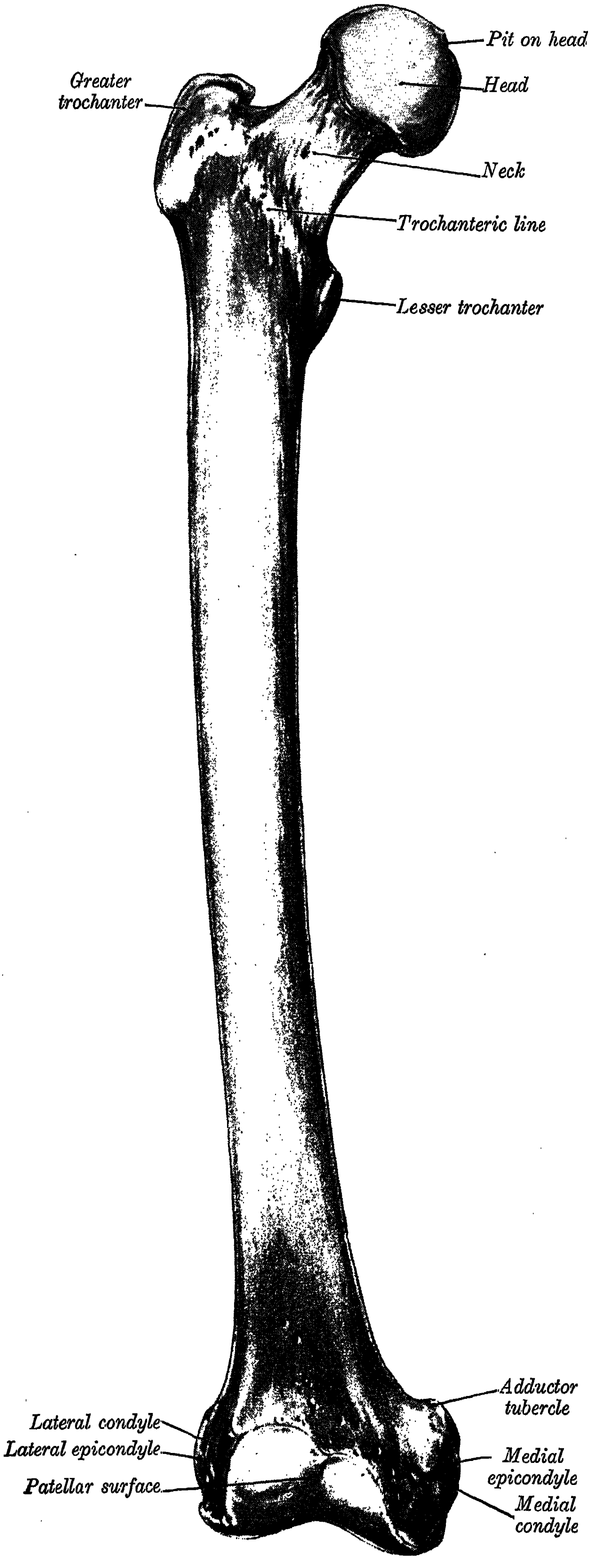
The *trochanteric line* marks the junction of the anterior surface of the neck with the shaft of the femur (fig. 453). It is a prominent roughened ridge, which commences in a tubercle at the upper and medial part of the anterior surface of the greater trochanter and runs downwards and medially. It reaches the lower border of the neck on a level with the lesser trochanter, but in front of it. Below, it is continuous with the *spiral line* (p. 388).

The *trochanteric crest* (fig. 455) marks the junction of the posterior surface of the neck with the shaft of the femur. It is a smooth rounded ridge, which commences at the posterosuperior angle of the greater trochanter and runs downwards and medially to terminate at the lesser trochanter. A little above its middle it presents a low rounded elevation, sometimes termed the *quadrate tubercle.*

Particular features.—The head of the femur is entirely intracapsular and is encircled immediately lateral to its greatest diameter by the labrum acetabulare. Its circumference is sharply defined, except on the anterior surface, where the cartilage covered surface extends on to the front of the neck. The pit which marks the head below and behind its centre (fig. 451) gives attachment to the ligament of the head of the femur (ligamentum teres). The inferomedial part of the anterior surface of the head is related to the femoral artery, from which it is separated by the tendon of the psoas major and the articular capsule.

The neck of the femur is marked by numerous vascular foramina, especially on its anterior surface and on the upper part of its posterior surface. The angle which it makes with the shaft is widest at birth and diminishes steadily until the adult condition is reached. It is less in the female than in the male, owing to the increased breadth of the true pelvis and the greater obliquity of the shaft of the femur. The *anterior surface* of the neck

FIG. 453.—The right femur. Anterior aspect.



is entirely intracapsular and on this surface the capsular ligament extends laterally to the trochanteric line. On the *posterior surface* the capsular ligament does not reach the trochanteric crest (fig. 456), and only a little more than the medial half of the neck lies within the capsule. The part of the anterior surface adjoining the head is covered with cartilage and is related to the iliofemoral ligament in the erect posture. A faint groove crosses the posterior surface in an upward and lateral direction; it is produced by the obturator externus tendon as it passes to the trochanteric fossa. The neck of the femur does not lie in the same plane as the shaft, but is carried forwards as it passes upwards and medially. On this account the transverse axis of the head of the femur makes an angle with the transverse axis of the lower end of the bone, and this angle is known as the angle of femoral *torsion*.

The **greater trochanter** (fig. 452) provides insertion for most of the muscles of the gluteal region. The gluteus minimus is inserted into the rough impression on its anterior surface. The gluteus medius is inserted into the oblique, flattened strip, which runs downwards and forwards across its lateral surface. The area in front of this insertion is separated from the tendon by the trochanteric bursa of the gluteus medius; the area behind the insertion is covered by the deep fibres of the gluteus maximus, and a portion of the trochanteric bursa of that muscle may be interposed. The upper border of the trochanter gives insertion to the piriformis, and its medial surface to the common tendon of the obturator internus and the two gemelli. At their insertions these two tendons are frequently blended with each other. The trochanteric fossa receives the insertion of the obturator externus.

The **lesser trochanter** receives the insertion of the psoas major on its summit and on the medial part of its anterior surface. The base of the trochanter is expanded and its medial or anterior surface gives

insertion to the iliacus, which extends downwards for a short distance behind the spiral line. The upper fibres of the adductor magnus play over the posterior surface of the lesser trochanter and a bursa is sometimes interposed between them.

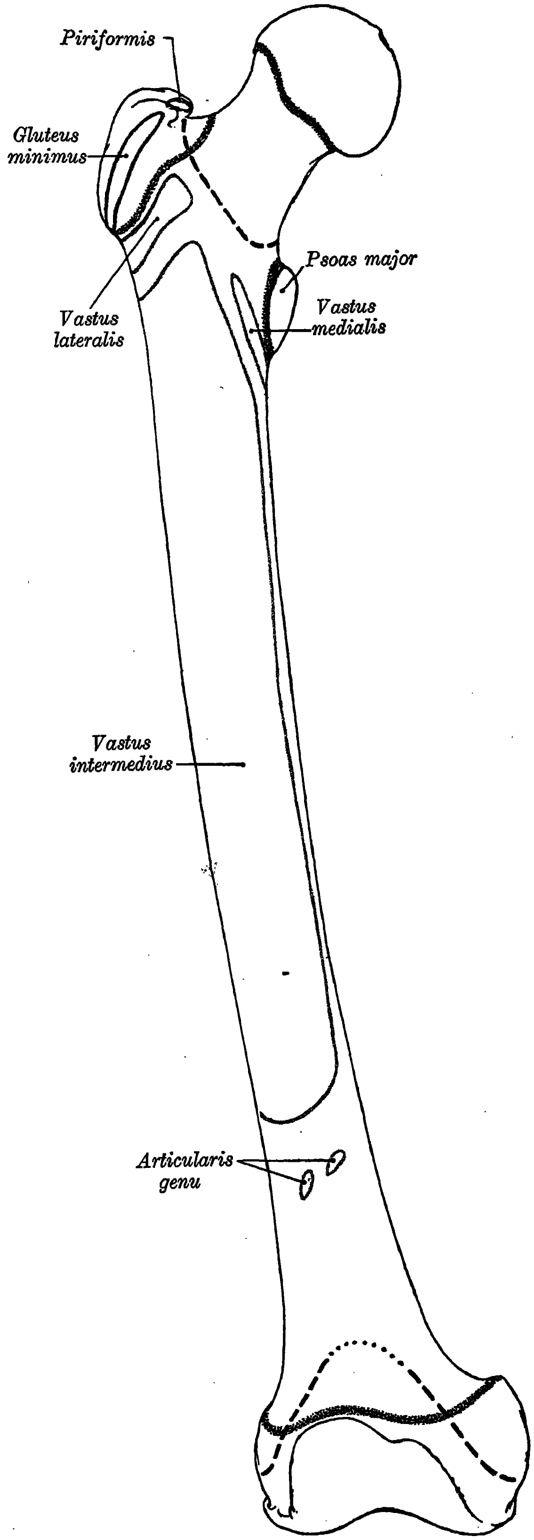
The *trochanteric line* marks the lateral limit of the capsular ligament of the hip-joint. Its upper part, including the tubercle already noticed (p. 385), receives the attachment of the upper band of the iliofemoral ligament; its lower part receives the lower band of the same ligament. The highest fibres of the vastus lateralis arise from the upper end of the line, and the highest fibres of the vastus medialis from its lower end.

The *trochanteric crest*, above the *quadrate tubercle*, is covered by the gluteus maximus muscle; below the tubercle it is separated from that muscle by the quadratus femoris and the upper border of the adductor magnus. The tubercle itself, and a portion of the bone below, receive the insertion of the quadratus femoris muscle.

The **shaft** of the femur (figs. 453 and 455) is thinnest at its middle: it expands a little as it is traced upwards, but it widens appreciably near the lower end of the bone.

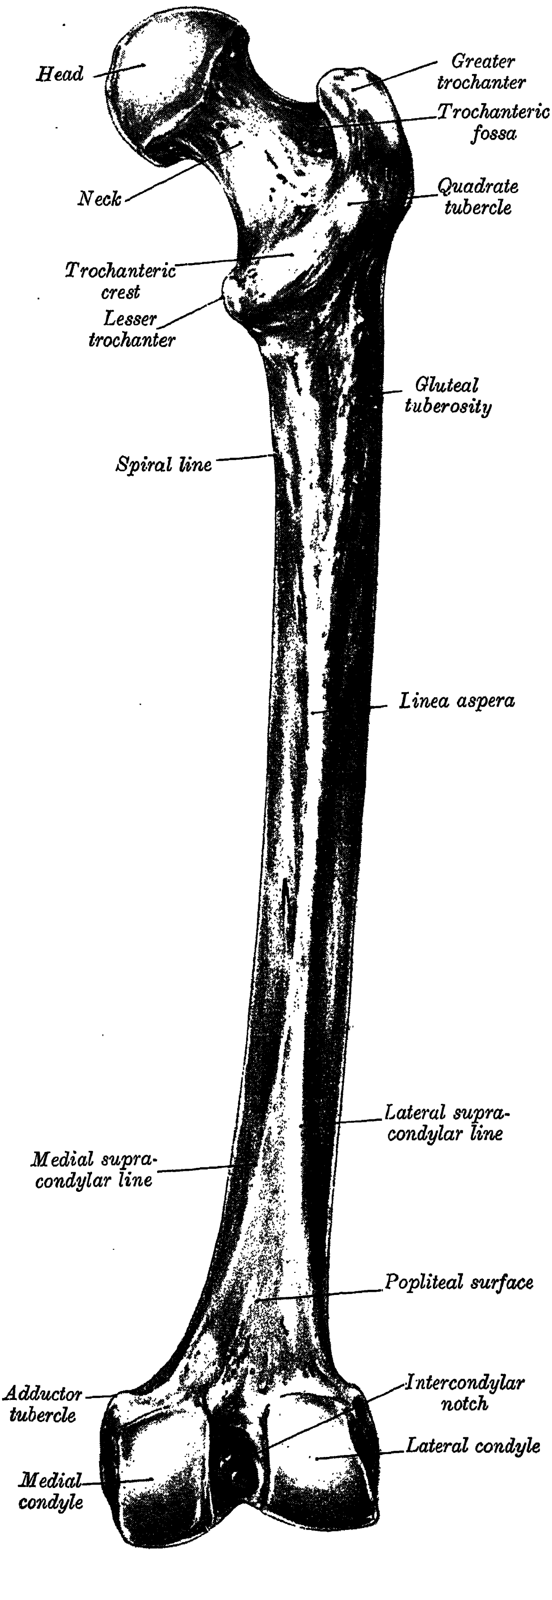
In its middle third the shaft possesses three surfaces and three borders. The *anterior surface*, which is smooth and gently convex in all directions, is easy to identify. It is placed between the lateral and the medial borders, which are both rounded and ill-defined. The *lateral surface* is directed more backwards than laterally, and is bounded in front by the lateral border and behind by the posterior border. The posterior border is formed by a broad, rough ridge, termed the **linea aspera**, which usually forms a crestlike projection, with distinct lateral and medial lips. In this situation the compact substance is increased in amount in order to compensate for the weakness caused by the curve of the bone. The *medial surface* is directed medially and slightly backwards; smooth,

FIG. 454.—Key to fig. 453.



The stippled lines mark the position of the epiphyseal lines. The interrupted lines correspond to the attachments of the capsular ligaments. The dotted part of the lower line indicates the site of communication between the cavity of the knee-joint and the suprapatellar synovial bursa.

FIG. 455.—The right femur. Posterior aspect.



like the two other surfaces, it is bounded in front by the medial border and behind by the linea aspera.

In its upper third the shaft presents a fourth surface, which is directed backwards. This *posterior surface* is bounded on the medial side by a narrow, roughened line termed the *spiral line*, which is continuous above with the lower end of the trochanteric line, and below with the medial lip of the linea aspera. On the lateral side the surface is bounded by a broad, roughened ridge termed the *gluteal tuberosity*, which extends upwards and laterally to the root of the greater trochanter and is continuous below with the lateral lip of the linea aspera. The posterior surface in this part of the bone is therefore V-shaped.

In its lower third also the shaft possesses a fourth, or *posterior surface*. This posterior surface is placed between the *medial* and *lateral supracondylar lines*, which are continuous above with the corresponding lips of the linea aspera. These two lines form definite but not conspicuous ridges, and of the two the lateral is the more distinct. Near its upper end the medial supracondylar line is in part obliterated; it is in this situation that the principal artery of the limb lies in close relation with the bone as it passes from the thigh to the popliteal fossa. The posterior surface of the lower third forms a flattened, triangular area, which is termed the *popliteal surface* of the femur (fig. 455); in its lower and medial part it presents a rough and slightly elevated area.

Particular features.—The shaft (figs. 454 and 456) is thickly covered with muscles and cannot be felt satisfactorily through the skin. Its *anterior* and *lateral surfaces* give origin in their upper three-fourths to the vastus intermedius; below that muscle the

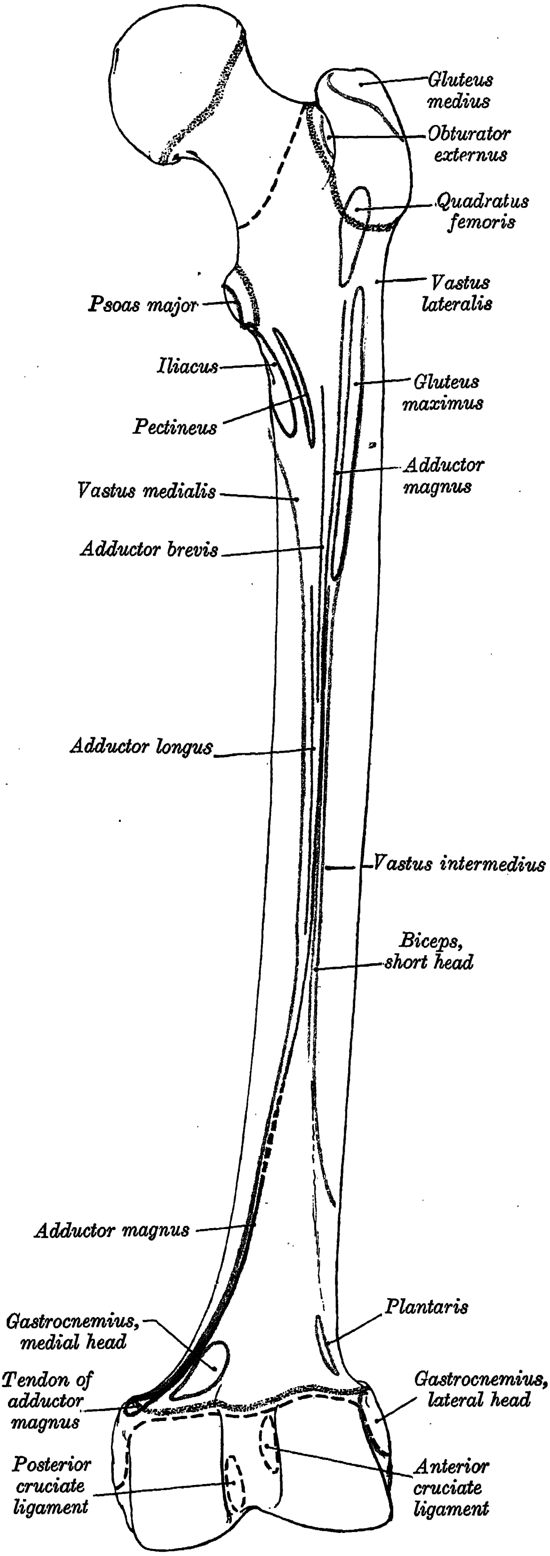
articularis genu arises by several small slips from the front of the bone. The lower portion of the anterior surface for 5 or 6 cm. above the patellar articular surface is covered by the suprapatellar bursa, which intervenes between the bone and the muscles mentioned. The lower portion of the lateral surface is covered by the vastus intermedius. The *medial surface* is devoid of muscular attachments and is covered by the vastus medialis.

The vastus lateralis has a linear origin which commences in front at the root of the greater trochanter and follows it to the upper end of the gluteal tuberosity. It then descends along the lateral margin of the tuberosity to the lateral lip of the linea aspera, from the upper half of which it takes origin. The vastus medialis also has a linear origin. It commences at the lower end of the trochanteric line and follows the spiral line to the medial lip of the linea aspera. At the lower end of the linea aspera it follows the medial supracondylar line in its upper half.

The *gluteal tuberosity* may take the form of an elongated, roughened depression or it may project as a salient ridge. Occasionally a part of it is sufficiently prominent to merit the name of a *third trochanter*. It receives the insertion of the deeper fibres of the lower half of the gluteus maximus muscle. The medial edge of the tuberosity provides insertion for the pubic fibres of the adductor magnus; the succeeding fibres of that muscle are inserted into the linea aspera and the upper part of the medial supracondylar line; the remaining fibres form a stout tendon which is inserted into the adductor tubercle (*vide infra*) and sends a membranous expansion to the lower part of the medial supracondylar line.

Between the gluteal tuberosity and the spiral line the posterior surface receives the insertions of the pectineus and the adductor brevis muscles. The pectineus is inserted into a line, sometimes slightly roughened, which descends from the root of the lesser trochanter to the upper end of the linea aspera. The adductor brevis is inserted lateral to the pectineus and ex-

Fig. 456.—Key to fig. 455.



The stippled lines mark the positions of the epiphyseal lines; the interrupted lines indicate the attachments of the capsular ligaments.

tends downwards to the upper part of the linea aspera, where it is attached medial to the adductor magnus.

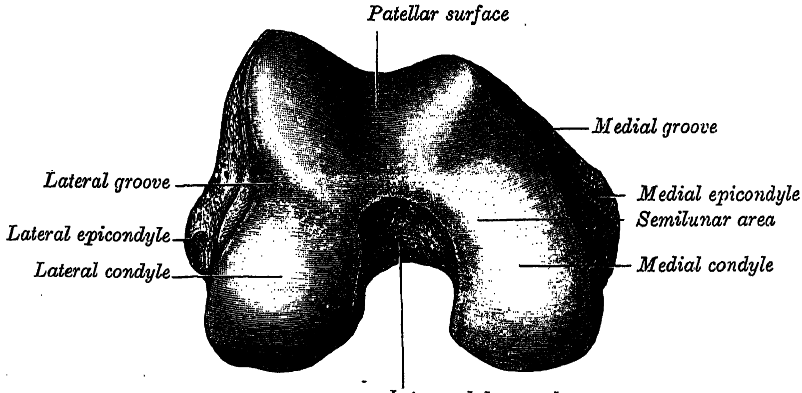
In addition to the attachments already described, the **linea aspera** receives the insertion of the adductor longus and the attachment of the lateral intermuscular septum, and gives origin to the short head of biceps femoris. The structures attached to the linea aspera may now be enumerated. From the lateral to the medial side they are: vastus lateralis, lateral intermuscular septum, short head of biceps femoris, adductor magnus, adductor brevis (to upper part only), adductor longus and vastus medialis; but it should be noted that the tendinous fibres are inseparably blended at their bony attachments. The perforating arteries cross the linea aspera from the medial to the lateral side, under cover of tendinous arches in the adductor magnus and the short head of the biceps femoris. The foramina for the nutrient arteries are situated close to the linea aspera. They vary in number and position. One is usually placed near the upper end of the linea aspera, and a second, which is not always present, near its lower end. The foramina are directed upwards through the compact substance.

The **popliteal surface** of the femur forms the floor of the upper part of the popliteal fossa. It is covered by a variable amount of fat, which separates the popliteal artery from the bone. The superior medial genicular artery arises from the popliteal artery as it lies in the intercondylar notch. It arches medially above the medial condyle, but is separated from the bone by the medial head of the gastrocnemius, which takes origin from the rough elevation placed a little above the medial condyle. The superior lateral genicular artery arches upwards and laterally above the lateral condyle, but is separated from the bone by the plantaris muscle, which arises from a small roughened area on the lower part of the lateral supracondylar line.

The *lateral supracondylar line* is most distinct in its upper two-thirds, to which the short head of the biceps femoris and the lateral intermuscular septum are attached. Its lower part is marked by a small roughened area which gives origin to the plantaris and often encroaches on to the popliteal surface. The medial supracondylar line is feebly marked in its upper two-thirds, where it gives origin to the vastus medialis. Near its upper end it is crossed by the femoral vessels as they enter the fossa from the subsartorial (adductor) canal. It is often sharp and prominent for 3 or 4 cm. above the adductor tubercle, and in this situation it gives attachment to a membranous expansion from the tendon of the adductor magnus muscle.

The **lower end** of the femur is widely expanded in order to provide a good bearing surface for the transmission of the weight of the body to the top of the tibia. It consists of two prominent masses of bone, termed the *condyles*, which are partially covered by a large *articular surface*. Anteriorly the two condyles are united and are in line with the front of the shaft; posteriorly they are separated by a deep notch, termed the *intercondylar notch*, and they project backwards considerably beyond the plane of the popliteal surface.

FIG. 457.—The lower end of the right femur. Inferior aspect.



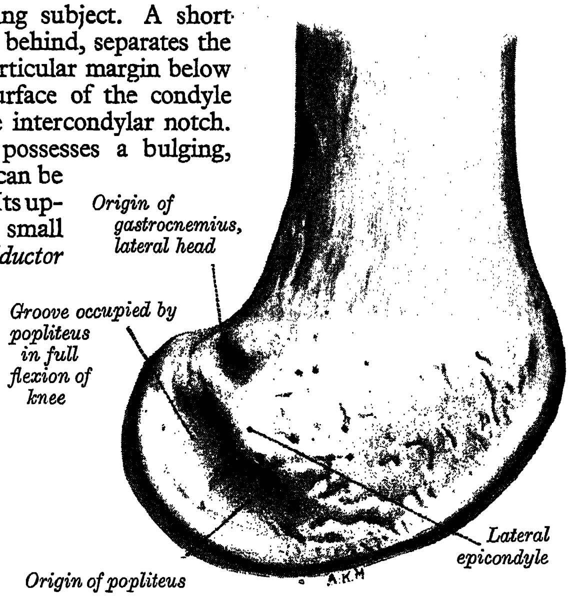
The *articular surface* forms a broad Λ-shaped area for articulation with the patella, or knee-cap, above and the tibia below (fig. 457). The *patellar surface* extends over the anterior surfaces of both condyles, but much the larger part of it is on the lateral condyle. It is concave from side to side, being grooved in its long axis to accommodate the posterior surface of the patella. The *tibial surface* is divided into medial and lateral parts by the intercondylar notch, but anteriorly

each part is directly continuous with the patellar surface. The medial part forms a broad strip which covers the convex inferior and posterior surfaces of the medial condyle, and is gently curved with the convexity of the curve directed medially. The lateral tibial surface covers the same aspects of the lateral condyle but forms a rather broader strip, which passes straight backwards.

The **lateral condyle** (fig. 458) is flattened on its lateral surface and is not so prominent as the medial condyle, but it is stouter and stronger, for it is placed more directly in line with the shaft and probably takes a greater share in the transmission of the weight to the tibia. The most prominent point on its lateral aspect is termed the *lateral epicondyle*, and the whole of this surface can be felt through the skin in the living subject. A short groove deeper in front than behind, separates the lateral epicondyle from the articular margin below and behind. The medial surface of the condyle forms the lateral wall of the intercondylar notch.

The **medial condyle** possesses a bulging, convex medial aspect, which can be palpated without difficulty. Its uppermost part is marked by a small projection termed the *adductor tubercle* (fig. 453) because it gives insertion to the tendon of the adductor magnus muscle. The tubercle is an important bony landmark for the surgeon, and can be identified most readily when it is approached from above. The most prominent point on the medial surface of the condyle is below and a little in front of the adductor tubercle and is termed the *medial epicondyle*. The lateral surface of the condyle is roughened and forms the medial wall of the intercondylar notch.

Fig. 458.—The lower end of the right femur. Lateral aspect.



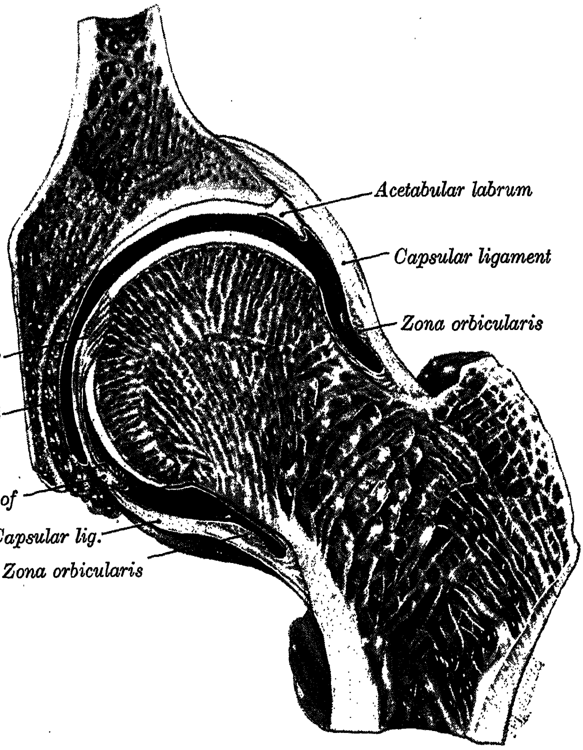
The **intercondylar notch** separates the two condyles below and behind. In front it is limited by the lower border of the patellar surface, and behind by the *intercondylar line*, which separates it from the popliteal surface. It lies within the capsular ligament of the knee-joint, but is covered with synovial membrane only over a very limited area.

Particular features.—The patellar surface extends higher on the lateral than on the medial side; its upper border therefore is oblique and runs downwards and medially (fig. 453). It is separated from the tibial surfaces by two faint grooves which cross the condyles obliquely. The lateral groove is the better marked (fig. 457); it runs laterally and slightly forwards from the front part of the intercondylar notch and expands to form a faint triangular depression, which rests on the anterior part of the periphery of the lateral semilunar cartilage (lateral meniscus), when the knee-joint is fully extended. The medial groove is restricted to the medial part of the medial condyle and rests on the anterior edge of the medial semilunar cartilage in the same position. Where this groove ceases the patellar surface is continued backwards on to the lateral part of the medial condyle as a semilunar area adjoining the anterior part of the intercondylar notch This area articulates with the medial vertical facet of the patella in forced flexion of the knee-joint; it is not distinctly outlined in most femora. The tibial surfaces are convex from side to side and from before backwards. The anteroposterior curvature of the two surfaces is not of the same degree throughout; the posterior part of each surface is the arc of a circle, but its anterior portion is part of a cycloid.* In full flexion of the knee-joint the sharply curved posterior parts of the tibial surfaces rest on the tibia and the semilunar cartilages (menisci), while their anterior parts are in contact with the infrapatellar pad of fat. In full extension the anterior parts rest on the tibia, while the posterior parts are in contact with the posterior part of the articular capsule.

* A cycloid is the curve traced by a point on the circumference of a wheel rolling along a straight line.

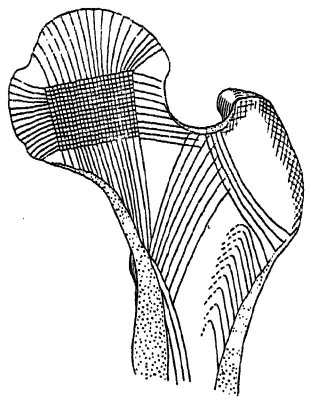
The medial condyle projects medially and downwards to such an extent that, despite the obliquity of the shaft, the lower surface of the lower end of the bone is practically horizontal. A curved strip, about 1 cm. wide, adjoining the medial margin of the articular

Fig. 459.—A section through the hip-joint. Compare with fig. 460 as regards the bone trabeculæ.



surface, is covered with synovial membrane and lies within the capsule of the knee-joint. The medial epicondyle, which lies above this area, gives attachment to the medial (tibial collateral) ligament of the knee-joint. In front of the epicondyle the medial condyle is related to the medial patellar retinaculum (tendinous expansion of vastus medialis).

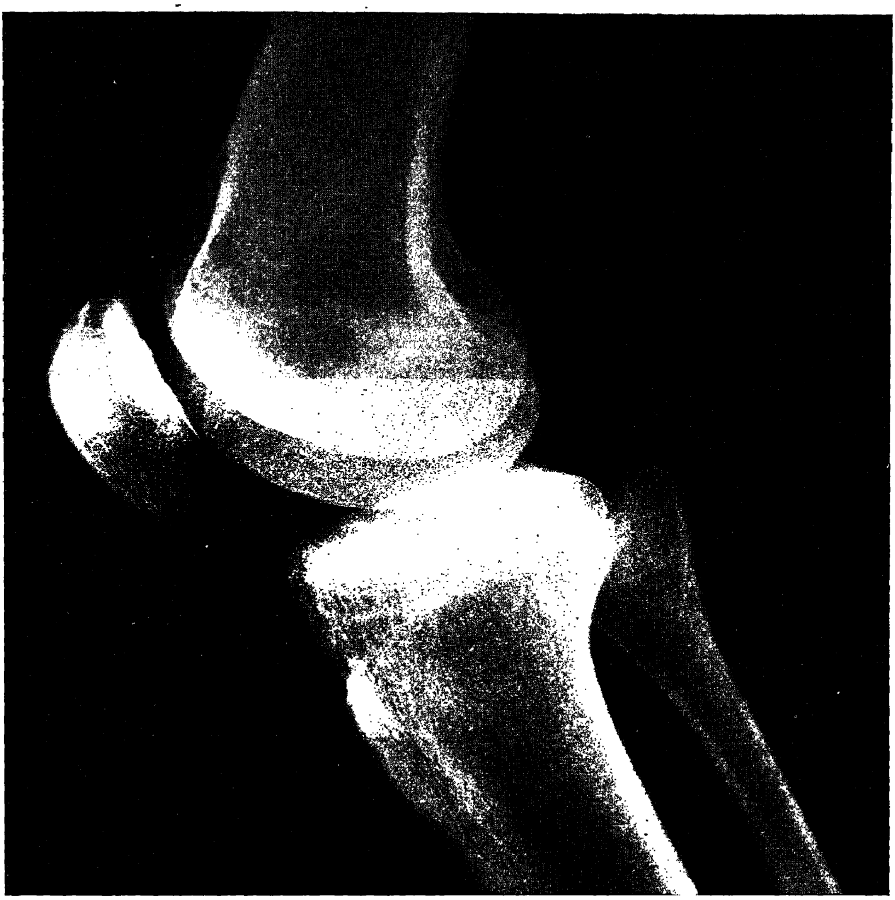
Fig. 460.—A scheme showing the disposition of the principal cancellous lamellæ in the upper end of the femur.



The **lateral condyle** is less prominent and its lateral surface projects but little beyond the lateral surface of the shaft. The lateral epicondyle gives attachment to the lateral (fibular collateral) ligament of the knee-joint, and above and behind it the bone bears an impression which gives origin to these fibres of the lateral head of the gastrocnemius that do not arise from the capsular ligament. The deepened, anterior end of the groove which lies between the epicondyle and the articular margin gives origin to the popliteus (fig. 458) muscle; the posterior or upper end of the groove lodges the tendon of the muscle only in full flexion of the knee. In extension the tendon passes across the margin of the articular surface below, and sometimes grooves it. Immediately adjoining the articular margin a strip of the lateral condyle, 1 cm. broad, is intracapsular, and is covered with synovial membrane, with the exception of the depression from which the popliteus arises.

The **intercondylar notch** separates the projecting portions of the two condyles, and is intracapsular but, to a large extent, extrasynovial. Its lateral wall, formed by the medial surface of the lateral condyle, bears a flattened impression which occupies its upper and posterior part and extends on to the floor of the notch close to the intercondylar line. This impression gives attachment to the upper end of the anterior cruciate ligament. The medial wall of the notch, formed by the lateral surface of the medial condyle, bears a similar but rather larger impression

PLATE IX



Radiograph of the knee region of an adult. Lateral view.

FIG. 1.—Radiograph of an adult knee. The gap between the lateral condyles of the femur and tibia is occupied by the articular cartilage of the two bones and the lateral semilunar cartilage.

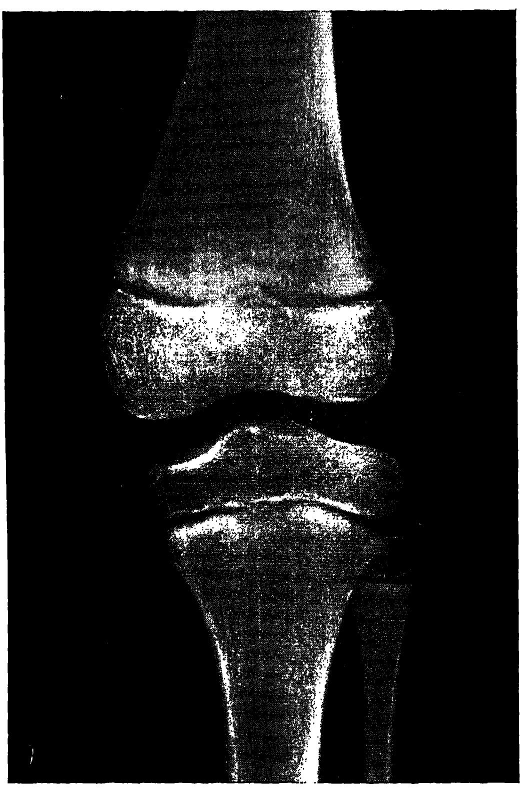


FIG. 2.—Radiograph of the knee of a child aged 7½ years. Note that the styloid process of the head of the fibula and the tubercles of the intercondylar eminence of the tibia are still cartilaginous and therefore cannot be recognised.

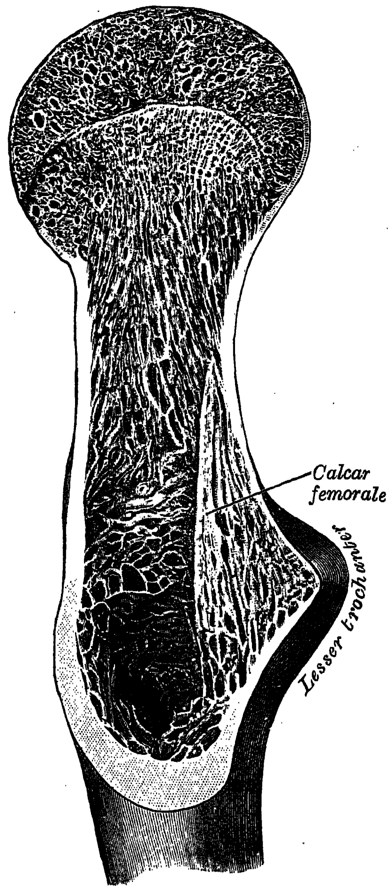
for the attachment of the upper end of the posterior cruciate ligament; it is placed anteriorly and extends on to the anterior part of the floor of the notch. These two impressions are relatively smooth, but the rest of the notch is rough and pitted by vascular foramina, although occasionally the bursal recess between the two ligaments extends upwards to reach it. The *intercondylar line* gives attachment to the capsular ligament and, laterally, to the oblique posterior (oblique popliteal) ligament of the knee-joint. The anterior border of the notch receives the upper attachment of the infrapatellar synovial fold.

Structure.—The shaft of the femur is a cylinder of compact bone, hollowed by a large medullary cavity. The wall of the cylinder is thick in the middle one-third of the shaft, where the bone is narrowest and the medullary cavity best formed; but above and below this the wall becomes thinner, while the medullary cavity is gradually filled up with spongy substance, so that the upper and lower ends of the shaft—and the articular extremities more especially—consist of spongy substance, invested by a thin compact layer.

Fig. 461.—An oblique section through the upper end of the left femur showing the calcar femorale.



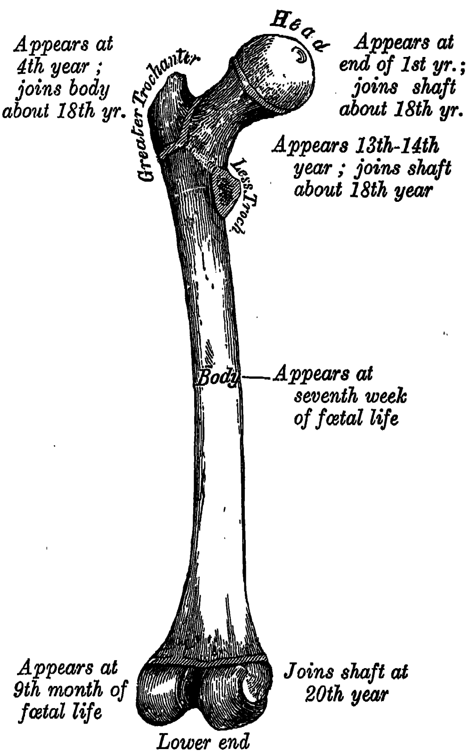
The trabeculæ in the ends of the femur are disposed along the lines of greatest pressure and tension. In the upper end (figs. 459, 460) the chief lamellæ are arranged in the following manner. A series of bony plates at right angles to the articular surface of the head converge to a central dense wedge; this wedge is supported by strong lamellæ which extend to the sides of the neck and are specially marked along its upper and lower borders. Any force therefore applied to the head of the femur is transmitted directly to the central wedge and thence to the junction of the neck with the shaft. This junction is in turn strengthened by a series of dense lamellæ which extend from the lesser trochanter to the lateral end of the superior border of the neck; this arrangement will obviously oppose considerable resistance to either tensile or shearing force. A smaller bar stretching across the junction of the greater trochanter with the neck and shaft resists the shearing force of the muscles attached to this prominence. These two bars—one at the junction of shaft and neck, the other at the junction of shaft and greater trochanter—form the upper layers of a series of arches which extend across between the sides of the shaft and transmit to it forces applied to the upper end of the bone. A thin vertical plate of bone, named the *calcar femorale* (fig. 461), springs from the compact wall of the shaft in the region of the linea aspera and extends into the spongy substance of the neck. Medially, it is attached to the inner surface of the posterior wall of the neck of the bone; laterally, it continues the plane of the posterior wall of the neck into the greater trochanter, where it shades off into the general spongy substance. It is thus situated in a plane anterior to the trochanteric crest and to the base of the lesser trochanter.

In the lower end, the trabeculæ spring on all sides from the inner surface of the cylinder, and descend in a direction perpendicular to the articular surface—the trabeculæ above the condyles being the strongest and having a more accurately perpendicular course. In addition to this, there are horizontal planes of

spongy substance, which in this situation is divided into a series of cubical compartments.

Ossification (figs. 454, 456, 462).—The femur is ossified from five centres: one each for the shaft, head, greater trochanter, lesser trochanter, and lower end. Except the clavicle, it is the first of the long bones to show traces of ossification. Ossification begins in the middle of the shaft in the seventh week of intrauterine life, and extends upwards and downwards. The secondary centres appear as follows: in the lower end, during the ninth month of intrauterine life (from this centre the condyles and epicondyles are formed); in the head at the end of the first year; in the greater trochanter during the fourth year; and in the lesser trochanter between the thirteenth and fourteenth years. The epiphyses, derived from the secondary centres, fuse independently with the shaft after puberty; the lesser trochanter joins first, then the greater, then the head, and, lastly, the lower end, which is not united until the twentieth year. It should be noted that the lower epiphyseal plate passes through the adductor tubercle (fig. 454).

FIG. 462.—A plan of the ossification of the femur. From five centres.



Applied Anatomy.—The lower end of the femur is usually the only epiphysis in which ossification has commenced at the time of birth. The presence of this centre of ossification is, therefore, a proof, in a new-born child found dead, that the child was viable, and is always relied upon in medico-legal investigations. The position of the epiphyseal plate should be carefully noted. It is on a level with the adductor tubercle, and the epiphysis does not, therefore, form the whole of the synovial covered portion of the lower end of the bone. It is essential to bear this point in mind when operations are performed on the lower end of the femur, since growth in length of the bone takes place chiefly from the lower epiphyseal cartilage, and any interference with it in a young child would involve such ultimate shortening of the limb, from want of growth, as to make the limb almost useless. Separation of the lower epiphysis may take place up to the age of twenty; but, as a matter of fact, few cases occur after the age of sixteen or seventeen. The epiphysis for the head is entirely intracapsular.

Fracture of the neck of the femur is usually termed *intracapsular* fracture, but this is not always a correct designation, as, owing to the attachment of the articular capsule, the fracture is partly within and partly without the capsule when the fracture occurs at the distal part of the neck. It generally takes place in old people, principally women, and usually from a very slight degree of indirect violence. Probably the main cause of its occurrence in old people is the senile degenerative change which takes place in the bone. Merkel believes that it is mainly due to the absorption of the calcar femorale. As a rule the fragments become united by fibrous tissue, but frequently no union takes place, and the opposed surfaces become smooth and eburnated.

Fractures at the junction of the neck with the greater trochanter are usually termed *extracapsular*, but this designation also is incorrect, for the fracture is partly within the capsule, as its attachment to the trochanteric line is beyond the line of fracture. These fractures are produced by direct violence to the greater trochanter, as from a fall laterally on the hip.

THE PATELLA

The **patella** (figs. 463, 464)*—the largest of the sesamoid bones—is situated in front of the knee-joint in the tendon of the quadriceps femoris. It is flattened and triangular, and has an anterior and a posterior surface, three borders, and an apex.

The *anterior surface* is convex, perforated by apertures for the passage of nutrient vessels, and marked by numerous rough, longitudinal striæ. It is separated from the skin by a bursa and is covered, in the recent state, by an expansion from the tendon of the quadriceps femoris; this expansion is continuous below with the superficial fibres of the ligamentum patellæ. The *posterior surface* presents in its upper part a smooth, oval, articular area, divided into two facets by a vertical ridge; the ridge corresponds to the groove on the patellar surface of the femur, and the facets to the medial and lateral parts of the same surface; the lateral facet is the broader and deeper. A narrow strip, broader above than below and often inconspicuous in the macerated specimen, is marked off from the medial part of the medial facet. This strip comes into contact with the medial condyle of the femur in extreme flexion of the knee-joint. Below the articular surface there is a rough, convex, non-articular area; its lower part gives attachment to the ligamentum patellæ; its upper part is covered by the infrapatellar pad of fat.

FIG. 463.—The left patella. Anterior aspect.

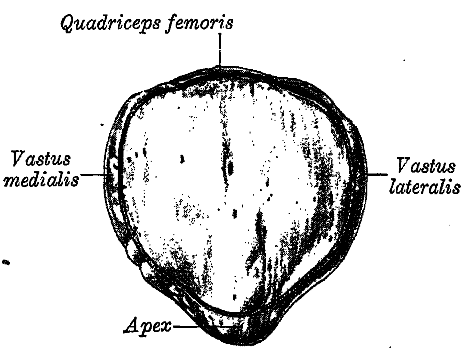


FIG. 464.—The left patella. Posterior aspect.

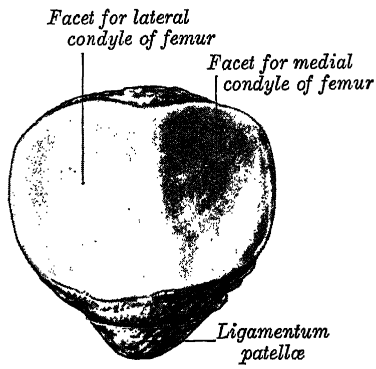

The *apex* is pointed, and gives attachment to the ligamentum patellæ.

The *base* or *superior border* is thick, and sloped from behind, downwards, and forwards: it gives attachment, except near its posterior margin, to that portion of the quadriceps femoris which is derived from the rectus femoris and vastus intermedius. The *medial* and *lateral borders* are thinner and they converge below: they give attachment to those portions of the quadriceps femoris which are derived from the vasti medialis et lateralis. Near the junction of the superior and lateral borders there is a small, shallow, circular depression into which a part of the tendon of the vastus lateralis is inserted.

Structure.—The patella consists of a nearly uniform dense spongy substance, covered by a thin compact lamina. The spaces immediately beneath the anterior surface are arranged parallel with it. In the rest of the bone they radiate from the articular surface towards the other parts of the bone.

Ossification.—The patella is ossified from a single centre which usually makes its appearance in the second or third year, but may be delayed until the sixth year. Ossification is completed about the age of puberty.

THE TIBIA (figs. 467–470)

General features.—The **tibia** is the medial and much the stronger of the two bones of the leg, and, excepting the femur, is the longest bone of the skeleton. It is prismoid in form, and possesses a shaft and two ends. Its *lower end* is smaller than

* The results of experimental excision of the patella in dogs are described by Eben J. Carey, Walter Zeit and Bernard F. McGrath, *American Journal of Anatomy*, vol. 40.

the upper end, and on its *medial side* a stout process, termed the medial malleolus, projects downwards beyond the rest of the bone. The *anterior border* of the shaft is a conspicuous, sharp crest, which curves medially at the lower end towards the medial malleolus; it is the most prominent of the three borders. The student should now be able to refer a given tibia correctly to its appropriate side.

The **upper end** of the tibia is expanded, especially in its transverse axis, to provide a good bearing surface for the body weight transmitted through the lower end of the femur. It comprises two prominent masses, named the *medial* and *lateral condyles*, and a smaller projection, termed the *tubercle of the tibia*. The condyles project backwards a little, so as to overhang the upper part of the posterior surface of the shaft, and superiorly each is covered by an articular surface, the two being separated by an irregularly roughened *intercondylar area*.

The **medial condyle** is the larger but does not overhang so much as the lateral condyle. Its upper articular surface (fig. 465), oval in outline, is concave in both diameters, and its lateral border projects upwards, deepening the concavity and covering an elevation, termed the medial intercondylar tubercle. The posterior surface of the condyle is marked, immediately below the articular margin, by a horizontal, roughened groove. Its medial and anterior surfaces form a rough strip, separated from the anterior surface of the shaft by an inconspicuous ridge.

Fig. 465.—The upper surface of the right tibia.

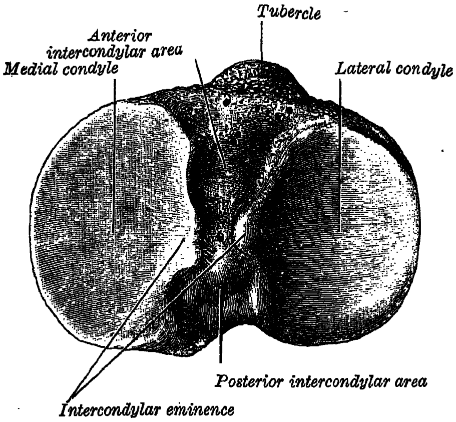

Fig. 466.—An outline of fig. 465 showing the attachments of the semilunar cartilages (menisci) and cruciate ligaments.

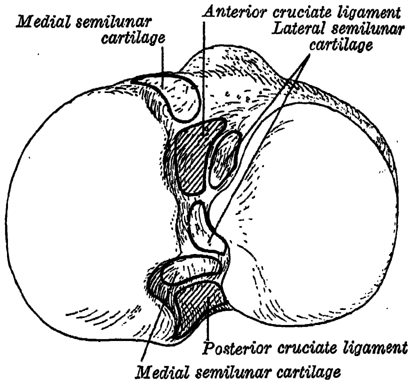


The **lateral condyle** overhangs the shaft, especially at its posterolateral part, which bears on its inferior surface a small circular facet for articulation with the upper end of the fibula. The upper surface (fig. 465) is covered with the articular surface for the lateral condyle of the femur. Nearly circular in outline, it is slightly hollowed in its central part, and its medial border extends upwards to cover an elevation, termed the lateral intercondylar tubercle. The posterior, lateral and anterior surfaces of the condyle are rough.

The anterior surfaces of the two condyles become continuous in front with a large triangular area, the apex of which is directed downwards and is formed by the tubercle of the tibia. The lateral edge of this area forms a sharp ridge which separates the lateral condyle from the lateral surface of the shaft.

The *intercondylar area* (fig. 465) is a roughened strip on the superior surface which intervenes between the articular surfaces of the two condyles. It is narrowest at its middle, where it is marked by an elevation termed the *intercondylar eminence*. The lateral and medial parts of the eminence project slightly upwards, and constitute the *lateral* and *medial intercondylar tubercles*. Both behind and in front of the eminence the intercondylar area becomes wider, as the curved margins of the articular surfaces recede from each other.

The **tubercle of the tibia** is placed at the upper end of the anterior border of the shaft, and is the truncated apex of the triangular area on the front of the bone where the anterior surfaces of the two condyles become continuous. It forms a low eminence, divided into a lower roughened and an upper smooth portion. The lower part can be felt through the skin, from which it is separated only by a bursa

termed the subcutaneous infrapateller bursa; the upper part gives attachment to the ligamentum patellæ.

Particular features.—The *articular surface of the medial condyle* is oval in shape, with its long axis anteroposterior. It is related around its anterior, medial and posterior margins to the medial semilunar cartilage (medial meniscus), and the area of contact is flattened. The imprint of the cartilage, which is widest behind and narrower at the medial side and in front, can often be recognised on the bone. The rest of the surface is concave, and its raised lateral margin covers the medial intercondylar tubercle. The *articular surface of the lateral condyle* is more nearly circular in shape. Like the medial articular surface it is related to the corresponding semilunar cartilage, and bears its flattened imprint. Elsewhere the surface is very slightly concave to adapt it to the surface of the corresponding femoral condyle, and its raised medial margin is continued on to the lateral aspect of the lateral intercondylar tubercle. The edges of the two articular surfaces are sharp except at the posterior part of the lateral surface, where the margin is smooth and rounded; in this situation the tendon of the popliteus is intimately related to the bone. The anterior and lateral margins of the lateral surface and the anterior, medial and posterior margins of the medial surface give attachment to the coronary ligaments (p. 498).

The *intercondylar area* (fig. 466) is widest anteriorly. In its anteromedial part, just in front of the medial articular surface, it bears a slight depression which gives attachment to the anterior horn of the medial semilunar cartilage. Behind that depression a relatively smooth area affords attachment to the lower end of the anterior cruciate ligament. The anterior horn of the lateral semilunar cartilage is attached to the bone in front of the intercondylar eminence and lies lateral to the anterior cruciate ligament. The *intercondylar eminence* occupies the narrow, middle part of the area, and is surmounted by two tubercles, of which the medial is slightly the more prominent. The posterior slope of the eminence gives attachment to the posterior horn of the lateral semilunar cartilage, and behind that the intercondylar area inclines downwards and backwards. A depression behind the base of the medial intercondylar tubercle gives attachment to the posterior horn of the medial semilunar cartilage. The rest of the area is smooth and affords attachment to the lower end of the posterior cruciate ligament, as far back as the ridge to which the capsular ligament is attached.

The groove on the posterior surface of the *medial condyle* receives the insertion of the semimembranosus muscle; its upper border receives the capsular ligament, and its lower border the posterior and shorter fibres of the medial ligament of the knee-joint. The medial and anterior surfaces of the condyle, which are marked by numerous vascular foramina, give attachment to the medial patellar retinaculum.

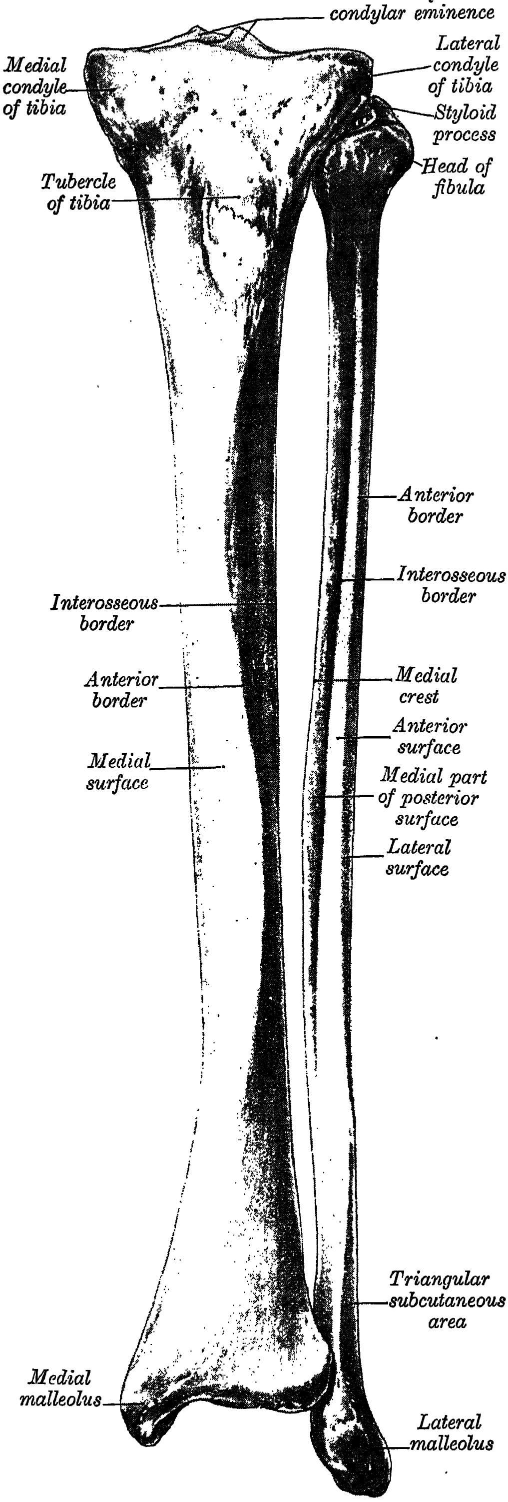
The *fibular facet* on the *lateral condyle* is directed downwards and slightly backwards and laterally. Above and to its medial side the posterior surface of the condyle is grooved by the tendon of the popliteus, but a bursa intervenes between the tendon and the bone. The lateral and anterior surfaces of the condyle are separated from the lateral surface of the shaft by a sharp margin which gives attachment to the deep fascia of the leg. An impression on the anterior surface, often well-marked though flattened, affords attachment for the iliotibial tract. Near the fibular facet the uppermost fibres of the extensor digitorum longus and peroneus longus arise from the lateral surface.

The tubercle of the tibia is subcutaneous in its lower part only; its upper part receives the attachment of the ligamentum patellæ. The two areas are sometimes separated by a rough crest, which receives the superficial fibres of the ligament. Above the tubercle the bone is related to the deep surface of the ligament, but the deep infrapatellar bursa and some fibro-fatty tissue intervene.

The shaft of the tibia (figs. 467, 469) is triangular on section, possessing medial, lateral and posterior surfaces, separated by anterior, interosseous and medial borders. It is thinnest at the junction of its middle and lower thirds, but expands considerably towards its upper and lower ends.

The *anterior border* commences at the tubercle of the tibia and runs downwards to the medial malleolus. It is subcutaneous throughout its whole length, and, except in its lower fourth, where it is rounded and indistinct, forms a sharp crest, which is familiarly known as the 'shin.' It is not straight, but follows a slightly sinuous course and its lower fourth diverges towards the medial side. The *interosseous border* commences below and a little in front of the fibular facet on the lateral condyle and descends to reach the anterior border of the fibular notch, which marks the lateral aspect of the lower end of the tibia. In nearly the whole of its length it affords attachment to the interosseous membrane which connects the tibia to the fibula. As a rule it is poorly defined at its upper end, but is easily identified in the rest of its extent. The *medial border* commences below the anterior end of the groove on the medial condyle and runs downwards to the posterior margin of the

FIG. 467.—The bones of the left leg. Viewed from in front.



medial malleolus. Its upper and lower fourths are rounded and ill-defined, but its middle third is sharper and can be recognised without difficulty.

The *medial surface* is bounded in front by the anterior border, and behind by the medial border. It is broad and smooth, and is subcutaneous throughout practically its whole extent. The *lateral surface*, also broad and smooth, is placed between the anterior and the interosseous borders. In its upper three-fourths it is directed laterally and is slightly concave from before backwards. Its lower fourth is carried round on to the front of the bone, owing to the deviation of the anterior border to the medial side and the forward inclination of the lower part of the interosseous border. This part of the surface is somewhat convex forwards. The *posterior surface* is bounded by the interosseous and the medial borders, and is widest at its upper end, where it is crossed from above downwards and medially by an oblique, roughened ridge, termed the *soleal line*. The area below this line is subdivided into medial and lateral parts by a faint *vertical line*, which begins at or just below the middle of the soleal line and soon fades away. A prominent vascular groove marks the bone near the upper end of the vertical line and descends to enter the large nutrient foramen; it may be situated either on the lateral or on the medial side of the vertical line.

Particular features.—The *anterior border* provides attachment for the deep fascia of the leg throughout its whole extent. A little above the medial malleolus it receives the medial end of the superior extensor retinaculum (transverse ligament of the leg). Above the soleal line the *medial border* gives attachment to the fascia covering the popliteus muscle and to the posterior fibres of the medial (tibial collateral) ligament of the knee-joint; below the soleal line it gives origin for a short distance to fibres of the soleus muscle and attachment to the fascia which covers the deep muscles of the leg. At its lower end it becomes continuous with the medial

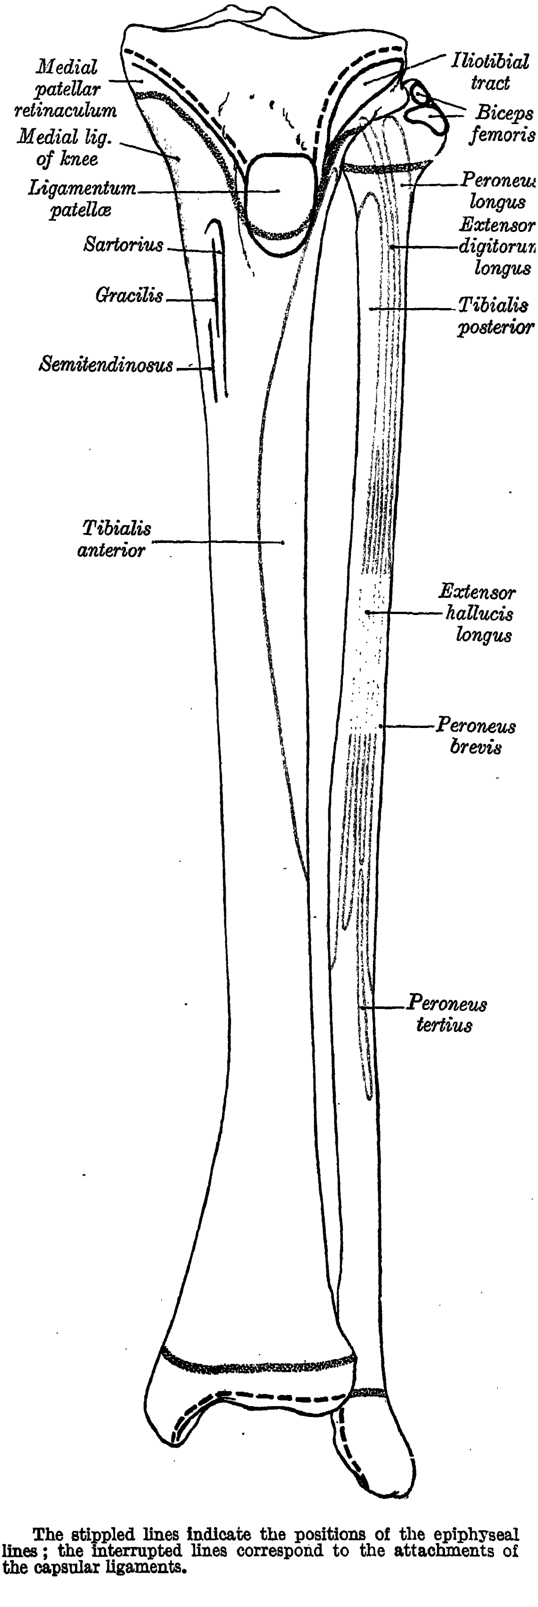
border of the groove which lodges the tendon of the tibialis posterior muscle. The *interosseous border* gives attachment to the interosseous membrane of the leg, except at its upper and lower ends. Its upper end is scarcely recognisable, and in this situation there is a large gap in the interosseous membrane for the passage of the anterior tibial vessels. Its lower end forms the anterior boundary of the fibular notch and gives attachment to the anterior inferior tibiofibular ligament.

The *medial surface* is usually roughened close to the upper part of the medial border over an area nearly 5 cm. long and 1 cm. wide; this area gives attachment to the longer fibres of the medial (tibial collateral) ligament of the knee-joint. In front of this roughened area the surface provides insertion for the tendons of the sartorius, gracilis and semitendinosus muscles, which however rarely produce markings on the bone. The gracilis, above, and the semitendinosus, below and behind, are inserted immediately in front of the ligamentous area; the sartorius is inserted into a line, which commences above and descends in front of the two other insertions (fig. 468). The rest of the surface is covered only by superficial fascia and skin, but its lower part is crossed obliquely by the long saphenous vein, as it ascends from in front of the medial malleolus.

The *lateral surface* gives origin in its upper two-thirds, or less, to the tibialis anterior muscle. Its lower part is devoid of muscular attachments, but is crossed by the tendon of the tibialis anterior (which lies along the lateral side of the anterior border), the extensor hallucis longus, the anterior tibial vessels and nerve (deep peroneal nerve), the extensor digitorum longus and peroneus tertius, in that order from the medial to the lateral side.

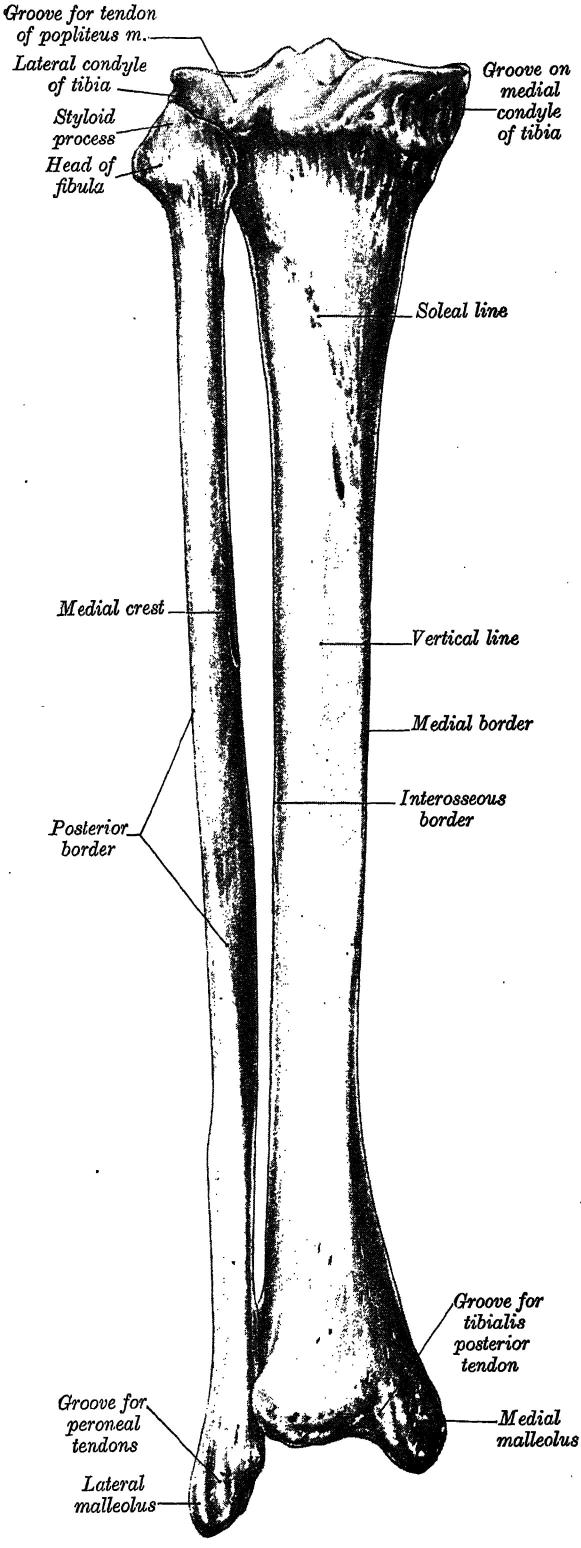
The *posterior surface* gives insertion to the popliteus over the triangular area above the soleal line, with the exception of the area adjoining the fibular facet. The *soleal line* gives attachment to the strong fascia which covers the popliteus muscle, and to the soleus muscle, its covering fascia, and the fascia covering the deep muscles of the leg. The upper end of the line does not reach the interosseous border and is marked by a tubercle, which gives attachment to the medial end of the tendinous arch in the soleus. Lateral to that tubercle the posterior tibial vessels and nerve descend on the

Fig. 468.—Key to fig. 467.



The stippled lines indicate the positions of the epiphyseal lines; the interrupted lines correspond to the attachments of the capsular ligaments.

FIG. 469.—The bones of the left leg. Viewed from behind.



surface of the tibialis posterior. Below the soleal line, the *vertical line* separates the origin of the flexor digitorum longus on the medial side from the origin of the tibialis posterior (fig. 470). The lower fourth, or more, of the posterior surface is devoid of muscular attachments, but is intimately related to the tendon of the tibialis posterior as it runs downwards and medially to reach the groove on the back of the medial malleolus. The flexor digitorum longus lies on the posterior surface of the tibialis posterior, crossing it obliquely from the medial to the lateral side, but the posterior tibial vessels and nerve and the flexor hallucis longus come into contact with the lateral part of this surface for a short distance above the lower end of the bone.

The lower end of the tibia is greatly expanded, and its medial portion projects downwards beyond the rest of the bone to form the medial malleolus. It possesses anterior, medial, posterior, lateral and inferior surfaces.

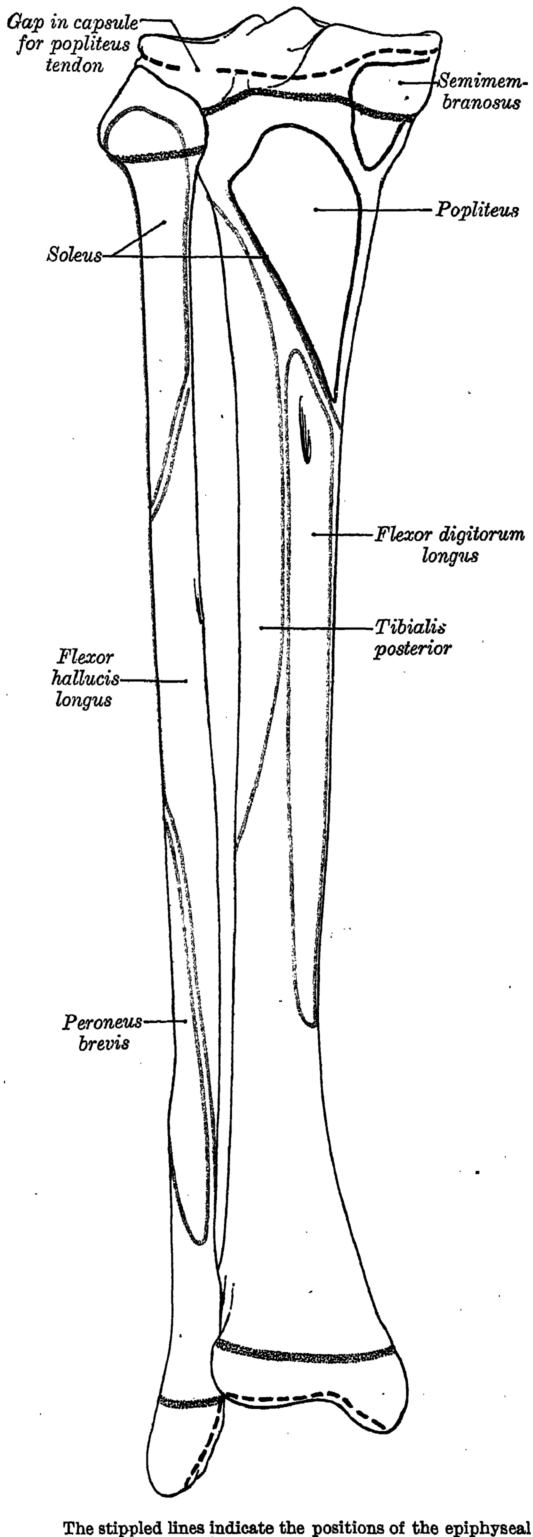
The *anterior surface* is smooth and bulges forwards beyond the inferior surface, from which it is separated by a narrow groove. It is continuous above with the lateral surface of the shaft. The medial surface also is smooth and is continuous above with the medial surface of the shaft and below with the medial surface of the medial malleolus. It is subcutaneous and can easily be felt through the skin. The *posterior surface* is crossed at its medial end by a groove which is usually conspicuous and can be traced down on to the posterior surface of the medial malleolus. Elsewhere this surface of the lower end is smooth and is continuous above with the posterior surface of the shaft. The *lateral surface* is formed by a triangular notch, termed the *fibular notch*, which is intimately related to the

lower end of the fibula. The anterior and posterior borders of the notch are salient and converge to meet above on the interosseous crest. The floor of the notch is roughened in its upper part for the attachment of the interosseous ligament which binds the lower ends of the two bones securely together. Its lower part is smooth and is sometimes covered with articular cartilage. The *inferior surface* is smooth for articulation with the body of the talus. Wider in front than behind, it is concave from before backwards and slightly convex from side to side. Medially it is uninterruptedly continuous with the articular surface of the medial malleolus.

The **medial malleolus** is a short but stout process. Its medial surface is smooth and convex, and can be felt easily through the skin. Its lateral surface is smooth and covered with a comma-shaped articular facet, which articulates with the medial side of the body of the talus. Its anterior surface is rough, and its posterior surface bears the lower end of the groove that marks the posterior surface of the lower end of the bone. The lower border of the malleolus is pointed in front, and behind that, it presents a depression for the attachment of the deltoid ligament of the ankle-joint.

Particular features.—The *anterior surface* of the lower end is related to the tendons, vessels and nerve which lie on the lower part of the lateral surface of the shaft and have already been enumerated (p. 399). The narrow groove adjoining the anterior border of the inferior surface gives attachment to the anterior ligament of the ankle-joint. The groove on the *posterior surface* lodges the tendon of the tibialis posterior, which at that level usually separates the flexor digitorum longus tendon from the bone. More medially the posterior tibial vessels and nerve and the flexor hallucis longus tendon are in contact with this surface. The floor of the *fibular notch*, especially in its rough upper part, gives attachment to the

FIG. 470.—Key to fig. 469.



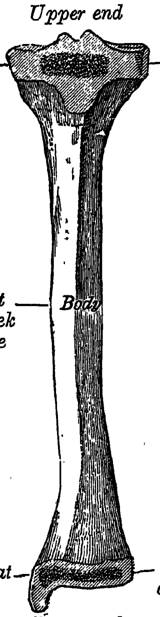
The stippled lines indicate the positions of the epiphyseal lines; the interrupted lines correspond to the attachments of the capsular ligaments

interosseous tibiofibular ligament; its lower smooth part may be covered with articular cartilage. The anterior and posterior borders of the notch give attachment respectively to the anterior and posterior inferior tibiofibular ligaments. The *medial malleolus* is shorter than the lateral malleolus, which lies on a more posterior plane. Its anterior surface gives attachment to the anterior and capsular ligaments of the ankle-joint. Its posterior surface is grooved by the tibialis posterior tendon, and the raised, medial margin of the groove gives attachment to the flexor retinaculum (laciniate ligament). The upper end of the deltoid ligament is attached to the lower border of the malleolus both to the pointed anterior part and to the depression behind it.

Structure.—The structure of the tibia is like that of the other long bones. The compact wall of the shaft is thickest at the junction of the middle with the lower one-third of the bone.

Ossification.—The tibia is ossified from three centres (figs. 468, 470, 471): one for the shaft and one for each end. Ossification begins in the middle of the shaft about the seventh week of intra-uterine life. The centre for the upper end appears before or shortly after birth, and from it a thin tongue-shaped process extends downwards in front to form the tubercle (fig. 471); the centre for the lower end appears in the second year. The lower end joins the shaft about the eighteenth year; the upper about the twentieth year. Two additional centres occasionally exist—one for the tongue-shaped process which forms the tubercle, and one for the medial malleolus.

FIG. 471.—A plan of the ossification of the tibia. From three centres.



THE FIBULA (figs. 467–470)

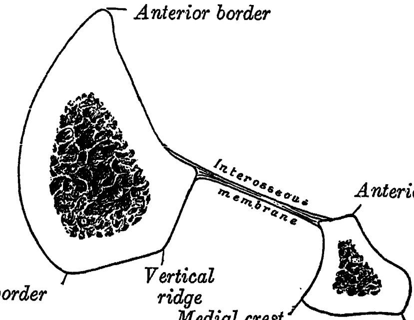
General features.—The **fibula** is the lateral bone of the leg, and is very slender as compared with the tibia, for it is not called upon to share in the transmission of the body weight. It possesses an upper end or head, a shaft and a lower end, which constitutes the lateral malleolus. The shaft shows considerable variation in its form, for it is moulded by the muscles to which it gives attachment; and these variations may prove confusing to the junior student. The *lower end* should be identified first. It is expanded antero-posteriorly but is flattened from side to side. It bears a triangular articular facet on the anterior part of its *medial surface*, which is directed medially to articulate with the talus. A well-marked depression, termed the malleolar fossa, lies *posterior* to the articular facet. The student has now been provided with sufficient information to enable him to determine the side to which a given fibula belongs.

The **head** of the fibula is slightly expanded in all its diameters, and projects beyond the shaft in front, behind and on the lateral side. It bears on its upper surface a nearly circular articular facet, which articulates with the inferior surface of the lateral condyle of the tibia; it is directed upwards, and slightly forwards and medially. A blunt elevation, termed the *styloid process*, projects upwards from the lateral part of its posterior surface. The head of the fibula can be felt through the skin on the posterolateral aspect of the knee, *nearly 2 cm. below the level of the knee-joint*. Immediately below the head a large nerve, termed the lateral popliteal nerve, crosses the posterolateral aspect of the constricted upper end of the shaft and can be rolled against the bone in the living subject. If sufficient pressure is exerted,

tingling sensations will be experienced on the dorsum of the foot, radiating to the toes, and especially to the medial side of the big toe.

The **lower end** or **lateral malleolus** projects downwards to a lower level than the tibia. Its lateral surface is subcutaneous and can be felt through the skin

FIG. 472.—A transverse section through the right tibia and fibula, showing the attachment of the crural interosseous membrane.



without difficulty; its posterior surface is marked by a broad groove with a prominent lateral border. Its anterior surface is rough and rounded and is continuous below with the inferior border. The medial surface (fig. 473) presents a triangular articular facet, with its apex pointing downwards, which articulates with the lateral surface of the talus in the ankle-joint; it is convex from above downwards. Behind the articular facet the bone is marked by a roughened depression, termed the *malleolar fossa*, which readily admits the tip of a finger.

FIG. 473.—The lower end of the right fibula. Medial aspect.

The **shaft** of the fibula (figs. 467, 469) possesses three borders and three surfaces, each of which can be associated with a particular group of muscles. The borders are anterior, posterior and interosseous, and they should be identified first. At its lower end the *anterior border* divides to enclose an elongated, triangular area which is continuous below with the lateral surface of the lateral malleolus. Traced upwards, it ascends to reach the anterior aspect of the head. The *posterior border* is continuous with the medial margin of the groove on the back of the lateral malleolus. Usually sharp and distinct in its lower part, it is often rounded in the upper half of its extent. The *interosseous border* lies to the medial side of the anterior border and as a rule is on a more posterior plane (fig. 472), but in the upper two-thirds of the bone these two borders are very close to each other, and the intervening surface may be 1 mm. or less in width.

The *lateral surface* is bounded by the anterior and posterior borders. It is associated with the peroneal muscles, and is directed laterally in its upper three-fourths. Its lower fourth inclines backwards and becomes continuous with the groove on the back of the lateral malleolus. The *anterior surface* is bounded by the anterior and the interosseous borders. It is usually directed forwards and medially, but frequently faces directly forwards. Wider below, it becomes

very narrow in its upper half, and may be reduced to little more than a rounded ridge on the upper part of the shaft. It is associated with the extensor muscles of the leg. The *posterior surface* is the largest of the three and is placed between the interosseous and the posterior borders. It is associated with the flexor muscles of the leg. In its upper two-thirds it is divided into two areas by a longitudinal ridge, termed the *medial crest*, which is separated from the interosseous border by a grooved surface, directed medially. The rest of the posterior surface faces backwards in its upper half or more, but its lower part curves round on to the medial aspect and is directed medially. The lower part of this area fits into the fibular notch on the tibia and is roughened for the attachment of the interosseous tibiofibular ligament.

The elongated, triangular area immediately above the lateral surface of the lateral malleolus is subcutaneous, but the rest of the shaft is covered with muscles and cannot be examined satisfactorily in the living subject.

Particular features.—The *head of the fibula* affords origin to fibres of the extensor digitorum longus in front, peroneus longus anterolaterally, and soleus behind. The tendon of biceps femoris gains its principal insertion into the anterolateral, sloping surface of the styloid process, but it is split near its insertion by the lower part of the lateral ligament of the knee-joint, and its smaller anterior part passes into the lateral aspect of the head, above the origin of the peroneus longus. A flattened impression on the lateral aspect of the head receives the lower attachment of the lateral ligament of the knee-joint. The margins of the articular facet provide attachment for the capsular ligament of the superior tibiofibular joint.

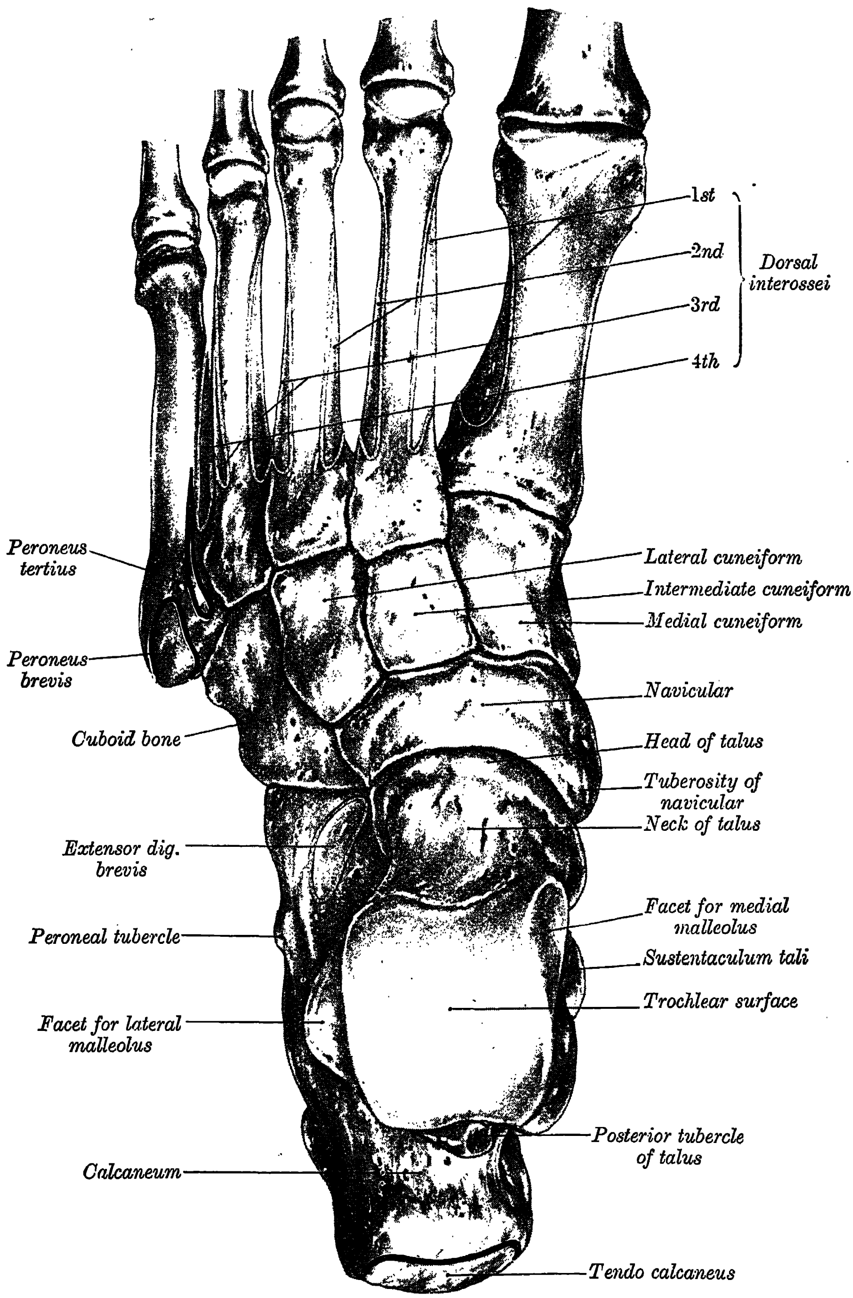
Fig. 474.—A plan of the ossification of the fibula. From three centres.

The *anterior border* of the fibula divides inferiorly into two ridges which enclose between them a subcutaneous triangular surface (fig. 473). The anterior intermuscular septum of the leg is attached to its upper three-fourths, and the lateral extremity of the superior extensor retinaculum (transverse ligament of the leg) to the lower part of the anterior border of the triangular area. The lower part of the posterior margin of the triangular area gives attachment to the lateral extremity of the superior peroneal retinaculum. The *interosseous border* terminates below at the upper extremity of the roughened area for the attachment of the tibiofibular interosseous ligament. It provides attachment for the interosseous membrane and does not reach so high as the head of the bone, on account of the gap in the upper part of the membrane for the transmission of the anterior tibial vessels. The *posterior border* is not always recognisable at its upper end; below, it becomes continuous with the medial border of the groove on the back of the lateral malleolus. Except at its lower end it gives attachment to the posterior intermuscular septum of the leg. The *medial crest* of the bone is intimately related to the peroneal artery, and the nutrient foramen of the fibula is situated either on the crest or in its immediate vicinity near the middle of the shaft. It gives attachment to a layer of the deep fascia of the leg which separates the tibialis posterior from the flexor hallucis longus and the flexor digitorum longus muscles.

The *anterior surface* of the fibula is often termed the *extensor surface*, for it gives origin to the extensor digitorum longus, the extensor hallucis longus and the peroneus tertius. The extensor digitorum longus arises from the whole breadth of the upper fourth of the surface and from the anterior part of the succeeding two-fourths; the extensor hallucis longus arises from its middle two-fourths behind the extensor digitorum longus; the peroneus tertius arises from its lower fourth or more, and is directly continuous with the lower part of the extensor digitorum longus. The *lateral surface* is frequently termed the *peroneal surface*, because it gives origin to the peroneus longus and the peroneus brevis. The peroneus longus arises from the whole extent of the upper third of the surface and from the posterior part of the middle third. The peroneus brevis arises in front of the lower half of the peroneus longus and extends downwards beyond it almost to the lower end of the bone. On account of the relative attachments of their fleshy bellies the tendon of the peroneus

brevis is closely applied to the bone below and separates it from the tendon of the peroneus longus. The *posterior surface*, which is divided longitudinally into two parts by the medial crest, is often termed the *flexor surface*. The portion which lies between the crest and the interosseous border is slightly hollowed out and gives origin to the tibialis posterior; it is

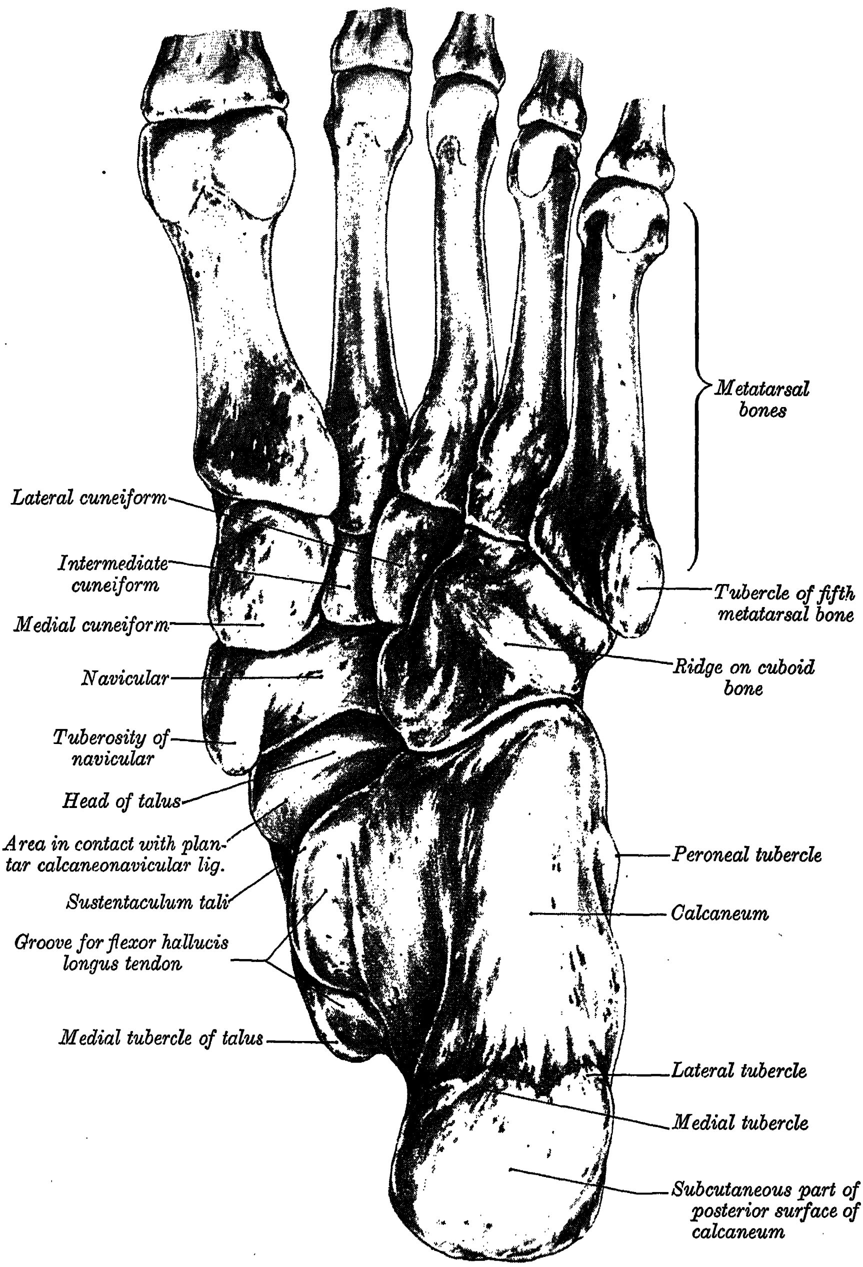
FIG. 475.—The tarsus and metatarsus of the left foot. Dorsal aspect.



often crossed by an oblique ridge which gives attachment to an intramuscular tendon. This part of the surface is usually confined to the upper three-fourths of the shaft, and at its lower end the medial crest becomes confluent with the interosseous border. The portion of the posterior surface which lies between the medial crest and the posterior border gives origin in its upper fourth to the soleus, which extends upwards on to the posterior aspect of the head; near the upper end of the medial part of this origin a roughened tubercle marks the lateral end of the tendinous arch which is thrown across the posterior tibial

vessels and nerve by the soleus muscle. Below the origin of the soleus the remainder of this surface gives origin to the flexor hallucis longus, whose origin extends downwards almost to the lower end of the bone. The triangular area of the shaft above the lateral malleolus is covered only by the superficial fascia and the skin. Above the lateral malleolus a triangular

FIG. 476.—The tarsus and metatarsus of the left foot. Plantar aspect.



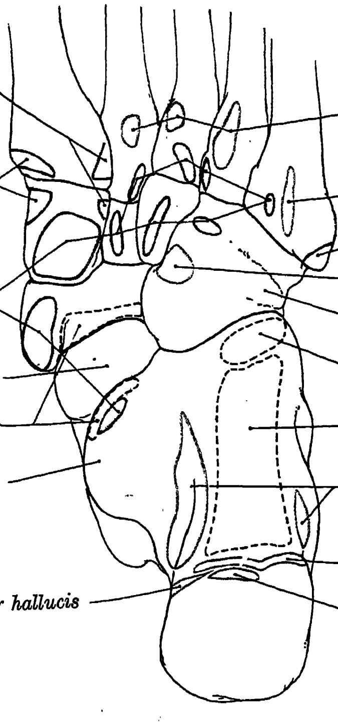
area on the medial surface of the shaft gives attachment to the interosseous tibiofibular ligament (fig. 473) and its anterior and posterior margins to the corresponding ligaments of the inferior tibiofibular joint.

The anterior surface of the *lateral malleolus* gives attachment to the anterior talofibular ligament. The lower border is marked in front by a slight notch and behind by a small projection which constitutes the apex of the malleolus. It is to the notch that the calcaneofibular ligament is attached. The groove on the posterior aspect lodges the tendons

of the peroneus brevis and peroneus longus ; the latter is the more superficial and is closely covered by the superior peroneal retinaculum. The *malleolar fossa* (fig. 473) is pitted by numerous small vascular foramina ; its upper part gives attachment to the inferior transverse tibiofibular ligament, its lower part to the posterior talofibular ligament.

Ossification.—The fibula is ossified from three centres (fig. 474) : one for the shaft, and one for each end. Ossification begins in the shaft about the eighth week of intrauterine life, in the lower end during the second year, and in the upper about the fourth year. The lower epiphysis—the first to ossify—unites with the shaft about the twentieth year ; the upper about the twenty-fifth year.

FIG. 477.—Key to fig. 476.



THE SKELETON OF THE FOOT

The skeleton of the foot has three segments : the tarsal bones, the metatarsal bones, and the phalanges or bones of the digits.

THE TARSUS (figs. 475–477)

The **tarsus** comprises seven short bones which make up the skeleton of the posterior half of the foot. It is homologous with the carpus but its constituent elements are larger and stronger, on account of the part they play in supporting and distributing the weight of the body in the erect attitude. Like the bones of the carpus the tarsal bones are arranged in a proximal and a distal row, but an additional element is interposed between the two rows on the medial side. The proximal row comprises the **talus** and the **calcaneum.** These two bones do not lie side by side ; the talus is placed above the calcaneum, but its long axis is directed forwards, medially and downwards, so that its anterior end or head comes to lie on the medial side of the calcaneum, though at a higher level. The distal row comprises four bones, named, from the medial to the lateral side, the **medial cuneiform,** the **intermediate cuneiform,** the **lateral cuneiform** and the **cuboid.**

These bones lie side by side and together contribute to the formation of a transverse arch, which is convex upwards. On the medial side the **navicular bone** is interposed between the talus and the medial three bones of the distal row. On the lateral side the calcaneum articulates directly with the cuboid bone.

Fig. 478.—The left talus. Superior aspect.

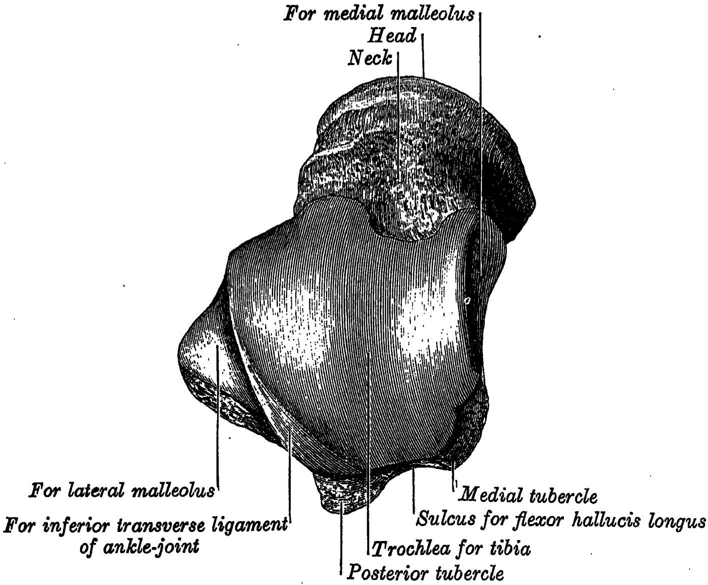


Fig. 479.—The left talus. Plantar aspect.

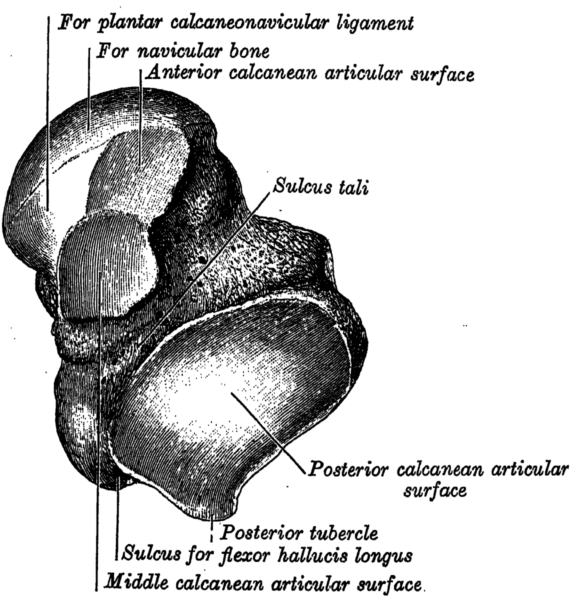

The foot is set at right angles to the leg, and the tarsus and metatarsus are arranged in such a way as to form intersecting longitudinal and transverse arches (fig. 497). As a result the weight is not transmitted to the ground from the tibia directly through the tarsus, but is distributed through the tarsal and metatarsal bones to the extremities of the arches (see p. 423). Each of the tarsal bones is roughly cuboidal in form and presents six surfaces for examination.

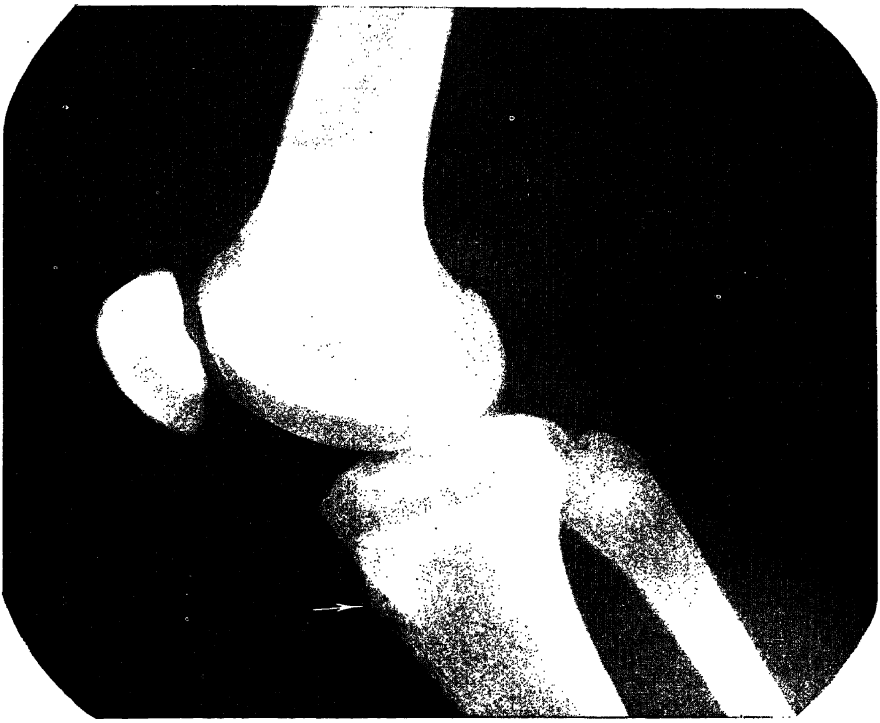

Fig. 1.—Radiograph of the knee of a boy aged 16 years. Lateral view. Note that the upper epiphysis of the tibia includes the tibial tubercle, which is indicated by the arrow.

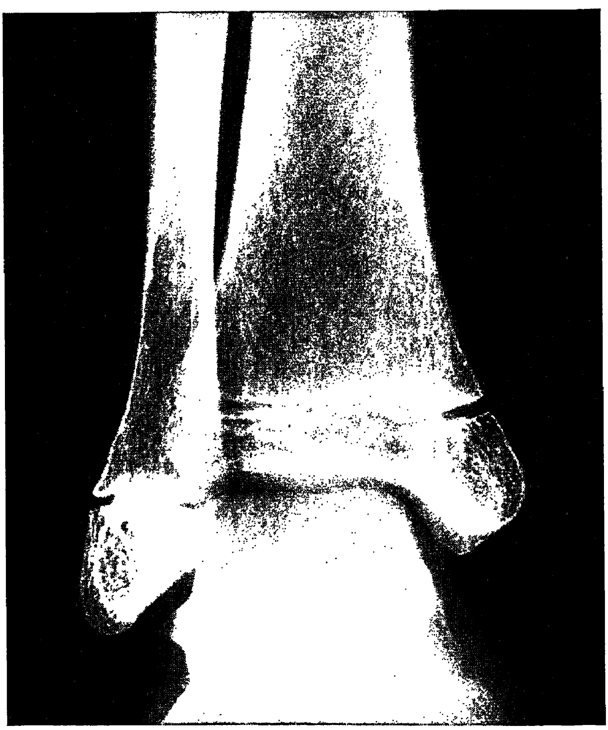

Fig. 2.—Radiograph of the ankle of a child aged 10 years. Note that the inferior epiphyseal line of the fibula is opposite the ankle joint.

PLATE XII

THE TALUS (figs. 478–481)

General features.—The **talus** is the principal connecting link between the foot and the bones of the leg, and takes an important part in the formation of the ankle-joint. The rounded head, which is placed at the *anterior* end of the bone, the trochlear surface for the tibia on the *superior* surface and the large triangular facet for the lateral malleolus on the *lateral* surface can be recognised without difficulty, and enable a talus to be referred to its appropriate side of the body.

The talus possesses a head, a neck and a body.

The **head** of the talus is directed forwards and slightly downwards and medially. Its *anterior surface*, which is oval and convex, with its long axis directed downwards and medially, articulates with the posterior surface of the navicular bone. The

FIG. 480.—The left talus. Medial aspect.

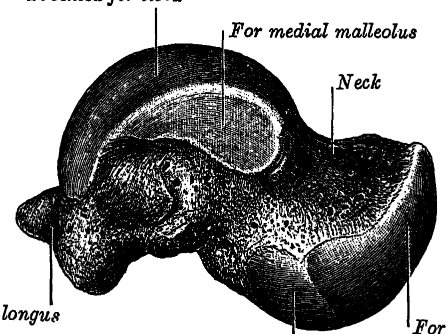

FIG. 481.—The left talus. Lateral aspect.

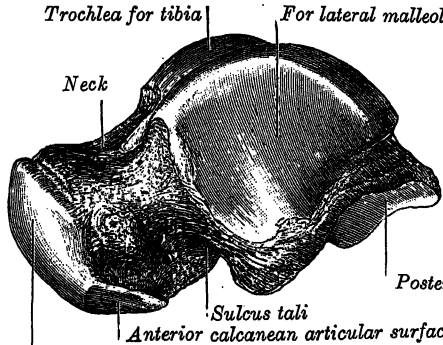

inferior surface is marked by three articular areas, which are separated by indistinct ridges. Of these areas the most posterior is the largest; oval in outline, it is gently convex and rests on the upper surface of a shelf-like projection from the medial side of the calcaneum named the sustentaculum tali. Anterior and lateral to this area, and usually continuous with it, a flattened articular facet rests on the anterolateral part of the upper surface of the calcaneum; it is continuous in front with the navicular surface. Medial to the two calcanean facets a part of the head of the talus is exposed on the plantar aspect of the articulated foot. This area is covered with articular cartilage and is continuous on the one hand with the calcanean areas and on the other with the navicular area. In the recent state it lies in contact with an important ligament named the *plantar calcaneonavicular* or '*spring*' *ligament* (p. 511).

The **neck** of the talus is the slightly constricted part which connects the head to the body. It is set very obliquely on the body and extends farther backwards

on the medial side than on the lateral side. Its roughened surfaces give attachment to ligaments, and the medial part of its inferior surface exhibits a deep groove, termed the *sulcus tali*. When the talus and calcaneum are articulated together this groove forms the roof of a bony canal, termed the *sinus tarsi*, which is occupied by the interosseous talocalcanean ligament.

The **body** of the talus is cuboidal in shape. Its superior surface is covered by a *trochlear* articular surface, which articulates with the lower end of the tibia in the ankle-joint. It is convex from before backwards and gently concave from side to side, and it is important to observe that it is widest anteriorly. The *lateral surface*, triangular in outline, is smooth for articulation with the lateral malleolus, and is concave from above downwards. Superiorly it is continuous with the trochlea; inferiorly its apex forms the *lateral tubercle* of the talus. The *medial surface* is covered in its upper part by a comma-shaped articular facet which is deeper in front than behind and articulates with the medial malleolus. Below the facet the surface is rough and is pitted by numerous vascular foramina. The *posterior surface* is rough, is small in extent and is marked by an oblique groove placed between two tubercles. The *posterior tubercle*, which is usually the larger, is on the lateral side of the groove; the *medial tubercle* is less prominent and lies immediately behind the sustentaculum tali of the calcaneum (fig. 476). The *inferior surface* rests on the upper surface of the calcaneum and is covered with an oval concave facet, the long axis of which runs forwards and laterally.

Particular features.—*The talus is devoid of any muscular attachments*, but it provides attachment for numerous ligaments (figs. 563 and 564), as it takes part in the formation of the ankle, the talocalcanean and the talocalcaneonavicular joints.

The long axis of the neck is inclined downwards and forwards and medially, making an angle of about 150° with the long axis of the body. This angle is smaller (130°-140°) in the newly-born child, and helps to account for the inverted position of the foot in young children. The dorsal surface of the neck gives attachment anteriorly to the dorsal talonavicular ligament and the anterior ligament of the ankle-joint; the posterior part of this surface therefore lies within the capsular ligament of the ankle-joint. The lateral part of the neck gives attachment to the anterior talofibular ligament, which extends downwards along the neighbouring anterior border of the lateral surface. The inferior surface of the neck gives attachment to the interosseous talocalcanean ligament, which is usually subdivisible into three parts (p. 509).

The *medial border of the trochlear articular surface* is straight but its *lateral border* inclines medially at its posterior part, which is often broadened and flattened to form a small elongated triangular area. It is this part of the bone which comes into contact with the inferior transverse tibiofibular ligament in dorsiflexion of the ankle-joint.

The *posterior tubercle* receives the attachment of the posterior talofibular ligament, which extends upwards to the groove, or depression, between the tubercle and the posterior border of the trochlea. Its lower border gives attachment to the posterior talocalcanean ligament. The *groove* between the posterior and medial tubercles lodges the tendon of the flexor hallucis longus and is continuous below and in front with the groove on the inferior surface of the sustentaculum tali. The *medial tubercle* gives attachment by its medial aspect to the medial talocalcanean ligament below, and to the most posterior of the superficial fibres of the deltoid ligament above.

The roughened area below the comma-shaped articular facet on the medial surface provides attachment for the deep fibres of the deltoid ligament.

The long axis of the posterior calcanean facet on the inferior surface of the body runs forwards and laterally at an angle of about 45° with the median plane. In about 10 per cent. of cases * a small pressure facet is found at the lateral end of the posterior wall of the sulcus tali; it is continuous with the anterolateral part of the posterior calcanean facet.

The Calcaneum (figs. 482–485)

General features.—The **calcaneum** is the largest and strongest of the tarsal bones; it projects backwards beyond the bones of the leg so as to provide a useful lever for the muscles of the calf, which are inserted into its posterior surface. It is irregularly cuboidal in shape, and its long axis is directed forwards, upwards and somewhat laterally. The student will experience no difficulty in distinguishing the small articular anterior end from the larger, roughened, posterior end, nor in dis-

* R. B. S. Sewell, *Journal of Anatomy and Physiology*, vol. xxxviii.

tinguishing the rough plantar surface from the upper surface, which bears a large, articular facet about its middle. Finally the lateral surface is flattened, whereas the medial surface is hollowed out from above downwards and backwards. The student should now be able to assign a calcaneum correctly to its appropriate side of the body.

The *upper surface* is subdivisible into three areas. The posterior third is roughened, convex from side to side and concave from behind forwards; it supports a mass of fibro-fatty tissue interposed between the tendo calcaneus and the back of the ankle-joint. The middle third is covered by the *posterior facet for the talus*, which is oval in outline and convex anteroposteriorly. The anterior third is partly articular and partly non-articular. In front of the posterior articular facet there is a rough depression, which becomes narrower and takes the form of a groove on the medial side. This is termed the *sulcus calcanei* or *groove of*

FIG. 482.—The left calcaneum. Superior aspect.

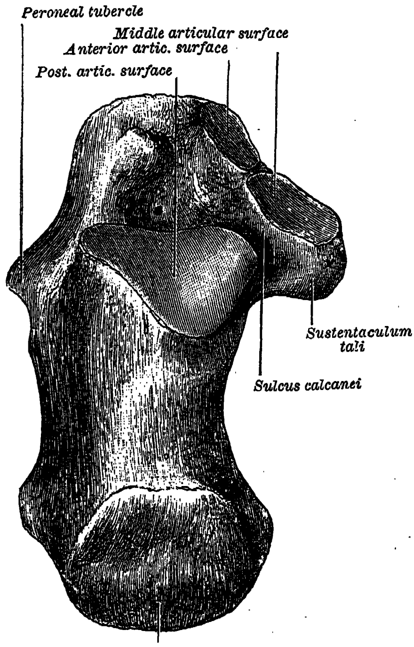

FIG. 483.—The left calcaneum. Plantar aspect.

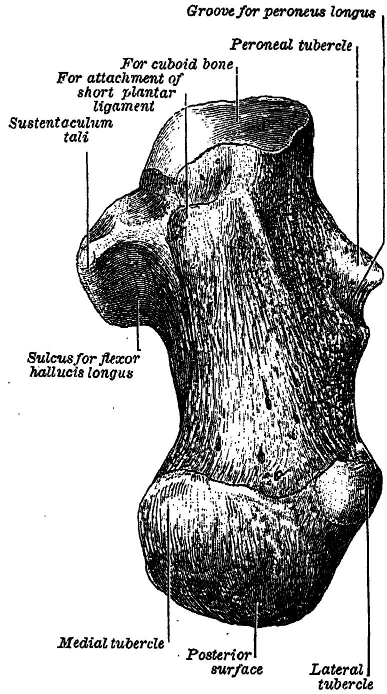

the calcaneum; it corresponds to the sulcus tali and helps it to complete the sinus tarsi in the articulated foot. In front of and medial to this groove an elongated articular area covers the upper surface of a projecting shelf termed the sustentaculum tali, and extends forwards and medially on to the body of the bone. This area is not infrequently subdivided into two parts by a narrow non-articular interval which marks the anterior limit of the sustentaculum tali. They constitute the *middle* and *anterior facets for the talus*.

The *anterior surface* is the smallest of the six surfaces, and is entirely covered by an obliquely-set concavoconvex facet which articulates with the cuboid bone.

The *posterior surface* is divided into three areas. The uppermost is smooth and is separated from the tendo calcaneus by a bursa and some fatty tissue. The middle area is the largest; it is roughened to give insertion to the tendo calcaneus. The lowest area slopes downwards and forwards and is subcutaneous.

The *plantar surface* is rough and is marked by three tubercles. The *lateral* and *medial tubercles* are placed at the posterior part of this surface and are separated from each other by a slight notch. The medial tubercle is the larger of the two. Near the anterior part of this surface the *anterior tubercle* forms a rounded prominence which is separated from the anterior border by a narrow rough area.

The *lateral surface* is almost flat and is much deeper behind than in front. In its anterior part it presents a small elevation, termed the *peroneal tubercle*, which is exceedingly variable in its size. When well developed, it exhibits an oblique groove on its postero-inferior part, for the peroneus longus tendon, and a shallower groove on its anterosuperior aspect, for the peroneus brevis tendon. About 1 cm. or more behind the peroneal tubercle a second elevation may mark the bone; it gives attachment to part of the lateral ligament of the ankle-joint.

FIG. 484.—The left calcaneum. Lateral aspect.

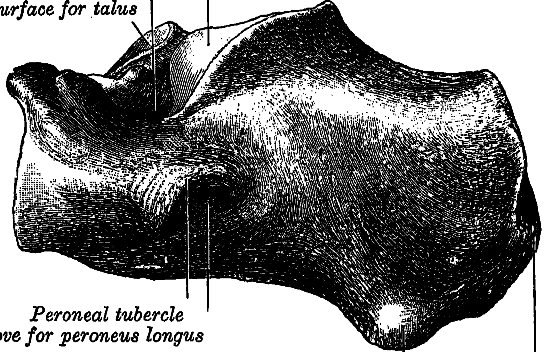

FIG. 485.—The left calcaneum. Medial aspect.

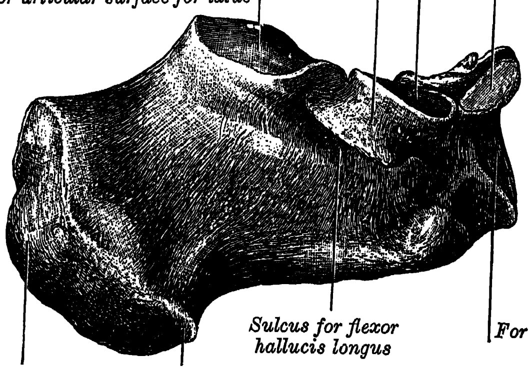


The *medial surface* is concave from above downwards and backwards, and its concavity is accentuated by a shelf-like process, termed the *sustentaculum tali*, which projects medially from the anterior part of its upper border (fig. 482). The superior surface of this process bears the middle facet for the talus, and its inferior surface is marked by a groove which is continuous with the groove on the posterior surface of the talus and lodges the flexor hallucis longus tendon. The medial surface of the sustentaculum tali can be felt indistinctly through the skin immediately below the tip of the medial malleolus; occasionally it presents a groove for the flexor digitorum longus tendon.

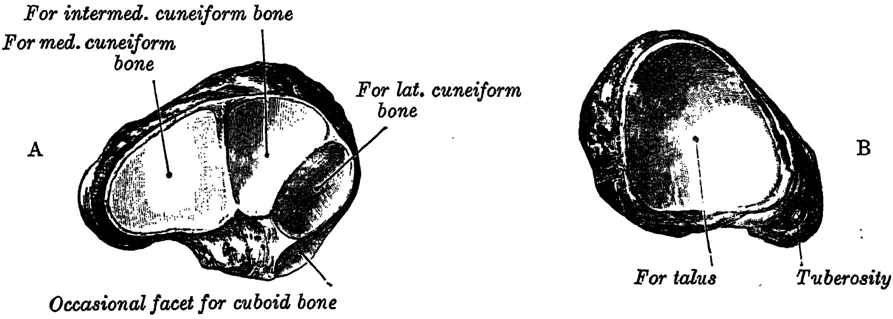
Particular features.—The *groove of the calcaneum* gives attachment to the interosseous talocalcanean ligament (p. 509). In addition, the non-articular area in front of the posterior facet for the talus gives partial origin to the extensor digitorum brevis and attachment to the principal band of the inferior extensor retinaculum (cruciate ligament) and to the stem of the bifurcated ligament.

The *medial tubercle* gives origin by its prominent medial margin to the abductor hallucis (fig. 477) and attachment to the superficial part of the flexor retinaculum (laciniate ligament), and in front to the plantar aponeurosis and the flexor digitorum brevis. The *lateral tubercle* gives origin to the abductor digiti minimi, which extends medially to arise from the front of the medial tubercle also. The roughened strip between the medial and lateral tubercles, behind, and the anterior tubercle, in front, gives attachment to the long plantar ligament, while the short plantar (plantar calcaneocuboid) ligament springs from the anterior tubercle and the narrow rough area in front of it (fig. 477). The lateral tendinous head of the flexor digitorum accessorius (quadratus plantæ) arises from the bone in front of the lateral tubercle close to the lateral margin of the long plantar ligament.

The *posterior surface* is wider below than above. Close to the medial side of the insertion of the tendo calcaneus it receives the insertion of the plantaris muscle.

The anterior part of the *lateral surface* is crossed by the tendons of the peroneus longus and brevis, but in most of its extent is covered only by the skin and superficial fascia. The peroneus brevis tendon, after passing behind the lateral malleolus, runs forwards and slightly downwards above and in front of the peroneal tubercle; the peroneus longus tendon passes downwards and forwards below and behind the tubercle, which gives attachment to a slip from the inferior peroneal retinaculum (p. 651). The calcaneofibular ligament is attached to the bone about 1 cm. or more behind the peroneal tubercle, and the site is usually indicated by a low rounded elevation.

FIG. 486.—The left navicular bone. A. Anterior aspect. B. Posterior aspect.



The *sustentaculum tali* assists, by its upper surface, in the formation of the talocalcaneonavicular joint; its lower surface is grooved by the flexor hallucis longus tendon, and the margins of the groove give attachment to the deep part of the flexor retinaculum (laciniate ligament). The medial margin of the process is a narrow roughened strip, convex from before backwards. Anteriorly it gives attachment to the plantar calcaneonavicular or 'spring' ligament (p. 511); behind that it gives attachment to a slip from the tibialis posterior tendon and to some of the superficial fibres of the deltoid ligament; its posterior part receives the medial talocalcanean ligament. Below the attachment of the deltoid ligament the tendon of the flexor digitorum longus is related to this aspect of the process and sometimes its position is indicated by a groove. Below the groove for the flexor hallucis longus the medial surface gives origin to the large, fleshy, medial head of the flexor digitorum accessorius (quadratus plantæ).

THE NAVICULAR BONE (fig. 486)

The **navicular bone** is situated in the medial part of the tarsus and is interposed between the head of the talus behind and the cuneiform bones in front.

The *anterior surface* is convex from side to side and is subdivided into three facets (of which the most medial is the largest) for articulation with the three cuneiform bones. The *posterior surface*, oval and concave, articulates with the head of the talus. The *superior surface* is roughened and is convex from side to side. The *medial surface* also is rough and is continued downwards to form a prominent projection termed the *tuberosity*. It can be felt through the skin about 2·5 cm. below and in front of the medial malleolus. The *plantar surface*, also roughened, is concave, and is separated from the tuberosity on the medial side by a groove. The

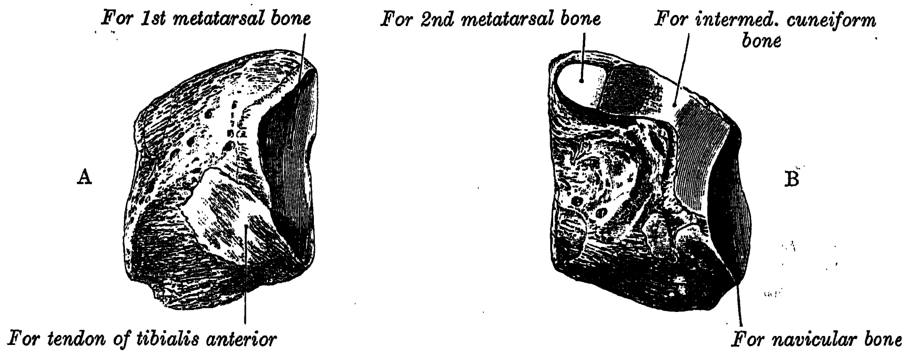
lateral surface is rough and irregular, but frequently presents a facet for articulation with the cuboid bone.

Particular features.—The facet for the medial cuneiform is triangular in outline, with its rounded apex on the medial side. The facets for the intermediate and lateral cuneiform bones are also triangular, but their apices lie inferiorly. The dorsal surface gives attachment to the dorsal talonavicular, cuneonavicular, and cubonavicular ligaments. The *tuberosity* of the navicular bone provides the principal insertion for the tibialis posterior tendon, and the groove which lies on its lateral side on the plantar surface transmits the part of this tendon which runs forwards to reach the cuneiform bones and the bases of the middle three metatarsal bones. A slight projection marks the plantar surface of the bone on the lateral side of the groove. Together with the posterior edge of this surface it gives attachment to the plantar calcaneonavicular or 'spring' ligament. The roughened part of the lateral surface gives attachment to the calcaneonavicular part of the bifurcated ligament.

THE CUNEIFORM BONES (figs. 487–489)

The **cuneiform bones**, three in number, are wedge-shaped and articulate with the navicular bone behind and the bases of the first, second and third metatarsal bones in front. The medial cuneiform bone is the largest of the three, and the intermediate the smallest. In the intermediate and in the lateral cuneiform bone the dorsal surface is the base of the wedge and the plantar surface represents the

FIG. 487.—The left medial cuneiform bone.
A. Medial aspect. B. Lateral aspect.



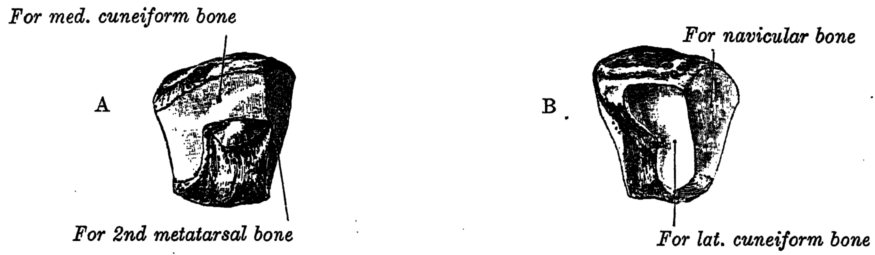
edge, but in the medial cuneiform bone the wedge is reversed so that its edge is represented by the narrow, dorsal surface of the bone. This arrangement is an important factor in the constitution of the transverse arch of the foot. The posterior surfaces of the three cuneiform bones form a slight concavity for the navicular bone, but the anterior parts of the medial and lateral cuneiforms project farther forwards than the intermediate cuneiform bone, and bound a deep recess in which the base of the second metatarsal bone is lodged.

Particular features.—The **medial cuneiform bone** (fig. 487) is the most medial bone of the distal row of the tarsus; it articulates with the navicular bone behind and with the base of the first metatarsal bone in front. The *dorsal surface* is rough and narrow, and represents the edge of the wedge. The *plantar surface* represents the base of the wedge; it receives a substantial slip from the tendon of the tibialis posterior muscle. The *anterior surface* bears a large kidney-shaped facet for articulation with the base of the first metatarsal bone, and the little notch which represents the hilum lies on its lateral margin. The *posterior surface* bears a piriform facet which articulates with the navicular bone. Concave from above downwards, it is narrower at its upper than at its lower end. The *medial surface* is rough and subcutaneous. It is slightly convex from above downwards and its antero-inferior angle is marked by a large, flattened impression which receives the insertion of most of the fibres of the tibialis anterior tendon. The *lateral surface* is partly articular and partly non-articular. Along its posterior and upper margins it is covered with an Γ-shaped smooth strip, which articulates with the intermediate cuneiform bone. The

upper and anterior part of this strip is separated by a vertical ridge from a small, almost square, facet which articulates with the upper part of the medial surface of the base of the second metatarsal bone. Below this facet the bone is attached to the medial side of the base of the second metatarsal bone by a strong interosseous ligament, and behind that the interosseous intercuneiform ligament connects it to the medial side of the intermediate cuneiform bone. The antero-inferior part of the lateral surface is roughened where it receives the insertion of part of the peroneus longus tendon.

FIG. 488.—The left intermediate cuneiform bone.

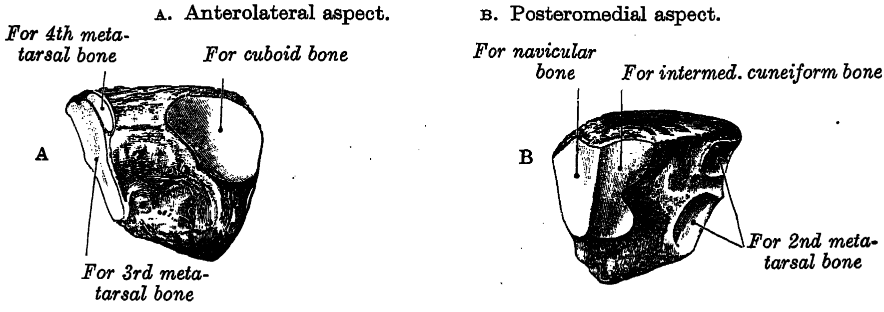
A. Anteromedial aspect. B. Posterolateral aspect.



The **intermediate cuneiform bone** (fig. 488) articulates in front with the base of the second metatarsal and behind with the navicular bone. It is of very regular wedge-like form, the base of the wedge forming the roughened, *dorsal surface*, and the edge the narrow, *plantar surface*, which receives a slip from the tibialis posterior tendon. The *anterior* and *posterior surfaces* are covered each with a triangular articular facet, for the base of the second metatarsal and the navicular bone, respectively. The *medial surface* is partly articular and partly non-articular. Along its posterior and upper margins it bears a Γ-shaped strip, occasionally subdivided into two parts, for articulation with the medial cuneiform. The

FIG. 489.—The left lateral cuneiform bone.

A. Anterolateral aspect. B. Posteromedial aspect.



lateral surface also is partly articular and partly non-articular. Along its posterior margin it bears a vertical strip, usually indented at its middle, for articulation with the lateral cuneiform bone. Strong interosseous ligaments connect the non-articular parts of the lateral and medial surfaces to the lateral and medial cuneiform bones.

The **lateral cuneiform bone** (fig. 489) is placed between the intermediate cuneiform and the cuboid bones. In front it articulates with the base of the third metatarsal and behind with the navicular bone. Like the intermediate cuneiform, its *dorsal surface*, rough and almost rectangular, represents the base of the wedge, and its *plantar surface*, narrow and rough, the edge. The latter receives a slip from the tibialis posterior tendon and may give partial origin to the flexor hallucis brevis. The *anterior surface* is completely covered with a triangular articular facet for the base of the third metatarsal bone. The *posterior surface* is rough in its lower part but is smooth and articular in its upper two-thirds, which articulate with the navicular by means of a triangular facet. The *medial surface* is partly articular and partly non-articular. Along its posterior margin it bears a vertical strip, indented at its middle, for the intermediate cuneiform bone, and along its anterior margin a narrower strip, often divided into two small facets, serves for articulation with the lateral aspect of the base of the second metatarsal bone. The *lateral surface* also is partly articular and partly non-articular. A large triangular or oval facet is situated posteriorly for

articulation with the cuboid bone; a small facet, semi-oval in shape, is placed at the upper part of its anterior margin for articulation with the dorsal part of the medial side of the base of the fourth metatarsal bone. The non-articular portions of the medial and lateral surfaces give attachment to strong interosseous intercuneiform and cuneocuboid ligaments, which play an important part in maintaining the transverse arch of the foot.

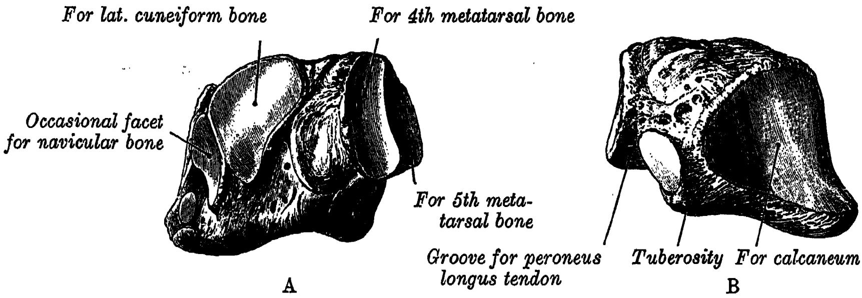
THE CUBOID BONE (fig. 490)

General features.—The **cuboid bone** is the most lateral bone of the distal row of the tarsus, and is situated between the calcaneum behind and the fourth and fifth metatarsal bones in front.

The *dorsal surface*, directed laterally as well as upwards, is rough for ligamentous attachments. The anterior part of the *plantar surface* is crossed by an oblique *groove for the peroneus longus tendon*, which is bounded behind by a prominent ridge. This ridge ends laterally in an enlargement termed the *tuberosity of the cuboid bone*. The lateral aspect of the tuberosity is faceted for the sesamoid bone or cartilage which is frequently found in the peroneus longus tendon. Behind the ridge the plantar surface is rough and, owing to the obliquity of the calcaneocuboid joint, extends backwards and medially so that the medial border of this surface is much

Fig. 490.—The left cuboid bone.

A. Anteromedial aspect. B. Posterolateral aspect.



longer than the lateral border. The *lateral surface* is rough and exhibits a deep notch which marks the commencement of the groove for the peroneus longus tendon. The *medial surface* is much more extensive and is partly articular and partly non-articular. It is marked near its middle by a smooth oval facet for articulation with the lateral cuneiform bone; behind this a small facet for the navicular bone is sometimes present. The two form a continuous articular surface but are separated by a vertical ridge. The *anterior surface* is divided by a vertical ridge into two articular areas; the medial facet is quadrilateral in form and articulates with the base of the fourth metatarsal bone; the lateral facet, triangular in outline with the apex on the lateral side, articulates with the base of the fifth metatarsal bone. The *posterior surface*—smooth, triangular and concavoconvex—articulates with the anterior surface of the calcaneum; its medial plantar angle projects backwards as a process which helps to support the anterior end of the calcaneum.

Particular features.—The dorsal surface gives attachment to the dorsal calcaneocuboid, cubonavicular, cuneocuboid and cubometatarsal ligaments. The ridge on the plantar surface gives attachment to the deep fibres of the long plantar ligament, which conceals the attachment of the short plantar (plantar calcaneocuboid) ligament to the posterior border of this surface. The projecting posteromedial part of the plantar surface receives a slip from the tendon of the tibialis posterior and gives origin to the flexor hallucis brevis muscle. The rough part of the medial surface of the cuboid affords attachment for the interosseous cuneocuboid and cubonavicular ligaments, and in its posterior part to the medial calcaneocuboid, which is the lateral limb of the bifurcated ligament.

The Homologies of the Carpus and the Tarsus.—In the most primitive reptiles the carpus and tarsus resemble one another very closely and, on the assumption that the radius, which

is the pre-axial bone of the forearm, is homologous with the tibia, which is the pre-axial bone of the leg—a view which is generally but not universally accepted—little difficulty is experienced in determining the homologies of their constituent elements. In man the carpus remains relatively primitive and the identification of its elements in the reptilian carpus is a comparatively simple problem. Owing to the adoption of the erect attitude the human tarsus has been modified very considerably, and it is only by reference to the primitive reptilian condition that any clue can be obtained to the homologies of the carpal and tarsal bones.

The following tabular statement presents the view which has obtained most support.

Reptilian Carpus.	*Human Carpus.*	*Reptilian Tarsus.*	*Human Tarsus.*
Os radiale	Scaphoid bone (less its tubercle)	Os tibiale	Talus
Os intermediale	Lunate bone	Os intermediale	(Os trigonum)

Os carpale 1	Trapezium bone	Os tarsale 1	Medial cuneiform bone
„ „ 2	Trapezoid bone	„ „ 2	Intermediate cuneiform bone
„ „ 3	Capitate bone	„ „ 3	Lateral cuneiform bone
„ „ 4 and 5	Hamate bone	„ „ 4 and 5	Cuboid bone

THE METATARSUS

The **metatarsal bones**, five in number, are situated in the anterior part of the foot in front of the tarsus and behind the phalanges. They are numbered from the medial to the lateral side.

The Common Characters of the Metatarsal Bones

Like the metacarpals, the metatarsals are miniature long bones, and each possesses a shaft, a base or proximal end, and a head or distal end.

With the exception of the first and, to a lesser degree, the fifth, the **shafts** are long and slender, and are slightly convex longitudinally on their dorsal aspects and concave on their plantar aspects. They are prismoid in form and taper from the base to the head.

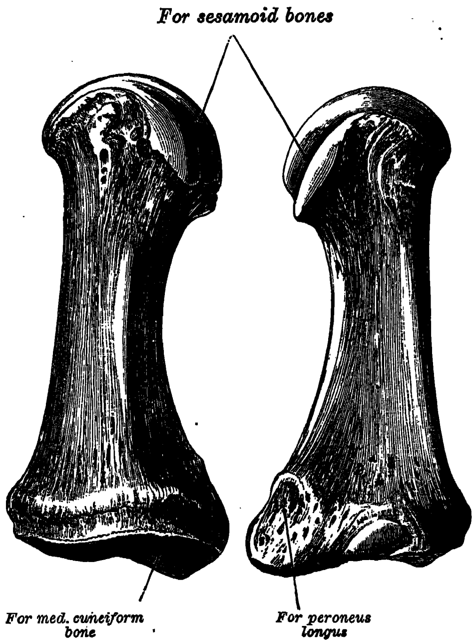
The **bases** articulate with the distal row of the tarsus and with one another. The line of each tarsometatarsal joint, excluding the first, passes backwards and laterally, and the bases of the metatarsals are therefore set somewhat obliquely relative to their shafts—a fact which assists in the recognition of the side of the body to which the bones belong.

The **heads** articulate with the proximal phalanges of their own digits, each by means of a convex articular surface which extends farther on the plantar than on the dorsal surface; the plantar extension ends on each side on the summit of a slight eminence. The sides of the heads are flattened, and each shows a depression surmounted dorsally by a tubercle, which gives attachment to one of the collateral ligaments of the metatarsophalangeal joint.

The Characters of the Individual Metatarsal Bones

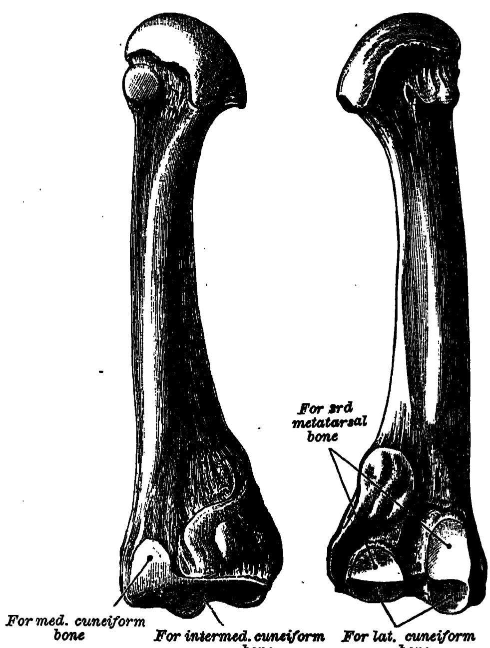
The first metatarsal bone (fig. 491) is the shortest and thickest of the metatarsal bones. The *body* is strong, and of well-marked prismoid form. The *base* has no articular facets on its sides, but there is occasionally a pressure facet on the lateral side caused by contact with the second metatarsal bone. Its posterior surface, of large size and kidney-shaped, articulates with the first cuneiform bone; the lateral border of the facet shows a slight indentation, which represents the hilum of the kidney. Its circumference is grooved for the tarsometatarsal ligaments, and medially gives insertion to a part of the tendon of the tibialis anterior; its plantar angle presents a rough, oval prominence for the insertion of

FIG. 491.—The left first metatarsal bone Medial and lateral aspects.



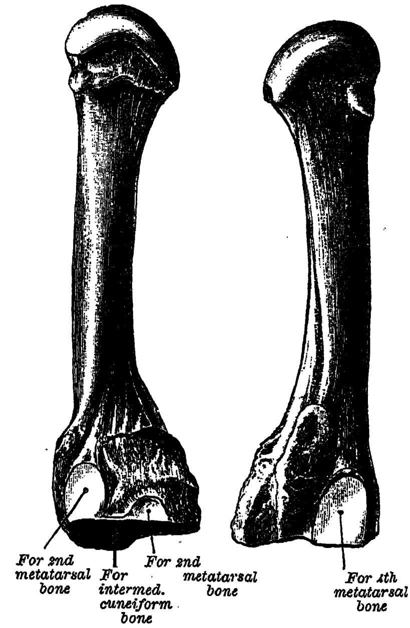
the tendon of the peroneus longus. The lateral surface of the shaft is flat and gives origin to the medial head of the first dorsal interosseous muscle. The *head* is large; on its plantar surface there is a median elevation separating two grooved facets on which sesamoid bones glide.

FIG. 492.—The left second metatarsal bone. Medial and lateral aspects.



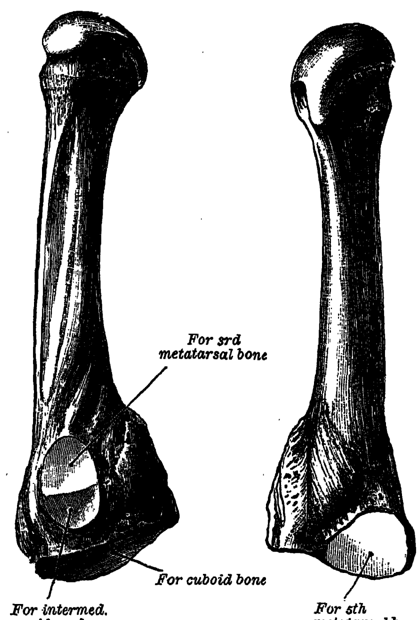
The second metatarsal bone (fig. 492) is the longest of the metatarsal bones. Its wedge-shaped *base* bears four articular facets: one on its posterior surface, of a triangular form, for articulation with the intermediate cuneiform bone; one at the upper part of its medial surface, for articulation with the medial cuneiform bone; and two on its lateral surface,

FIG. 493.—The left third metatarsal bone. Medial and lateral aspects



an upper and a lower, separated by a rough non-articular interval. Each of these lateral articular surfaces is divided by a vertical ridge; the anterior two facets articulate with the third metatarsal bone; the posterior two (sometimes continuous) with the lateral cuneiform bone. A pressure facet is occasionally present caused by contact with the first metatarsal

FIG. 494.—The left fourth metatarsal bone. Medial and lateral aspects.

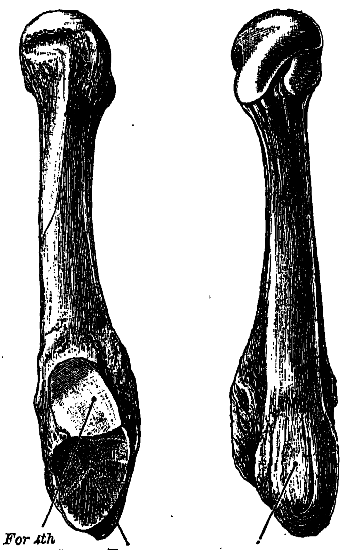


bone; it is oval in shape, and is situated on the medial side of the base, in front of the facet for the medial cuneiform bone. The medial and lateral surfaces of the shaft give origin respectively to the lateral head of the first dorsal interosseous muscle and the medial head of the second.

The **third metatarsal bone** (fig. 493) has a triangular *base*, which articulates posteriorly with the lateral cuneiform bone; medially it articulates by two facets with the second metatarsal bone; and laterally, by a single facet situated at the dorsal angle, with the fourth metatarsal bone. The medial surface of the shaft gives origin to the lateral head of the second dorsal interosseous muscle and to the first plantar; the lateral surface gives origin to the medial head of the third dorsal interosseous muscle.

The **fourth metatarsal bone** (fig. 494) is smaller than the third. The posterior surface of its *base* bears an oblique quadrilateral facet for articulation with the cuboid bone; on its lateral side a single facet, for the fifth metatarsal bone; on its medial side a facet

FIG. 495.—The left fifth metatarsal bone. Medial and lateral aspects.



divided by a ridge into an anterior portion for the third metatarsal bone, and a posterior portion for the lateral cuneiform bone. The medial surface of the shaft gives origin to the lateral head of the third dorsal interosseous muscle and to the second plantar; the lateral surface gives origin to the medial head of the fourth dorsal interosseous muscle.

The **fifth metatarsal bone** (fig. 495) is recognised by a rough eminence, termed the *tubercle*, on the lateral side of its base. The *base* articulates posteriorly with the cuboid bone by a triangular, obliquely cut surface; and medially, with the fourth metatarsal bone. The tendon of the peroneus tertius is inserted on the medial part of its dorsal surface, and that of the peroneus brevis on the dorsal surface of the tubercle. A strong band of the plantar aponeurosis connects the projecting part of the tubercle with the lateral tubercle of the calcaneum. The plantar surface of the base is grooved by the tendon of the abductor digiti minimi, and gives origin to the flexor digiti minimi brevis. The medial side of the shaft gives origin to the lateral head of the fourth dorsal interosseous muscle and to the third plantar.

The Phalanges of the Foot (Phalanges Digitorum Pedis)

The **phalanges** of the foot correspond in number and general arrangement with those of the hand; there are two in the big toe, and three in each of the other toes. They are, however, much smaller, and their shafts, especially those of the bones of the first row, are compressed from side to side.

The **proximal phalanges** closely resemble those of the hand. The *shaft* of each is compressed from side to side, convex above, concave below. The *base* is concave for articulation with the head of the corresponding metatarsal bone, and the *head* possesses a trochlear surface for articulation with the middle phalanx.

The **middle phalanges** are remarkably small and short, but rather broader than the proximal phalanges.

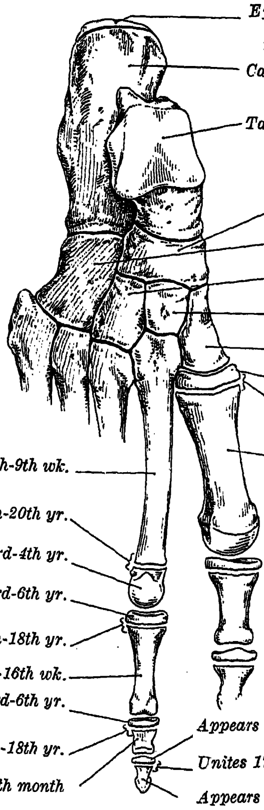
The **distal phalanges** resemble those of the fingers; but they are smaller, and are flattened from above downwards; each presents a broad base for articulation with the

corresponding middle phalanx, and an expanded distal extremity for the support of the nail and the end of the toe. Each bears a roughened *tuberosity* on the plantar aspect of its distal end.

Ossification of the Bones of the Foot (fig. 496)

The **tarsal bones** are ossified each from a single centre, excepting the calcaneum, which has a scale-like epiphysis for its posterior part. The centres make their appearance as follows: in the calcaneum, at the sixth month of intrauterine life; in the talus, about the seventh month; in the cuboid, at the ninth month; in the lateral cuneiform, during the first year; in the medial cuneiform, during the third year; in the intermediate cuneiform and navicular, during the fourth year. The epiphysis for the posterior part of the calcaneum begins to ossify between the sixth and tenth years, and unites with the rest of the bone

Fig. 496.—A plan of the ossification of the bones of the foot.



soon after puberty. The posterior tubercle of the talus is sometimes ossified from an independent centre, and may then remain separate or it may be connected to the rest of the bone by cartilage. This additional ossicle is named the *os trigonum*.

The **metatarsal bones** are ossified each from two centres: a primary centre for the shaft, and a secondary or epiphyseal centre for the base or proximal end of the first, and for the head or distal end of each of the other four.* Ossification begins in the middle of the shaft about the eighth or ninth week of intrauterine

* As in the first metacarpal bone (see page 366), so in the first metatarsal, there is sometimes a second epiphysis for the head.

life. The epiphysis for the base of the first metatarsal appears about the third year; those for the heads of the other metatarsals between the third and fourth years; all unite with the shafts between the seventeenth and twentieth years. An epiphysis is frequently present on the tubercle of the base of the fifth metatarsal bone (Holland).*

The phalanges are each ossified from two centres: a primary one for the shaft and an epiphysis for the base. The primary centres for the distal phalanges appear about the eighth week of intrauterine life: those for the proximal phalanges between the twelfth and sixteenth weeks, and those for the intermediate phalanges after the sixteenth week (that for the phalanx of the fifth toe

Fig. 497.—The skeleton of the left foot. Medial aspect.

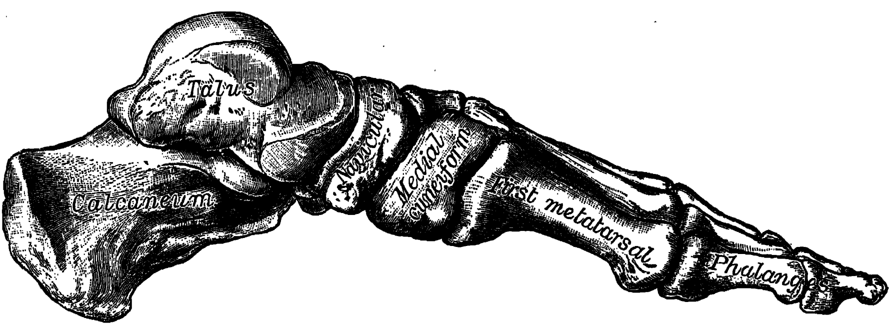


Fig. 498.—The skeleton of the left foot. Lateral aspect.

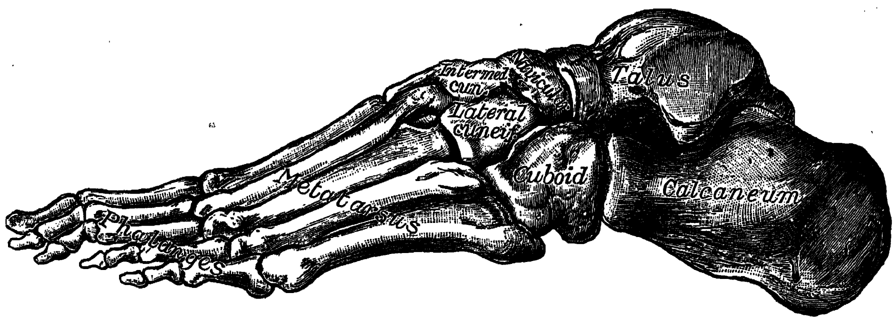

does not usually appear until after birth). The epiphyseal centres appear between the third and sixth years, and unite with the shafts about the seventeenth or eighteenth year.

Comparison of the Bones of the Hand and Foot

The hand and foot are constructed on similar principles—each comprising a proximal part, the carpus or tarsus, an intermediate portion, the metacarpus or metatarsus, and a distal portion, the phalanges. The proximal part consists of a series of more or less cubical bones which allow a slight amount of gliding on one another and are chiefly concerned in distributing forces transmitted to or from the bones of the forearm or leg. The intermediate part is made up of slightly movable long bones, which assist the carpus or tarsus in distributing forces, and also give greater breadth for the reception of such forces. The separation of the individual bones from one another allows of the attachments of the interosseous muscles and protects the dorsipalmar

* C. Thurstan Holland, *Journal of Anatomy*, vol. lv. 1921.

and dorsiplantar vascular anastomoses. The distal portion is the most movable, and its separate elements enjoy a varied range of movements, the chief of which are flexion and extension.

The functions of the hand and foot are, however, very different, and the general similarity between them is greatly modified to meet these requirements. Thus, the foot forms a firm basis of support for the body in the erect posture, and is therefore more solidly built, and its component parts are less movable on each other than those of the hand. The architecture of the bones of the hand is designed to provide an efficient instrument of prehension, and its component parts are not only capable of a greater range of movement but possess a greater degree of independent mobility. In the case of the proximal phalanges the difference is readily noticeable; those of the foot are smaller and their movements more limited than those of the hand. The difference between the metacarpal bone of the thumb and the metatarsal bone of the big toe is very much more marked. The position of the metacarpal bone of the thumb permits of great mobility; as compared with the other metacarpal bones, it is carried forwards and rotated round its long axis through an angle of approximately 90°, and it is capable of a considerable range of movement at its articulation with the carpus. The metatarsal bone of the big toe assists in supporting the weight of the body, is constructed with great solidity, lies parallel with the other metatarsals, and has a limited degree of movement. The carpus is small in proportion to the rest of the hand, is placed in line with the forearm, and forms a transverse arch, the concavity of which constitutes a bed for the flexor tendons. The tarsus forms a considerable part of the foot, and is placed at right angles to the leg, a position which is almost peculiar to man, and has relation to his erect posture. In order to allow of their supporting the weight of the body efficiently while making provision for the requisite spring and elasticity of the gait, the tarsus and metatarsus are built up into a series of arches (figs. 497, 498), the disposition of which will be considered after the articulations of the foot have been described.

THE SESAMOID BONES *

The **sesamoid bones** are more or less rounded nodules of bone imbedded in certain tendons and usually related to articular surfaces. Their functions probably are to modify pressure, to diminish friction, and occasionally to alter the direction of the pull of a muscle. The fact that they are present as cartilaginous nodules in the fœtus and in greater numbers than in the adult shows that they are not developed to meet certain physical requirements in the adult. They must be regarded as integral parts of the skeleton phylogenetically inherited.† Physical necessities probably come into play in selecting and in regulating the degree of development of the original cartilaginous nodules.

Sesamoid bones are invested by the fibrous tissue of the tendons, except on the surfaces in contact with the parts over which they glide, where they present smooth articular facets.

In the upper limb the sesamoid bones of the joints are found only on the palmar surface of the hand. Two, of which the medial is the larger, are present at the metacarpophalangeal joint of the thumb, imbedded in the tendons of the adductor pollicis and the flexor pollicis brevis; one is frequently present in the corresponding joint of the index finger, and one (or two) in the same joint of the little finger. Sesamoid bones are found occasionally imbedded in the palmar ligaments at the metacarpophalangeal joints of the middle and ring fingers, at the interphalangeal joint of the thumb, and at the distal interphalangeal joint of the index finger.

In the lower limb the largest sesamoid bone of the joints is the patella, developed in the tendon of the quadriceps femoris. On the plantar aspect of the foot, two, of which the medial is the larger, are always present at the metatarsophalangeal joint of the big toe, imbedded in the tendons of insertion of the flexor hallucis brevis; one sometimes at the metatarsophalangeal joints of the second and fifth toes, one

* Consult an article by A. H. Bizarro, *Journal of Anatomy* vol. lv. 1921.

† Thilenius, *Morpholog. Arbeiten*, v. 1896.

occasionally at the corresponding joints of the third and fourth toes, and one at the interphalangeal joint of the big toe.

Sesamoid bones apart from joints are seldom found in the tendons of the upper limb; one is sometimes seen in the tendon of the biceps opposite the radial tuberosity. Sesamoid bones or cartilages are, however, present in several of the tendons of the lower limb—viz. one in the tendon of the peroneus longus where it glides on the cuboid bone; one, appearing late in life, in the tendon of the tibialis anterior, opposite the smooth facet on the anteromedial part of the medial surface of the medial cuneiform bone; one in the tendon of the tibialis posterior, opposite the medial side of the head of the talus; one in the lateral head of the gastrocnemius, behind the lateral condyle of the femur; and one in the tendon of the psoas major where it glides over the ilium. Sesamoid bones are found occasionally in the tendons which wind round the medial and lateral malleoli, and one is sometimes present in the tendon of the gluteus maximus where it passes over the greater trochanter of the femur.

ARTHROLOGY

A *JOINT* or *articulation* is formed where two or more bones of the skeleton meet one another. In long bones the ends are the parts which form the joints: in flat bones the joints usually are formed at the edges: and in short and irregular bones the joints may occur at various parts of their surfaces.

The function of the joint is the most important factor in the determination of its character and structure. In some situations, e.g. in the skull, it is important that no movement should be permitted between contiguous bones; in other situations, e.g. in the vertebral column, a slight degree of mobility is advantageous, provided that it can be obtained without any loss of strength; and in still other situations the provision of a more or less wide range of movement is all-important.

In the earlier sections the development of the skeletal system and its component parts has been described, and it has been shown how in the first place the individual bones are laid down as condensations of the mesenchyme. Later, adjoining areas of condensation may become continuous with one another before they undergo the processes of chondrification and ossification. Centres of chondrification and ossification appear and outline the individual bones, which are connected to one another by plates of mesenchyme. The subsequent history of this mesenchymal plate differs in different types of joint. It may become converted into white fibrous tissue; it may be converted into cartilage; or it may break down and leave a space between the two opposed bones. In the first case the connecting medium between the bones concerned is white fibrous tissue, made up of numbers of bundles of short, white connective tissue fibres running between the opposing ends: such joints are immovable and are termed *fibrous joints*. In the second case the connecting medium between the bones concerned is white fibrocartilage; such joints are capable of a limited range of movement, and are termed *cartilaginous joints*. In the third case the opposed bones are separated from one another by a space, lined by a special membrane which is termed synovial membrane; the joint possesses a more or less wide range of movement and is termed a *synovial joint*.

In joints where only a slight degree of movement is required, the desired result is obtained by the provision of a cartilaginous joint when adequate leverage is available, e.g. in the joints between the bodies of the vertebræ. In some situations, however, e.g. in the joints of the carpus and metacarpus, the necessary leverage cannot be obtained and synovial joints are essential to provide even very limited degrees of movement.

All the joints in the human body fall into one of these three categories, and the salient features of each group must be considered, before the individual joints of the body can be described in detail.

A CLASSIFICATION OF THE JOINTS

Joints are divided into three classes: *fibrous joints, cartilaginous joints,* and *synovial joints.*

1. Fibrous Joints. [Articulationes Fibrosæ]

Fibrous joints are articulations in which the surfaces of the bones are fastened together by intervening fibrous tissue, and in which there is no appreciable motion, as in the joints between the bones of the cranium. There are two principal groups of fibrous joints: sutures and syndesmoses. Sutures, however, can be subdivided into seven different varieties.

A **suture** is an articulation met with only in the skull, where the margins of

the bones articulate with one another (fig. 499), but are separated by a thin layer of fibrous tissue, which is named the *sutural ligament* and is continuous externally with the periosteum on the outside of the skull (pericranium), internally with the fibrous layer of the dura mater (the membrane which covers the brain).

When the bony margins are provided with saw-like edges the articulation is named *sutura serrata*, as in the sagittal suture. When the margins present a series of tooth-like processes which widen towards their free ends, the articulation is named a *denticulate suture*. Where one bone overlaps another, as in the suture between the temporal and parietal bones, it is named *sutura squamosa*; where the overlapping edges are ridged or serrated it is named *sutura limbosa*;

Fig. 499.—A section through the sagittal suture.

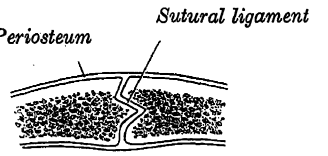

Fig. 500.—A section through the spheno-occipital joint of an infant.

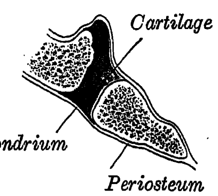

where there is simple apposition of contiguous rough surfaces, as between the palatine processes of the maxillæ, or between the horizontal plates of the palatine bones, it is named *sutura plana*.

A *gomphosis* or *peg-and-socket suture* is articulation by the insertion of a conical process into a socket; it is seen in the articulations of the roots of the teeth with the alveoli of the mandible and maxillæ. A *schindylesis* or *wedge-and-groove suture* is a joint where a ridge fits into a grooved surface; it is seen in the articulation between the rostrum of the sphenoid and the upper border of the vomer.

Syndesmosis is a joint in which the opposed bony surfaces are connected by an interosseous ligament, as in the inferior tibiofibular joint.

2. Cartilaginous Joints. [Articulationes Cartilagineæ]

In these articulations the opposed bony surfaces are connected to each other by cartilage, and a limited amount of movement may be possible. There are two varieties of cartilaginous joints, viz. primary and secondary.

Primary cartilaginous joint.—This is usually a temporary form of joint, for the connecting cartilage, which is hyaline in character, is, in most cases, converted ultimately into bone. Primary cartilaginous joints are found between the epiphyses and diaphyses of long bones, between the occipital and sphenoid bones at and for some years after birth, and between the petrous parts of the temporal bones and the jugular processes of the occipital bone. No movement is permitted at these joints, for the cartilaginous plate is relatively thin and the necessary leverage cannot be obtained.

Secondary cartilaginous joint.—In this joint the opposed bony surfaces are covered with hyaline cartilage, and are connected to each other by a flattened disc of fibrocartilage of a more or less complex structure (fig. 501). The bones are also connected by bands of white fibrous tissue termed ligaments, which, however, do not form a complete capsule round the joint. A limited degree of movement is permitted and it is rendered possible by the compressibility of the cartilaginous disc and the degree of leverage which is available. Secondary cartilaginous joints are represented by the joints between the vertebral bodies, the joint between the manubrium and the body of the sternum, and the joint between the pubic bones (pubic symphysis). All these articulations lie in the median plane of the body.

3. Synovial Joints. [Articulationes Synoviales]

Most of the joints of the body, *including all the joints of both limbs,* with the exception of the inferior tibiofibular syndesmosis and the pubic symphysis,

belong to the synovial group. They have certain definitely characteristic features. (1) The contiguous bony surfaces are covered with articular cartilage and are not attached to one another. (2) There is a joint cavity, which is reduced to a potential space in the normal healthy condition during life. (3) The joint is completely surrounded by an articular capsule, which consists of a capsular ligament lined with a synovial membrane. (4) The synovial membrane lines the whole of the interior of the joint with the exception of the cartilage-covered ends of the articulating bones. (5) The bones are usually connected by a variable number of ligaments which are additional to the capsular ligament and usually superficial to it. (6) On account of the nature of the connexions between the bones concerned, movement is always possible in a synovial joint: it may vary from a simple gliding movement, very limited in range, such as is permitted between the individual bones of the carpus, to the wide range of movement of the shoulder-joint.

In addition, the joint-cavity may be divided, completely or incompletely, by an *articular disc* of fibrocartilage (fig. 503). These structures act as shock-reducing agents and they serve to ensure perfect contact between the moving surfaces in any position of the joint (p. 429). The periphery of articular discs is continuous with the capsular ligament of the joint, while their free surfaces are covered with synovial membrane, unless they are subjected to pressure, as in the knee-joint.

The **articular cartilage** which covers the articular surface of a bone is usually hyaline in character, but in the cases of bones which ossify in membrane it may be white fibrocartilage. It contains neither nerves nor blood-vessels, and its nutrition is derived from the vascular network in the synovial membrane at its periphery, and to a certain extent from the synovia which lubricates the joint (*vide infra*). Macroscopically its free surface is smooth and has no covering perichondrium; microscopically the surface is finely irregular, and minute shred-like projections indicate the effects of normal wear and tear. The deepest part of the articular cartilage is calcified and is firmly attached to the articular surface of the bone, which is formed by a compact layer termed the *articular lamella*. The lacunæ of this lamella are large but no Haversian canals or canaliculi are present. The vessels of the neighbouring spongy substance approach the articular lamella but do not perforate it, so that it is denser and firmer than ordinary bone.

The **capsular ligament** consists of parallel and interlacing bundles of white connective tissue fibres. It forms a sort of cuff or brassard, each end of which is attached to a continuous line around the articular end of one of the bones concerned, usually in the immediate neighbourhood of the periphery of the articular surface, but this arrangement is subject to considerable variation. It is perforated by the articular vessels and nerves, and may present one or more apertures through which the synovial membrane protrudes to form a pouch or sac. The capsular ligament usually shows two or more localised thickenings in which the constituent fibre bundles are generally parallel to one another. These thickenings are the **ligaments of the joint** and they are named according to their position or attachments. In some joints the capsular ligament is reinforced or replaced by the tendons, or by expansions from the tendons, of neighbouring muscles. Some joints possess accessory ligaments which stand clear of the capsular ligament. Such accessory ligaments may be situated outside the capsule, or they may be intracapsular.

All ligaments are tough, inelastic and unyielding, but at the same time flexible and pliant, so that they offer no resistance to normal movements. On the other hand they are designed to prevent the occurrence of excessive or abnormal movements, and every ligament becomes taut at the normal limit of some particular movement. They are not designed to withstand prolonged tension, and pain always results when they are subjected to it.

The **synovial membrane** lines the capsular ligament and covers those parts of the bones which are within the capsule, but ceases at the margins of the articular cartilages, which it usually overlaps to a slight extent. It gives a covering to all intracapsular structures, e.g. tendons, ligaments or articular discs, with certain important exceptions. The semilunar cartilages of the knee-joint, which are subjected normally to considerable pressure, have no

synovial covering although they are clothed with synovial membrane in the fœtus; and an area on the anterior part of the capsular ligament of the hip-joint corresponding to the front of the head of the femur is devoid of synovial lining. In many joints the synovial membrane forms fringe-like processes, usually containing small pads of fat, which project into the interior and fill up any irregularities or potential spaces in the joint (fig. 533). The synovial membrane secretes a small quantity of viscid glairy fluid termed *synovia.* This fluid acts as a lubricant and may help to nourish the articular cartilage. It contains small percentages of salts, albumen, extractives, etc., some of which are no doubt contributed by the wearing away of the articular cartilage.

Histologically the synovial membrane is composed of a delicate, vascular, connective tissue, which is covered on its free surface by an incomplete layer

FIG. 501.—A section through a secondary cartilaginous joint. Diagrammatic.

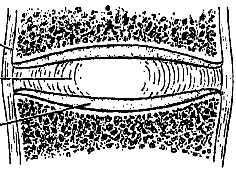

FIG. 502.—A section through a simple synovial joint. Diagrammatic.

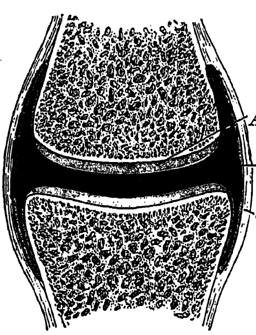

FIG. 503.—A section through a synovial joint with an articular disc. Diagrammatic.

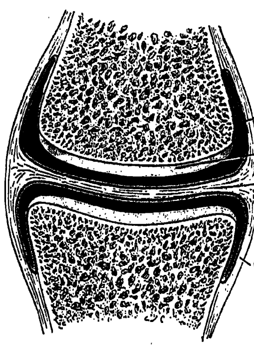


of flattened cells, resembling an endothelium. The collagenous groundwork of the tissue is traversed by numerous fine fibres and contains many connective tissue cells of different types. The cell elements of the synovial membrane are migratory and highly phagocytic. They may be present in the synovia, and are capable of absorbing micro-organisms and foreign particles injected into the joint. In addition, they probably absorb the cartilaginous debris which must result from ordinary wear and tear.

The synovial sheaths of tendons (vaginæ mucosæ) and the synovial bursæ (bursæ mucosæ) are closely related in structure and function to the synovial membrane of joints.

Classification.—Synovial joints are classified according to the kind of motion permitted in them. There are two varieties in which the movement is uniaxial; that is to say, all movements take place around one axis. In one, the *ginglymus* or *hinge-joint,* this axis is, practically speaking, transverse; in the other, the *articulatio trochoidea* or *pivot-joint,* it is longitudinal. There are two varieties where the movement is bi-axial; these are the *articulatio condyloidea* or *condyloid joint* and the *articulatio sellaris* or *saddle-joint.* There is one form where the movement is poly-axial, the *articulatio cotylica* or *ball-and-socket joint*; and finally there is the *articulatio plana* or *plane joint.*

In uni-axial and poly-axial joints it is not difficult, from the mechanical point of view, to ensure that the opposed articular surfaces shall make perfect contact in all positions of the joint, but the same object is by no means easy to

attain in biaxial joints, where movements are possible around two axes which are at right angles to each other. In many situations this difficulty is overcome by the provision of articular discs. The opposite surfaces of a disc do not correspond to each other, but each is accurately adapted to the bone with which it is in contact. When movement occurs round one of the two axes, the disc remains stationary relative to one of the bones but moves with it over the other; when movement occurs round the other axis, the disc remains stationary relative to the opposite bone and moves with it. For example, when the sternal end of the clavicle is elevated or depressed, the clavicle moves over the clavicular surface of the articular disc of the joint, but when the bone is moved forwards or backwards, the disc remains stationary relative to the clavicle and moves with it over the clavicular notch of the manubrium sterni. This arrangement ensures perfect contact between the bones and the disc in all positions of the joint, and in this sense, the discs may be said to adapt the opposed articular surfaces to each other.

Ginglymus or **hinge-joint.**—In this form the articular surfaces are moulded to each other in such a manner as to permit motion in one plane only. On each side of the articular surfaces the bones are connected together by strong collateral ligaments, which form their chief bond of union. The best examples of hinge-joints are the interphalangeal joints, and the joint between the humerus and ulna.

Articulatio trochoidea or **pivot-joint.**—Where the movement is limited to rotation, the joint is formed by a pivot turning within a ring, or a ring turning on a pivot, the ring being formed partly of bone, partly of ligament. In the superior radio-ulnar joint, the ring is formed by the radial notch of the ulna and the annular ligament; here, the head of the radius rotates within the ring. In the articulation of the odontoid process (dens) of the axis with the atlas, the ring is formed in front by the anterior arch, and behind by the transverse ligament, of the atlas; here, the ring rotates round the odontoid process.

Condyloid articulation.—In this form of joint, an ovoid, convex, articular surface, or condyle, is received into an elliptical concavity in such a manner as to permit of active flexion, extension, adduction, abduction and circumduction, but no active axial rotation. The radiocarpal joint is an example of this form of articulation. (*See also* p. 473.)

Saddle-articulation.—In this variety the opposing surfaces are reciprocally concavoconvex, and the movements are the same as in the preceding form. The best example of the saddle-articulation is the carpometacarpal joint of the thumb.

Articulatio cotylica or **ball-and-socket joint.**—In this type of joint the distal bone is capable of motion around an indefinite number of axes, which have one common centre. It is formed by the reception of a globular head into a cup-like cavity, hence the name 'ball-and-socket.' Examples of this form of articulation are found in the hip- and shoulder-joints.

A **plane joint** is one which admits of gliding movement only; it is formed by the apposition of plane, or nearly plane, surfaces, the amount of motion in such joints being limited by the ligaments or osseous processes surrounding the articulations. It is seen in the joints between the articular processes of the vertebræ, and in most of the carpal and tarsal joints.

The Kinds of Movement permitted in Joints

The movements permitted in joints may be divided into four kinds: gliding and angular movements, circumduction, and rotation. Frequently these are more or less combined in the various joints, so as to produce an infinite variety, and it is seldom that only one kind of motion is found in any particular joint. Where movement is limited in range, the reciprocal articular surfaces are approximately equal in size, but where movement is free, they show considerable differences, the more movable bone usually possessing the larger surface.

Gliding movement is the simplest kind of motion that can take place in a joint, one surface gliding over another without any angular or rotatory movement. It is common to most movable joints; but in some, as in most of the articulations of the carpus and tarsus, it is the only motion permitted. This

movement is not confined to plane surfaces, but may take place between any two contiguous surfaces, of whatever form.

Angular movement implies diminution, or increase, of the angle between adjoining bones. Two types of angular movement are so common, especially in the joints of the limbs, that they must be defined. They occur around axes which are set at right angles to each other and are : (1) *flexion* and its opposite, *extension*, and (2) *abduction* and its opposite, *adduction*.

Flexion occurs around an axis which is transverse or obliquely transverse, and usually results in the approximation of two morphologically ventral surfaces. This definition is not entirely satisfactory, for its first part does not hold good for the joints of the thumb ; and its second part, in the cases of the shoulder, hip and ankle joints. The thumb lies in a plane set at right angles to the plane of the fingers. As a result its dorsal surface is directed laterally, and flexion and extension at each of its joints occur around an anteroposterior axis. At the shoulder-joint flexion carries the arm forwards and medially, and its morphologically ventral surface is brought no nearer to the ventral aspect of the trunk. At the hip-joint, owing to the changes which occur in the early stages of development (p. 101), flexion approximates the morphologically dorsal surface of the thigh to the ventral surface of the trunk. The condition at the ankle-joint is complicated by the fact that the foot is set at a right angle to the leg. Bending movement at the ankle implies a diminution of the angle and is frequently termed flexion. On the other hand it results in the approximation of two morphologically dorsal surfaces and might, with an equal amount of justification, be termed extension. It will avoid confusion and misunderstanding if the self-explanatory terms *dorsi-flexion* and *plantar-flexion* are used in connexion with the movements at the ankle-joint.*

Abduction and adduction occur around a more or less anteroposterior axis, except in the case of the carpometacarpal joint of the thumb, where, for reasons already stated, these movements occur around a transverse axis. The terms imply movements from and to the median plane of the body, except in the cases of the digits, where the plane of reference is the median plane of the middle digit (in the hand) or the second digit (in the foot).

Circumduction is that form of motion which takes place between the head of a bone and its articular cavity, when the bone is made to circumscribe a conical space ; the base of the cone is described by the distal end of the bone, the apex is in the articular cavity ; this kind of motion is best seen in the shoulder- and hip-joints.

Rotation is a form of movement in which a bone moves round a longitudinal axis ; the axis of rotation may lie in a separate bone, as in the case of the pivot formed by the odontoid process of the axis, around which the atlas turns ; or a bone may rotate around its own longitudinal axis, as in the rotation of the humerus at the shoulder-joint ; or the axis of rotation may be not quite parallel to the long axis of the bone, as in the movement of the radius on the ulna during pronation and supination of the hand, where it is represented by a line connecting the centre of the head of the radius with the centre of the head of the ulna.

Accessory movements.—The movements which can be performed actively at any joint do not necessarily include all the movements which the structure of the joint would permit. Certain movements which cannot be performed voluntarily can nevertheless be produced when resistance is encountered to active movements (accessory movements, first type), e.g. it is only when some solid object, such as a cricket ball, is grasped in the hand, that the fingers can be rotated at the metacarpophalangeal joints. Other movements can be produced only passively (accessory movements, second type) and their widest range is obtained when the muscles acting on the joint are fully relaxed, e.g. when the

* Flexion has also been defined as the position assumed by the joints of the fœtus 'in utero.' Such a definition would imply that 'dorsi-flexion' of the ankle-joint is really 'flexion.' This view is supported by the physiological observation that in reflexes involving all the joints of the lower limb flexion at the hip- and knee-joints is always associated with 'dorsi-flexion' of the ankle-joint, and extension of the hip- and knee-joints with 'plantar-flexion' of the ankle-joint. The definitions based on morphological and physiological criteria are contradictory to each other and this emphasises the desirability for the use of the make-shift terms suggested in the text.

arm is partially abducted at the shoulder-joint, the humerus can be drawn away from the glenoid cavity. Such movements are commonly termed 'passive movements', but as all movements, whether active or not, can be performed passively when the muscles concerned are relaxed, the term *accessory movements* will be used to designate all movements which cannot be performed actively in the absence of resistance.

The possibility of accessory movements implies a certain amount of play between the articular surfaces of a joint, and this prevents undue strain or pressure on those surfaces when the joint is subjected to violent stresses. A considerable amount of play is permitted in the shoulder-joint, but none in the hip-joint. As a result damage of the articular surfaces is very much commoner in the latter, and the disease of osteoarthritis, which has its origin in trauma of an articular surface, is of much more frequent occurrence in the hip-joint than in the shoulder-joint.

Limitation of movements is effected by a number of different factors, of which the *tension of ligaments* is very important, as can be seen when attempts are made to produce hyperextension of the dissected knee or hip-joints. In life, however, the *tension of the muscles which are antagonistic to the movement* is equally important, if not more so, for it is open to doubt whether under normal conditions the tension of the antagonist muscles ever permits a ligament to be put fully on the stretch. The part played by muscles in limiting movement is well seen in flexion of the hip-joint. When this movement is performed with the knee extended, it is much more limited in range than when it is performed with the knee flexed. In the latter case flexion of the knee relaxes the hamstring muscles, and this permits the thigh to be flexed until it comes into contact with the anterior abdominal wall. The movement is then limited by *the approximation of the soft parts concerned*—a third factor which is present in connexion with some other movements, e.g. flexion of the elbow and knee.

In synovial joints, where the bones concerned are connected by ligaments and muscles only, the articular surfaces are in constant apposition in all positions of the joint throughout life. The maintenance of this apposition is assisted by atmospheric pressure and the force of cohesion, but these factors are merely subsidiary to the influence exerted by the muscles. The balance between the normal tonus of the different muscle groups which act on the joint is responsible for maintaining the articular surfaces in constant apposition. In this connexion it cannot be emphasised too strongly that the stability of any joint depends on the tonus of the muscles which act on it. The erect attitude is maintained by the balance between opposing muscle groups, and in the maintenance of this and other normal postures the ligaments play no part.

Nerve supply.—Movable joints are innervated by the nerves of supply to the muscles which act on them, and it is probable that this arrangement establishes local reflex arcs which tend to ensure stability. The part of the articular capsule which is rendered taut on the contraction of a given muscle or group of muscles is innervated by the nerve or nerves supplying their antagonists. For example, the inferior part of the articular capsule of the hip-joint, which is put on the stretch in abduction, is supplied by the obturator nerve. Tension of this part of the capsule produces a reflex contraction of the adductor muscles which, usually, is successful in preventing overstretching or tearing of the ligaments.

THE MANDIBULAR JOINT

The bony parts entering into the formation of the mandibular joint are: above, the articular eminence and the anterior portion of the articular fossa of the temporal bone; below, the head of the mandible. The *articular surfaces* are covered with a variety of white fibrocartilage in which the fibres predominate and the cartilage cells are few in number. An articular disc divides the joint into an upper and a lower cavity. The ligaments of the joint are the following:

Capsular.	Sphenomandibular.
Temporomandibular.	Stylomandibular.

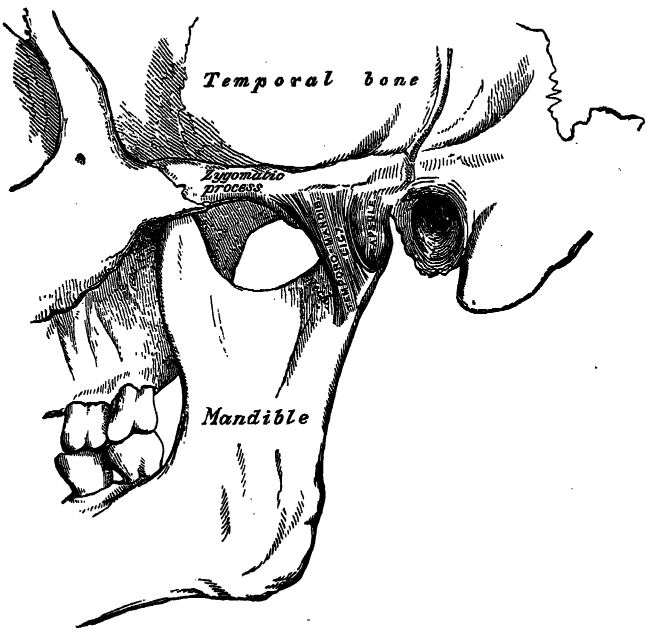
The capsular ligament is a thin, loose envelope, attached, above, to the

articular eminence in front; to the lips of the squamotympanic fissure behind; and between these two attachments, to the circumference of the articular fossa; below, to the neck of the mandible. The *synovial membrane* of the joint lines the capsular ligament and is continued over the upper and lower surfaces of the articular disc.

The **temporomandibular ligament** (fig. 504) is placed on the lateral side of the joint and is intimately related to the capsular ligament. It is attached, above, to the lateral surface of the zygomatic process of the temporal bone and to the tubercle on its root; below, to the lateral surface and posterior border of the neck of the mandible. It is broader above than below, and its fibres are directed obliquely downwards and backwards. The ligament is covered superficially by the parotid gland.

The **sphenomandibular ligament** (fig. 505) is placed on the medial side of the joint and is separated from the capsular ligament by a considerable interval. It is a flat, thin band which is attached above to the spine of the sphenoid bone, and, becoming broader as it descends, is fixed to the lingula of the mandibular

FIG. 504.—The left mandibular joint. Lateral aspect.



foramen. Its lateral surface is in relation, above, with the lateral pterygoid muscle and the auriculotemporal nerve; lower down, it is separated from the neck of the mandible by the maxillary (internal maxillary) vessels; still lower, the inferior dental (inferior alveolar) vessels and nerve and a lobule of the parotid gland lie between it and the ramus of the mandible. Its medial surface is in relation, below, with the medial pterygoid muscle, and, above, it is separated from the wall of the pharynx by an interval containing fat and some veins of the pharyngeal plexus. The upper attachment of the ligament is a secondary attachment,* and some of its fibres can be traced through the medial end of the petrotympanic fissure to the primary attachment, viz. the anterior process of the malleus. It represents a portion of the cephalic extremity of Meckel's cartilage (p. 99).

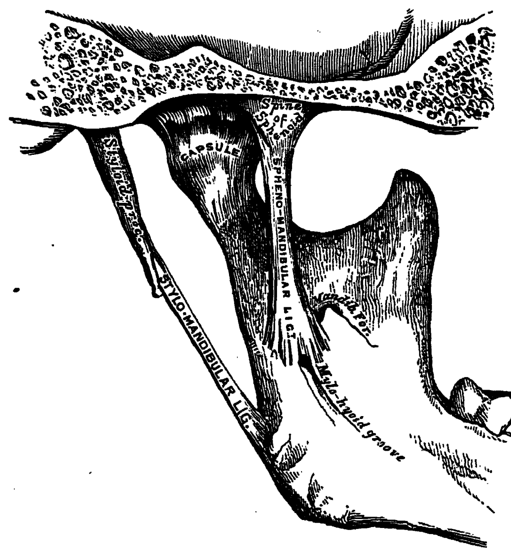
The **articular disc** (fig. 506) is a thin, oval plate consisting mainly of fibrous tissue; it is placed between the condyle of the mandible and the articular fossa, and divides the joint into two cavities. Its upper surface is concavoconvex from before backwards, to accommodate itself to the form of the articular fossa and the articular eminence. Its under surface, in contact with the head of the mandible, is concave. Its circumference is connected to the capsular ligament

* J. Cameron, *Journal of Anatomy and Physiology*, vol. xlix.

and, in front, to the tendon of the lateral pterygoid muscle. It is usually thickest a little behind its centre, where it occupies the deepest part of the articular fossa.

The **stylomandibular ligament** (fig. 505) is a specialised band of the deep cervical fascia (p. 537), which stretches from the apical part of the styloid process of the temporal bone to the angle and posterior border of the ramus of the mandible between the insertions of the masseter and medial pterygoid muscles. It separates the parotid from the submandibular (submaxillary) gland, and from its deep surface some fibres of the styloglossus take origin. Although classed among the ligaments of the mandibular joint, it can only be considered as accessory to it.

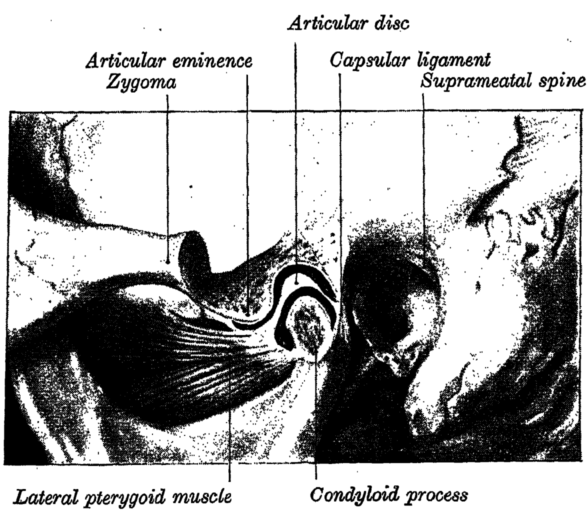
FIG. 505.—The left mandibular joint. Medial aspect.



The *nerves* of the mandibular joint are derived from the auriculotemporal and masseteric branches of the mandibular nerve; the *arteries*, from the superficial temporal branch of the external carotid artery, and from the maxillary artery (internal maxillary artery).

Movements.—The mandible may be depressed and elevated, or carried forwards and backwards; a slight amount of side-to-side movement is also permitted. When the mouth is opened the body of the mandible is depressed, and the head and articular disc are pulled forwards and downwards on to the

FIG. 506.—A sagittal section through the left mandibular joint.



articular eminence on each side; at the same time the head rotates on the articular disc round a more or less transverse axis. On closure of the mouth the reverse actions take place. When the mandible is carried horizontally forwards, as in protruding the lower incisor teeth in front of the upper, the disc and the head of the mandible glide forwards and downwards on the articular fossa and articular eminence on each side. The grinding or chewing movement is produced by the head, with its disc, gliding alternately forwards and backwards,

on one side, while on the other they move simultaneously in the opposite directions ; at the same time the head undergoes a vertical rotation on the disc. On one side the head advances and rotates, while on the other it recedes and rotates.

Muscles producing the movements :

Depression.—Digastric, Mylohyoid, Geniohyoid and Lateral Pterygoid (of both sides).
Elevation.—Masseter, Temporal and Medial Pterygoid (of both sides).
Protrusion.—Medial and Lateral Pterygoid (of both sides).
Retraction.—Temporal (posterior fibres—both sides).
Lateral movement.—Medial and Lateral Pterygoid (of one side).

Applied Anatomy.—The mandible can be dislocated in one direction only—viz. forwards. When the mouth is open, the head of the mandible is situated on the articular eminence, and any sudden violence, or even a sudden muscular spasm, as during a convulsive yawn, may displace it forwards into the infratemporal fossa. The displacement may be unilateral or bilateral. Reduction is accomplished by depressing the jaw with the thumbs placed on the last molar teeth, and at the same time elevating the chin. The downward pressure overcomes the spasm of the masseter, temporal, and pterygoid muscles, and elevation of the chin throws the head of the mandible backwards ; the above-mentioned muscles then draw the head back into its normal position.

The external auditory meatus and the tympanic cavity lie immediately behind the joint ; any force, therefore, applied to the mandible is liable to be attended with damage to these parts, or inflammation in the joint may extend to them. On the other hand inflammation of the tympanic cavity may involve the articulation and cause its destruction, thus leading to ankylosis of the joint.

THE JOINTS OF THE VERTEBRAL COLUMN

The vertebræ from the third cervical to the first sacral inclusive are articulated to one another by : (1) a series of cartilaginous joints between the vertebral bodies ; and (2) a series of synovial joints between the vertebral arches.

1. The Joints of the Vertebral Bodies

The cartilaginous joints between the bodies of the vertebræ allow of only slight movement between adjoining bones, but when this slight movement takes place in a number of consecutive joints the total range of movement is considerable. The vertebral bodies are united by anterior and posterior longitudinal ligaments, and by intervertebral discs of fibrocartilage.

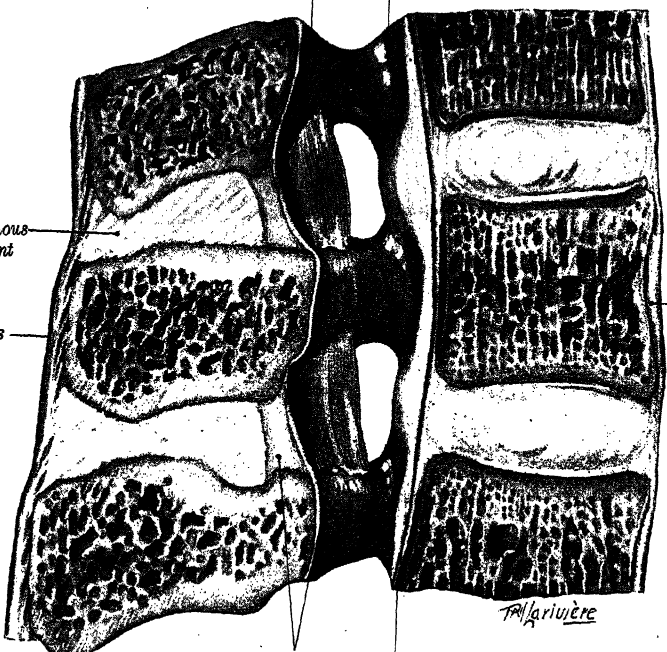
The **anterior longitudinal ligament** (fig. 507) is a strong band of fibres which extends along the anterior surfaces of the bodies of the vertebræ. It is broader below than above, thicker and narrower in the thoracic region than in the cervical and lumbar regions, and somewhat thicker and narrower opposite the bodies of the vertebræ than opposite the intervertebral discs. It is attached, above, to the basilar part of the occipital bone, from which it extends to the anterior tubercle of the atlas, then to the front of the body of the axis and is continued down as far as the upper part of the front of the sacrum. It consists of longitudinal fibres, which are firmly fixed to the intervertebral discs and to the margins of the vertebral bodies, but are loosely attached to the middle parts of the bodies. In the latter situation the ligament is thick and fills up the concavities on the anterior surfaces, and makes the front of the vertebral column more even. It is composed of several layers of fibres, of which the most superficial are the longest and extend between four or five vertebræ. The intermediate fibres extend between two or three vertebræ, while the deepest reach from one vertebra to the next. At the sides of the bodies the ligament consists of a few short fibres which connect adjacent vertebræ.

The **posterior longitudinal ligament** (figs. 507, 508) is situated within the vertebral canal on the posterior surfaces of the bodies of the vertebræ. Above, it is attached to the body of the axis, and is thence continued downwards to the sacrum ; its upper end is continuous with the membrana tectoria (p. 444). It

consists of smooth, glistening fibres, which are attached to the intervertebral discs and to the upper and lower margins of the vertebral bodies, but are separated from the middle parts of the bodies by the emerging basivertebral veins, and by veins which drain these into the anterior internal vertebral plexuses. In the cervical region the ligament is broad and of nearly uniform width, but in the thoracic and lumbar regions it presents a denticulated appearance, being narrow over the vertebral bodies and broad over the intervertebral discs. It consists of superficial layers occupying the interval between three or four vertebræ, and deeper layers which extend between adjacent vertebræ.

The intervertebral discs (figs. 507, 508) are interposed between the adjacent surfaces of the bodies of the vertebræ, from the axis to the sacrum, and form

Fig. 507.—A median sagittal section through a portion of the lumbar region of the vertebral column.

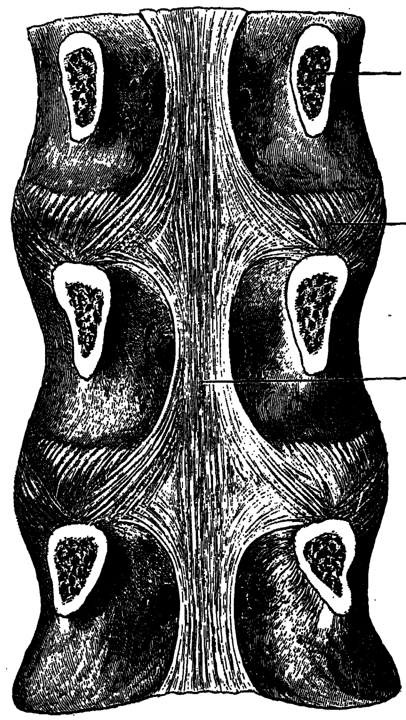


the chief bonds of connexion between the vertebræ. Their shape corresponds with that of the bodies between which they are placed. Their thickness varies in different regions of the column, and in different parts of the same disc; they are thicker in front than behind in the cervical and lumbar regions, and thus contribute to the anterior convexities of these parts of the column; while they are of nearly uniform thickness in the thoracic region, the anterior concavity of this part of the column being almost entirely due to the shape of the vertebral bodies. They are adherent, by their surfaces, to thin layers of hyaline cartilage which cover the upper and under surfaces of the bodies of the vertebræ. The intervertebral discs are closely connected to the anterior and posterior longitudinal ligaments; in the thoracic region they are joined laterally, by means of the intra-articular ligaments, to the heads of those ribs which articulate with two vertebræ. The intervertebral discs constitute about one-fourth of the length of the vertebral column, exclusive of the first two vertebræ; but this amount is not equally distributed between the various bones, the cervical and lumbar portions having, in proportion to their length, a much greater amount

than the thoracic region, with the result that these parts possess greater pliancy and freedom of movement.

Structure of the intervertebral discs.—Each is composed, at its circumference, of laminæ of fibrous tissue and fibrocartilage, forming the *annulus fibrosus* ; and, at its centre, of a soft, pulpy, highly elastic substance, of a yellowish colour, which projects considerably above the surrounding level when the disc is divided horizontally. This pulpy substance (*nucleus pulposus*), especially well developed in the lumbar region, contains the remains of the notochord. The laminæ of the annulus fibrosus are arranged concentrically ; the peripheral consist of ordinary fibrous tissue, the others of white fibrocartilage. The laminæ are not quite vertical in their direction, those near the circumference being curved outwards

FIG. 508.—The posterior longitudinal ligament of the vertebræ, in the lumbar region.



and closely approximated ; while those nearest the centre curve in the opposite direction, and are somewhat more widely separated. The fibres composing the laminæ are directed, for the most part, obliquely from above downwards, the fibres of adjacent laminæ cross one another, like the limbs of the letter X. This laminar arrangement exists in about the outer half of each disc. The nucleus pulposus consists of a fine fibrous matrix, containing angular cells united to form a reticular structure.

In the cervical region the cartilaginous joints between the bodies of the vertebræ are complicated occasionally by the presence of a small synovial cavity on each side between the bevelled lateral part of the under surface of the body and the lipped lateral margin of the upper surface of the body below. It is this little joint which is enlarged to form the principal joint in the case of the articulation between the atlas and the axis.

2. The Joints of the Vertebral Arches

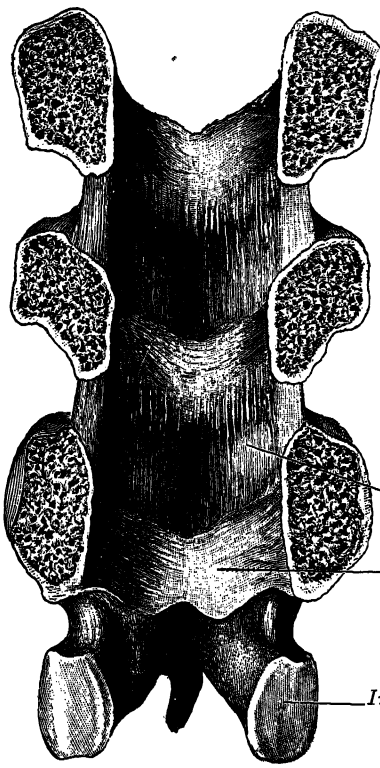
The joints between the articular processes of the vertebræ belong to the plane variety and are enveloped by articular capsules ; the laminæ, spines and transverse processes are connected by the following ligaments :

Ligamenta flava. Ligamentum nuchæ.
Supraspinous. Interspinous.
Intertransverse.

The **articular capsules** are thin and loose, and are attached just beyond the margins of the articular facets of adjacent articular processes ; they are longer and looser in the cervical than in the thoracic and lumbar regions.

The **ligamenta flava** (figs. 507, 509) connect the laminæ of adjacent vertebræ, and are best seen from the interior of the vertebral canal. Their attachments extend from the articular capsules to the regions where the laminæ fuse to form the spine ; here their posterior margins come into contact and are to a certain extent united, small intervals being left for the passage of vessels. The ligamenta flava consist of yellow elastic tissue, the fibres of which, almost perpendicular in direction, are attached to the lower part of the anterior surface of the

FIG. 509.—The ligamenta flava of the lumbar region. Anterior aspect.



lamina above, and to the posterior surface and upper margin of the lamina below. The ligaments are thin, but broad and long in the cervical region ; they are thicker in the thoracic region, and thickest in the lumbar region. They prevent excessive flexion and, by virtue of their elasticity, they help to control the movement, graduating it so that its limit is not reached abruptly. In this way they serve to guard against injury of the discs. They also assist in restoring the vertebral column to the erect attitude, after it has been flexed.

The **supraspinous ligament** (fig. 507) is a strong fibrous cord which connects together the apices of the spines from the seventh cervical vertebra to the sacrum ; fibrocartilage is developed in the ligament at its points of attachment to the tips of the spines. It is thicker and broader in the lumbar region than in the thoracic, and intimately blended in both situations with the neighbouring fascia. The most superficial fibres of this ligament extend over three or four vertebræ ; those more deeply seated pass between two or three vertebræ ; while the deepest connect the spines of neighbouring vertebræ. In front it is continuous with the interspinous ligaments. Between the spine of the seventh cervical vertebra and the external occipital protuberance its place is taken by the ligamentum nuchæ.

The **ligamentum nuchæ** is a fibrous membrane, which, in the neck, is homologous with the supraspinous ligament of the thoracic and lumbar vertebræ. It

extends from the external protuberance and external occipital crest to the spine of the seventh cervical vertebra. From its anterior border a fibrous lamina is given off, which is attached to the posterior tubercle of the atlas and to the spines of the cervical vertebræ, and forms a septum between the muscles of the two sides of the neck. In man it is the representative of an important elastic ligament which, in some of the lower animals, controls the movement of flexion of the head, functioning in the same way as the ligamenta flava in man.

The **interspinous ligaments** (fig. 507), thin and membranous, connect adjoining spines, and their attachments extend from the root to the apex of each process. They meet the ligamenta flava in front and the supraspinous ligament behind. They are narrow and elongated in the thoracic region ; broader, thicker, and quadrilateral in form in the lumbar region ; and only slightly developed in the neck.

The **intertransverse ligaments** are interposed between the transverse processes. In the cervical region they consist of a few, irregular, scattered fibres in the thoracic region they are rounded cords intimately connected with the deep muscles of the back ; in the lumbar region they are thin and membranous.

Movements of the vertebral column.—The range of movement possible between any two adjoining vertebræ is very restricted, and this limitation is to be attributed to the presence of the intervertebral disc connecting the vertebral bodies. The greater thickness of the discs in the cervical and lumbar regions as compared with the thoracic region is associated with the greater individual ranges of movement occurring in those regions. But, although the range of movement between any two adjoining vertebræ is small, the summation of these movements gives a relatively wide range of movement to the vertebral column as a whole.

The movements permitted in the vertebral column are : flexion or forward bending, extension or backward bending, bending to one or other side (usually termed lateral flexion), rotation and circumduction.

In *flexion* the anterior longitudinal ligament is relaxed and the anterior parts of the intervertebral discs are compressed ; while at the limit of the movement the posterior longitudinal ligament, the ligamenta flava, and the interspinous and supraspinous ligaments are stretched, as well as the posterior fibres of the intervertebral discs. The interspaces between the laminæ are widened, and the inferior articular processes glide upwards upon the superior articular processes of the subjacent vertebræ. It should be remembered, however, that tension of the extensor muscles of the back is the most important factor in limiting the movement. Flexion is most extensive in the cervical region.

In *extension* an exactly opposite disposition of the parts takes place.* This movement is limited by the tension of the anterior longitudinal ligament, and by the approximation of the spines. It is free in the cervical and lumbar regions, but is restricted in the thoracic region.

In *lateral flexion* the sides of the intervertebral discs are compressed, the extent of motion being limited by the resistance offered by the tension of the antagonist muscles and the surrounding ligaments. Lateral movements may take place in any part of the column, but are freest in the cervical and lumbar regions.

Circumduction is limited, and is merely a succession of the preceding movements.

Rotation is produced by the twisting of the vertebræ on the intervertebral discs ; this, although only slight between any two vertebræ, allows of a considerable extent of movement when it takes place in the whole length of the column, the front of the upper part of the column being turned to one or other side. This movement occurs to a slight extent in the cervical region, is freer in the upper part of the thoracic region, and almost negligible in the lumbar region.

* P. Wiles (*Proc. of the Roy. Soc. of Medicine*, vol. xxviii. 1935) is of opinion that in full extension the axis of movement lies just behind the articular processes and that it moves forwards as the column is straightened until, in full flexion, it passes through, approximately, the middle of the vertebral body.

The extent and variety of the movements are influenced by the shape and direction of the articular facets. In the *cervical* region the upward inclination of the superior articular facets allows of free flexion and extension. Extension can usually be carried farther than flexion ; at the upper end of the region it is checked by the locking of the posterior edges of the superior atlantal facets in the condylar fossæ of the occipital bone ; at the lower end it is limited by a mechanism whereby the inferior articular processes of the seventh cervical vertebra slip into grooves behind and below the superior articular processes of the first thoracic vertebra. Flexion is arrested just beyond the point where the cervical convexity is straightened ; the movement is checked by the apposition of the projecting lower lips of the bodies of the vertebræ with the shelving surfaces on the bodies of the subjacent vertebræ. Lateral flexion and rotation in the cervical region are always combined ; the upward and medial inclinations of the superior articular facets impart a rotatory movement during attempts at lateral flexion. In the *thoracic* region, notably in its upper part, all the movements are limited in order to reduce interference with respiration to a minimum. The almost complete absence of an upward inclination of the superior articular facets prohibits any marked flexion, while extension is checked by the contact of the inferior articular margins with the laminæ, and the contact of the spines with one another. Rotation is free in the thoracic region : the superior articular processes are segments of a cylinder whose axis passes through the vertebral bodies. The direction of the articular facets would allow of free lateral flexion, but this movement is considerably limited in the upper part of the region by the resistance of the ribs and sternum. In the *lumbar* region extension is free and wider in range than flexion. The inferior articular facets are not in close apposition with the superior facets of the subjacent vertebræ, and on this account a considerable amount of lateral flexion is permitted. The amount of rotation possible is almost negligible, owing to the arrangement of the articular processes.

Muscles producing the movements.—The vertebral column may be moved either by muscles attached to it and acting directly on it, or by muscles attached to other bones and acting indirectly on the column.

The principal muscles actively concerned in producing (1) *flexion* are the longus cervicis (longus colli), the scaleni, the sternomastoid, the rectus abdominis and the gluteus maximus (which, in the erect attitude, acts on the lumbar region through the hip-bone), of both sides in each case ; (2) *extension*, the sacrospinalis, the splenius capitis and the semispinalis capitis, of both sides in each case ; (3) *lateral flexion*, the longissimus and iliocostocervicalis portions of the sacrospinalis, the oblique muscles of the abdominal wall, and the muscles concerned in flexion, of one side only in each case ; and (4) *rotation*, the rotatores, the multifidus and the splenius cervicis.

3. The Sacrococcygeal Joint

This articulation is a cartilaginous joint, between the apex of the sacrum and the base of the coccyx, the bones being united by anterior, posterior and lateral sacrococcygeal ligaments, and by a disc of fibrocartilage.

The **anterior sacrococcygeal ligament** (fig. 540) consists of a few irregular fibres which descend from the anterior surface of the sacrum to the front of the coccyx.

The **superficial posterior sacrococcygeal ligament** is a flat band which arises from the margin of the sacral hiatus, and descends to be inserted into the posterior surface of the coccyx. This ligament completes the lower part of the sacral canal.

The **deep posterior sacrococcygeal ligament** extends from the back of the fifth sacral vertebra to the back of the coccyx.

The *intercornual ligaments* connect the cornua of the sacrum and coccyx on each side.

A **lateral sacrococcygeal ligament** exists on each side and connects the transverse process of the coccyx to the inferior lateral angle of the sacrum ; it completes the foramen for the fifth sacral nerve.

A thin disc of fibrocartilage is interposed between the contiguous surfaces of the sacrum and coccyx ; it is somewhat thicker in front and behind than at the sides. Occasionally the coccyx is freely movable on the sacrum ; in such cases an articular capsule lined with synovial membrane is present.

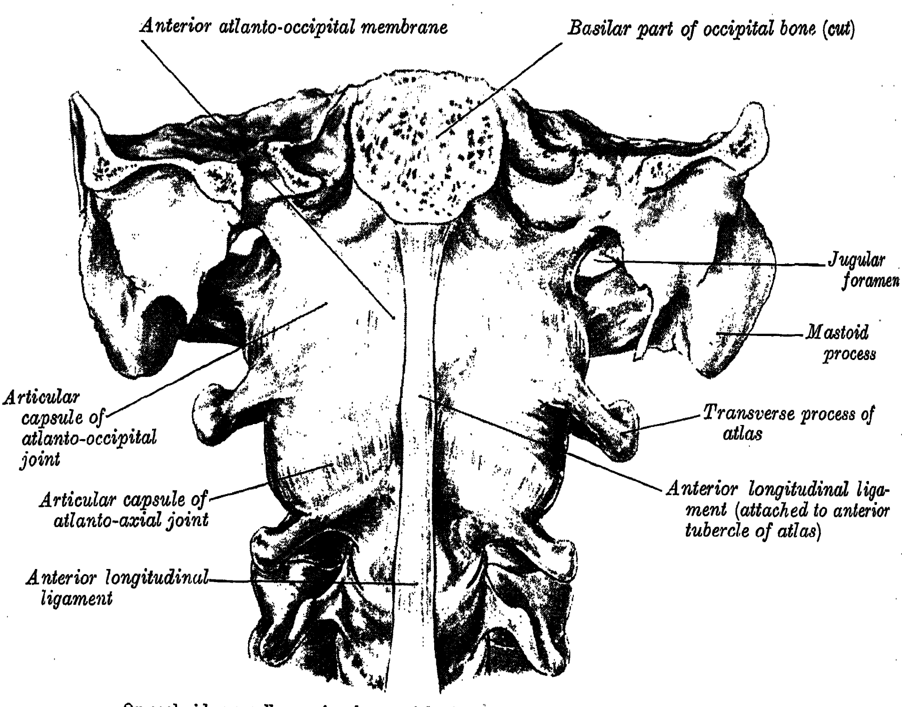
In the young subject the different segments of the coccyx are connected together by the extension downwards of the anterior and posterior sacro-coccygeal ligaments, thin annular discs of fibrocartilage being interposed between the segments. In the adult male, all the pieces become ossified together at a comparatively early period ; but in the female, this does not commonly occur until a later period of life. At a more advanced age the joint between the sacrum and coccyx is obliterated.

Backward and forward movements take place between the sacrum and coccyx ; their extent increases during pregnancy.

4. The Atlanto-Axial Joints

The articulation of the atlas with the axis is of a complicated nature and comprises three synovial joints. Of these one is placed on each side between the inferior facet of the lateral mass of the atlas and the superior facet of the axis: the other is median in position and is placed between the odontoid process (dens) and the anterior arch of the atlas.

Fig. 510.—The atlanto-occipital and atlanto-axial joints. Anterior aspect.



On each side a small, occasional, synovial joint is shown between the lateral part of the upper surface of the body of the third cervical vertebra and the bevelled, inferior surface of the body of the axis. The joint cavities have been opened.

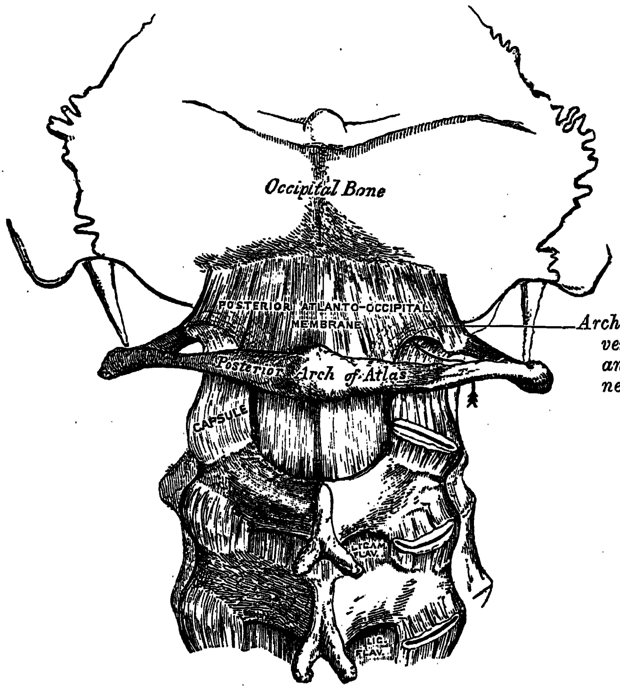
The lateral atlanto-axial joints are plane joints, but the *articular surfaces* involved are both slightly convex in their long axes.

The *capsular ligaments* are thin and loose ; they surround the joints and are lined with synovial membrane. Each is strengthened at its posterior and medial part by an *accessory ligament*, which is attached below to the body of the axis near the base of the odontoid process, and above to the lateral mass of the atlas near the transverse ligament.

In front the two vertebræ are connected by a continuation of the anterior longitudinal ligament (fig. 510). In this position it is a strong membrane, fixed

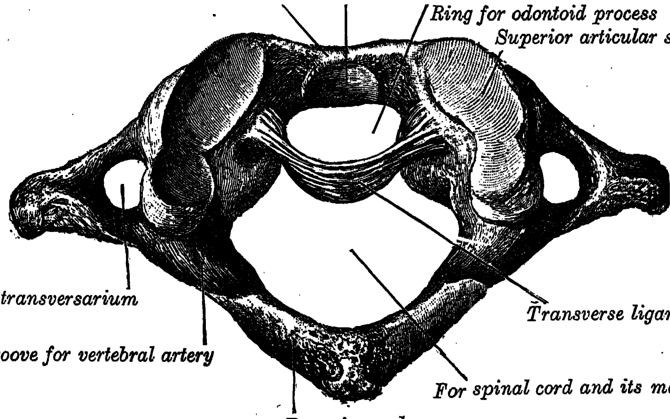
above to the lower border of the anterior arch of the atlas, and below to the front of the body of the axis. It is strengthened in the median plane by a rounded cord which connects the tubercle on the anterior arch of the atlas to the body of the axis.

FIG. 511.—The posterior atlanto-occipital membrane.



Behind, the atlas and axis are joined by a broad, thin membrane (fig. 511) attached above to the lower border of the posterior arch of the atlas, below to the upper edges of the laminæ of the axis ; it is in series with the ligamenta flava and is pierced near its lateral extremity by the second cervical nerve.

FIG. 512.—The atlas vertebra, with the transverse ligament.



The median atlanto-axial joint is a pivot-joint between the odontoid process of the axis and the ring formed by the anterior arch and the transverse ligament of the atlas ; the *articular surfaces* are reciprocally curved.

FIG. 513.—The atlanto-occipital and atlanto-axial joints, shown from behind after removal of the posterior part of the occipital bone and the laminæ of the upper cervical vertebræ. The atlanto-occipital joint-cavities have been opened.

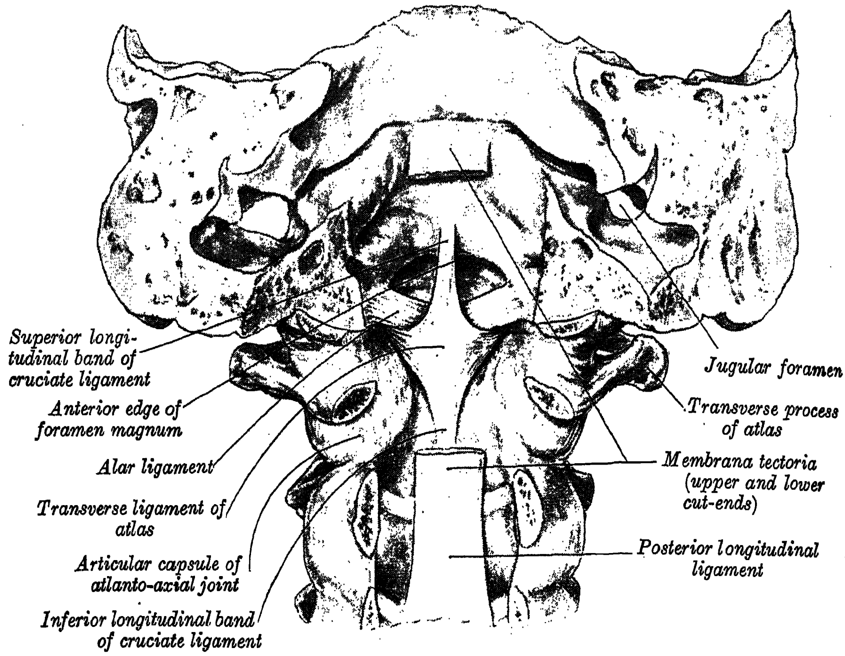


FIG. 514.—A median sagittal section through the occipital bone and first three cervical vertebræ.

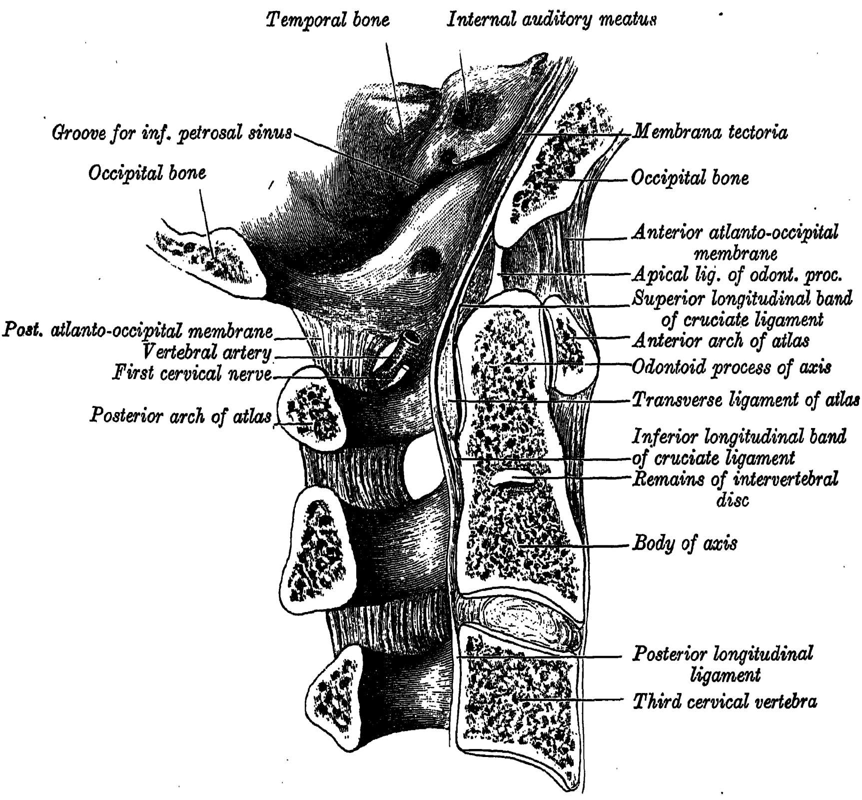


The *capsular ligament* is weak and loose and is lined with synovial membrane. A second synovial cavity is present and lies between the transverse ligament of the atlas and the posterior surface of the odontoid process : it is often continuous with the joint-cavity of one or other of the atlanto-occipital joints.

The **transverse ligament of the atlas** (figs. 512-514) is a thick, strong band which arches across the ring of the atlas and retains the odontoid process of the axis in contact with the anterior arch. It is concave in front, convex behind, broader in the middle than at the ends, and firmly attached on each side to a small tubercle on the medial surface of the lateral mass of the atlas. The median part of the anterior surface is covered by a thin layer of articular cartilage. As the ligament crosses the odontoid process, a small longitudinal band is prolonged upwards, and another downwards, from its superficial or posterior fibres. The upper band is attached to the upper surface of the basilar part of the occipital bone between the apical ligament of the odontoid process and the membrana tectoria ; the lower band is attached to the posterior surface of the body of the axis ; hence the whole ligament is named the *cruciate ligament of the atlas*. The transverse ligament divides the ring of the atlas into two unequal parts (fig. 512) : of these, the posterior and larger surrounds the spinal cord and its membranes and the spinal roots of the accessory nerves ; the anterior and smaller contains the odontoid process. The neck of the process is constricted where it is embraced posteriorly by the transverse ligament, so that this ligament suffices to retain the odontoid process in position after all the others have been divided.

Movements.—Movement must occur at all three joints at the same time, and it allows the rotation of the atlas (and with it the skull) upon the axis, the extent of rotation being limited by the alar ligaments (p. 444).

The opposed articular facets of the atlas and axis are both slightly convex in their long axes, as already stated. When, therefore, the upper facet glides forwards on the lower it also descends. The stretching of the fibres of the capsular ligament that would result from this forward movement is diminished owing to the contemporaneous descent of their upper attachments, and in this way excessive laxity of the capsule is obviated.

Muscles producing the movements.—The principal muscles by which these movements are produced are the obliquus capitis inferior, the rectus capitis posterior major and the splenius capitis of one side, acting with the sterno-mastoid muscle of the other side.

THE JOINTS OF THE VERTEBRAL COLUMN WITH THE CRANIUM

The articulation of the vertebral column with the cranium involves not only a pair of atlanto-occipital joints and their ligaments, but also a number of ligaments which connect the axis with the occipital bone.

1. The Atlanto-Occipital Joints

On each side the atlanto-occipital joint is placed between the superior articular facet of the lateral mass of the atlas and the condyle of the occipital bone : it is condyloid in type. The *articular surfaces* are reciprocally curved, but do not exactly correspond, as the atlantal facet may be constricted or occasionally subdivided into two, an arrangement which facilitates the lubrication of the joint. The ligaments connecting the bones are :

Two capsular.	Anterior and posterior atlanto-occipital membranes.

The **capsular ligaments** surround the condyles of the occipital bone and the superior articular facets of the atlas : they are thin and loose and are lined with synovial membrane. Their lateral portions are directed obliquely upwards and medially, and are reinforced by bundles of fibres, which are attached above to the jugular processes of the occipital bone, and below to the bases of the transverse processes of the atlas.

The atlanto-occipital joints frequently communicate with the joint between the odontoid process and the transverse ligament of the atlas.

The **anterior atlanto-occipital membrane** (fig. 510) is broad, and composed of densely woven fibres which pass between the anterior margin of the foramen magnum above, and the upper border of the anterior arch of the atlas below; laterally it is continuous with the capsular ligaments; in front, it is strengthened in the median plane by the continuation of the anterior longitudinal ligament, a strong, rounded cord, which connects the basilar part of the occipital bone to the tubercle on the anterior arch of the atlas (fig. 510).

The **posterior atlanto-occipital membrane** (fig. 511), broad but thin, is connected above to the posterior margin of the foramen magnum; below, to the upper border of the posterior arch of the atlas. On each side it arches over the groove for the vertebral artery, and with this groove bounds an opening for the entrance of the artery and the exit of the first cervical nerve. The free border of the membrane, arching over the artery and nerve, is sometimes ossified.

Movements.—The long axes of the two joints are set obliquely and run from behind forwards and medially. As a result of this obliquity and of the curvature of the occipital condyle, the corresponding articular surfaces of the two sides are in reality portions of the surface of an ellipsoid, the long axis of which is set transversely. The two joints therefore act as one, and movement may occur around transverse and anteroposterior axes, but not round a vertical axis. The movements permitted therefore are (*a*) flexion and extension, which give rise to the ordinary forward and backward nodding of the head, and (*b*) slight lateral motion to one or other side.

Muscles producing the movements:

Flexion.—Longus capitis, Rectus capitis anterior, and Sternomastoid.
Extension.—Recti capitis posteriores major et minor, Obliquus superior, Semispinalis capitis, Splenius capitis, and Trapezius (upper fibres).
Lateral flexion.—Rectus capitis lateralis, Semispinalis capitis, Splenius capitis, Sternomastoid and Trapezius (upper fibres).

2. The Ligaments connecting the Axis with the Occipital Bone

Membrana tectoria. Two alar. Apical ligament.

The **membrana tectoria** (figs. 513, 514) is situated within the vertebral canal. It is a broad, strong band, which covers the odontoid process and its ligaments and appears to be a prolongation upwards of the posterior longitudinal ligament of the vertebral column. It is fixed below to the posterior surface of the body of the axis, and, expanding as it ascends, is attached above to the upper surface of the basilar part of the occipital bone, in front of the foramen magnum, blending with the cranial dura mater. It covers the posterior aspect of the cruciate ligament of the atlas.

The **alar ligaments of the odontoid process** (fig. 513) are two strong, rounded cords, which arise one on each side of the upper part of the odontoid process, and passing obliquely upwards and laterally, are inserted into rough impressions on the medial sides of the condyles of the occipital bone. The alar ligaments are relaxed on extension of the head but become taut on flexion and help to limit the movement. They are so disposed that they would render free rotation of the head impossible, were it not for the fact that the movement of rotation is accompanied by a slight descent of the atlas (p. 443). This descent causes sufficient relaxation of the alar ligaments to compensate for the tension brought about by rotation. Rotation to the right is eventually checked by the tension of those fibres of the right alar ligament which are attached to the odontoid process in front of the axis of movement, and by tension of those fibres of the left alar ligament which are attached to the process behind the axis of movement. Rotation to the left is checked by the opposite fibres on each side.

The **apical ligament of the odontoid process** (fig. 514), which extends from the tip of the process to the anterior margin of the foramen magnum, lies between

the alar ligaments, being intimately blended with the deep portion of the anterior atlanto-occipital membrane and with the upper longitudinal band of the cruciate ligament of the atlas. It is regarded as a rudimentary intervertebral disc, and may contain traces of the notochord in its substance.

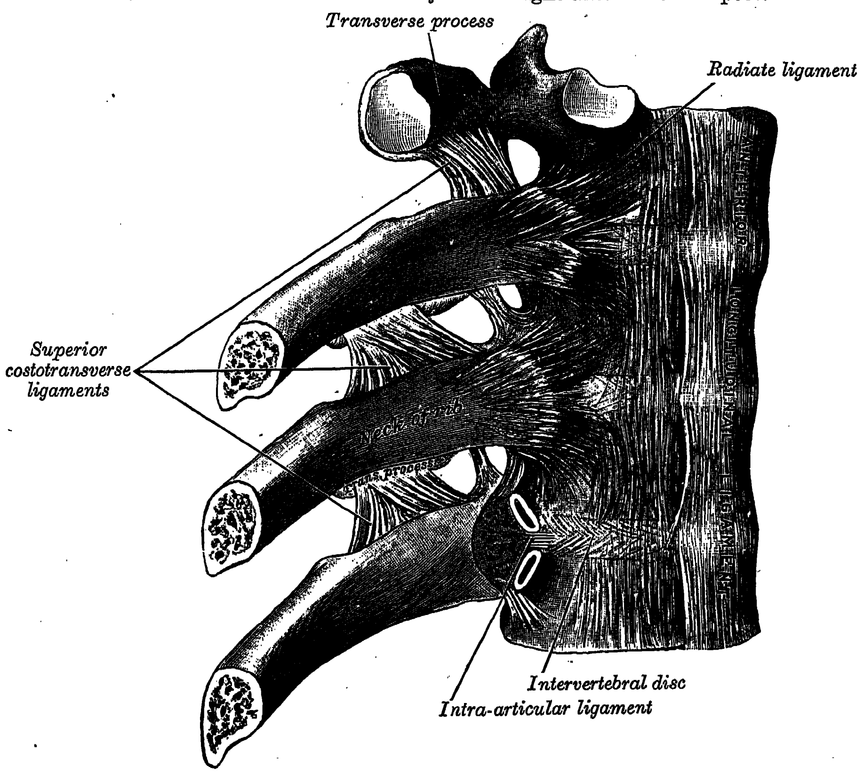
It must be remembered that, in addition to the ligaments which unite the atlas and axis to the skull, the ligamentum nuchæ (p. 437) connects the cervical vertebræ with the cranium.

Applied Anatomy.—Dislocation of the atlas from the axis, with rupture of the transverse ligament of the atlas and consequent injury to the spinal cord, is the mode in which death is produced in many cases of execution by hanging. Hanging may however produce a fracture through the axis, or a separation through the disc between the axis and the third cervical vertebra. Following infective conditions of the pharynx or in its vicinity, the cruciate ligament may become softened and occasionally a pathological dislocation of the atlas on the axis may result.

THE COSTOVERTEBRAL JOINTS

The articulations of the ribs with the vertebral column may be divided into two sets, one connecting the heads of the ribs with the bodies of the vertebræ, the other uniting the necks and tubercles of the ribs with the transverse processes.

FIG. 515.—The costovertebral joints. Right anterolateral aspect.



1. The Joints of the Heads of the Ribs (fig. 515)

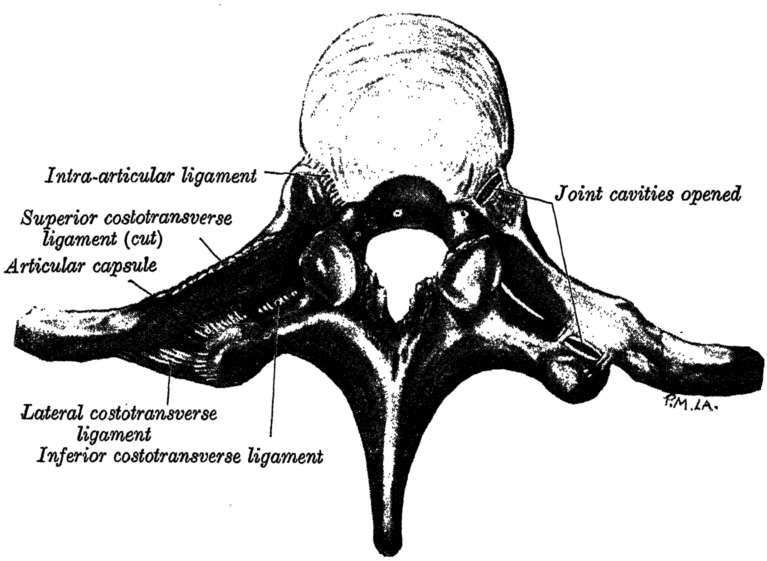
These articulations constitute a series of plane joints. They are formed by the articulation of the heads of the typical ribs with the facets on the contiguous margins of the bodies of the thoracic vertebræ, and with the intervertebral discs between them. The first, tenth, eleventh, and twelfth ribs each articulate with a single vertebra; in each of the other joints, an intra-articular ligament divides the joint cavity into two distinct parts. The ligaments of the joints are:

Capsular. Radiate.
Intra-articular.

The **capsular ligaments** connect the heads of the ribs with the circumferences of the articular cavities formed by the intervertebral discs and the adjacent vertebræ. Some of their upper fibres pass through the intervertebral foramen to the back of the intervertebral disc, while the posterior fibres are continuous with the inferior costotransverse ligament (ligament of the neck of the rib).

The **radiate ligament** connects the anterior part of the head of each rib with the sides of the bodies of two vertebræ, and the intervertebral disc between them. It is attached to the anterior part of the head of the rib, just beyond the articular surface. The superior fibres ascend and are connected with the body of the vertebra above ; the inferior fibres descend to the body of the vertebra below ; the middle fibres, the smallest and least distinct, are horizontal and attached to the intervertebral disc.

FIG. 516.—The costovertebral joints, viewed from above.



In the articulation of the first rib, the radiate ligament is attached to the body of the last cervical vertebra, as well as to that of the first thoracic. In the articulations of the tenth, eleventh and twelfth ribs, each of which articulates with a single vertebra, the radiate ligament is connected to the vertebra with which the rib articulates, and also to the vertebra immediately above it.

The **intra-articular ligament** is situated in the interior of the joint. It consists of a short band of fibres, flattened from above downwards, attached laterally to the crest separating the two articular facets on the head of the rib, and medially to the intervertebral disc ; it divides the joint into two cavities and its upper and lower surfaces are covered with synovial membrane. In the joints of the first, tenth, eleventh and twelfth ribs, intra-articular ligaments do not exist ; consequently, there is but one cavity in each of these articulations. The intra-articular ligament is the homologue of the *ligamentum conjugale*, which is present in some mammals and unites the heads of opposite ribs across the back of the intervertebral disc.

2. THE COSTOTRANSVERSE JOINTS (fig. 516)

The articular portion of the tubercle of a rib forms a plane joint with the transverse process of the vertebra to which it corresponds numerically. In the eleventh and twelfth ribs this articulation is wanting. In the upper six (or five) joints the *articular surfaces* are reciprocally curved, but in the lower joints the surfaces are flattened (p. 214).

The ligaments of the joints are:

Capsular.	Inferior costotransverse.
Superior costotransverse.	Lateral costotransverse.

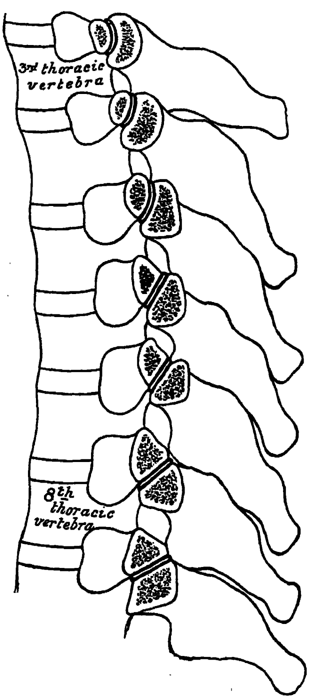
The **capsular ligament** is a thin membrane attached to the circumference of the articular surfaces, and lined with synovial membrane.

The **superior (anterior) costotransverse ligament** comprises an anterior and a posterior layer. The anterior fibres are attached below to the crest of the neck of the rib and pass upwards and laterally to the lower border of the transverse process immediately above. Laterally they are continuous with the fibres of the posterior intercostal membrane, and they are crossed anteriorly by the corresponding intercostal vessels and nerve. The posterior fibres are attached to the posterior surface of the neck of the rib and run upwards and medially behind the anterior fibres to reach the transverse process immediately above. Laterally they are intimately related to the external intercostal muscle.

The first rib has no superior costotransverse ligament. The neck of the twelfth rib is connected to the base of the transverse process of the first lumbar vertebra by a band of fibres, named the *lumbocostal ligament*; it is in series with the superior costotransverse ligaments.

An additional ligamentous band is usually present, although it is somewhat variable in its disposition. It is attached to a depression above and medial to the tubercle of the rib and, passing medial to the intertransverse ligament, it reaches the back of the inferior articular process, often sending a few fibres upwards to the base of the transverse process. Through the interval between this band and the medial border of the superior costotransverse ligament, the posterior primary ramus of the corresponding thoracic nerve runs backwards with its accompanying vessels.

FIG. 517.—A section through the costotransverse joints from the third to the ninth inclusive. Contrast the concave facets on the upper with the flattened facets on the lower transverse processes.



The **inferior costotransverse ligament** (ligament of the neck of the rib) consists of short but strong fibres, connecting the rough surface on the back of the neck of the rib with the anterior surface of the adjacent transverse process. A rudimentary ligament may be present at the eleventh and twelfth ribs.

The **lateral costotransverse ligament** (ligament of the tubercle of the rib) is a short, thick, strong fasciculus, which passes obliquely from the apex of the transverse process to the rough non-articular portion of the tubercle of the rib. The ligaments attached to the upper ribs ascend from the transverse processes; they are shorter and more oblique than those attached to the lower ribs, which descend slightly.

Movements.—The heads of the ribs are so closely connected to the bodies of the vertebræ by the radiate and intra-articular ligaments that only slight gliding movements of the articular surfaces on one another can take place. Similarly, the strong ligaments binding the necks and tubercles of the ribs to the transverse processes limit the movements of the costotransverse joints to slight gliding, the nature of which is determined by the shape and direction of the articular surfaces (fig. 517). The articular surfaces on the tubercles of the upper six ribs are oval in shape and convex from above downwards; they fit into corresponding concavities on the anterior surfaces of the transverse processes, so that upward and downward movements of the tubercles are associated with rotation of the rib-neck on its long axis. On the seventh, eighth, ninth and tenth ribs the articular surfaces on the tubercles are flat, and face obliquely downwards, medially and backwards. The surfaces with

which they articulate are placed on the upper aspects of the transverse processes ; when, therefore, the tubercles are drawn up they are at the same time carried backwards and medially. The joints of the heads of the ribs and the costotransverse joints move simultaneously and in the same directions, the total effect being that the neck of the rib moves as if on a single joint, of which the two articulations form the ends. In the upper six ribs the neck of the rib moves but slightly upwards and downwards ; its chief movement is one of rotation round its own long axis, rotation downwards of the front of the neck of the rib being associated with depression, rotation upwards with elevation of the anterior end of the rib and its costal cartilage. In the seventh, eighth, ninth and tenth ribs the neck of the rib moves upwards, backwards and medially, or downwards, forwards and laterally, with resultant increase or diminution of the infrasternal angle ; very slight rotation accompanies these movements.

Muscles producing the movements.—These are discussed with the mechanism of respiration (p. 558).

THE STERNOCOSTAL JOINTS (fig. 518)

The cartilages of the true ribs, with the exception of the first, articulate with the sternum by synovial joints. The cartilage of the first rib is directly united with the sternum, and the joint between this rib and the sternum is a primary cartilaginous joint.

The ligaments of the synovial joints are :

Capsular.	Intra-articular.
Sternocostal.	Costoxiphoid.

The **capsular ligaments** surround the joints between the sternum and the cartilages of the ribs from the second to the seventh inclusive. They are very thin, intimately blended with the sternocostal ligaments, and strengthened at the upper and lower parts of the articulations by a few fibres which connect the cartilages to the side of the sternum.

The **sternocostal ligaments** are broad, thin, membranous bands which radiate from the front and back of the sternal ends of the cartilages of the true ribs to the anterior and posterior surfaces of the sternum. Their superficial fibres intermingle with the fibres of the ligaments above and below them, with those of the opposite side, and on the front of the sternum with the tendinous fibres of origin of the pectoralis major, forming a thick fibrous membrane which envelops the bone, and is more distinct at its lower part than at its upper part.

The **intra-articular ligaments** are constantly present only between the second costal cartilages and the sternum. The cartilage of the *second rib* is connected with the sternum by means of an intra-articular ligament, attached laterally to the cartilage of the rib, and medially to the fibrocartilage which unites the manubrium and body of the sternum. Occasionally the cartilage of the *third rib* is connected with the first and second pieces of the body of the sternum by an intra-articular ligament. Still more rarely, similar ligaments are found in the other four joints of the series. In the lower two an intra-articular ligament sometimes obliterates the joint-cavity, so as to convert the articulation into a syndesmosis. After middle life the articular surfaces lose their polish, become roughened, and the synovial membrane apparently disappears. In old age, the cartilages of most of the ribs become continuous with the sternum, and the joint cavities are consequently obliterated.

The **costoxiphoid ligaments** connect the anterior and posterior surfaces of the seventh costal cartilage, and sometimes those of the sixth, to the front and back of the xiphoid process. They vary in length and breadth in different subjects ; those on the back of the joint are less distinct than those in front.

Movements.—Slight gliding movements are permitted in the sternocostal joints.

THE INTERCHONDRAL JOINTS (fig. 518)

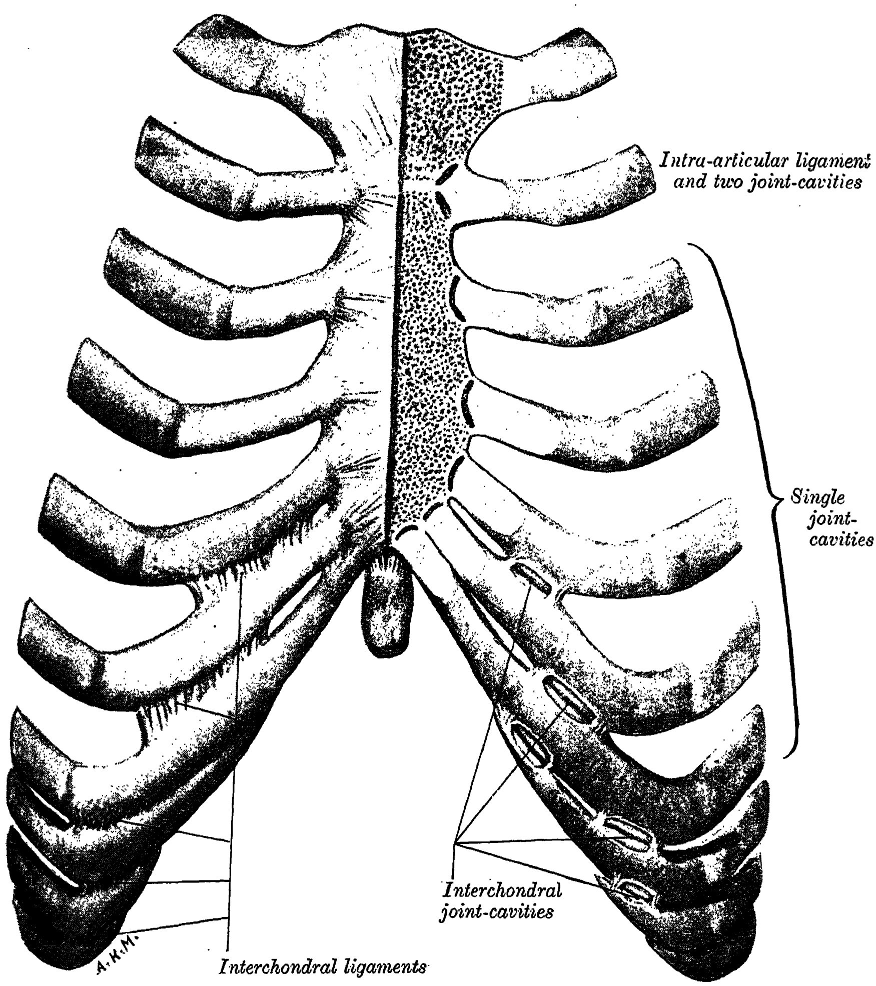
The contiguous borders of the sixth and seventh, the seventh and eighth, and the eighth and ninth, costal cartilages articulate with each other by small

smooth, oblong facets. Each articulation is enclosed in a thin *capsular ligament*, lined with synovial membrane and strengthened laterally and medially by *interchondral ligaments*, which pass from one cartilage to the other. Sometimes the fifth costal cartilages, more rarely the ninth, articulate by their lower borders with the adjoining cartilages by small, oval facets ; more frequently the connexion is by a few ligamentous fibres

The Costochondral Joints

The lateral end of each costal cartilage is received into a depression in the sternal end of the rib, and the two are enveloped by the periosteum.

Fig. 518.—The sternocostal and interchondral joints. Viewed from in front.



The Sternal Joints

The **manubriosternal joint.**—In the majority of cases the joint between the manubrium and the body of the sternum is cartilaginous in character, the bony surfaces being coated with hyaline cartilage and connected by a disc of fibro-

cartilage, which occasionally becomes ossified in advanced life. In rather more than thirty per cent. of subjects the central part of the disc undergoes absorption and the joint is converted into a synovial one. The two segments of the bone are also connected by the fibrous membrane which envelops the bone.

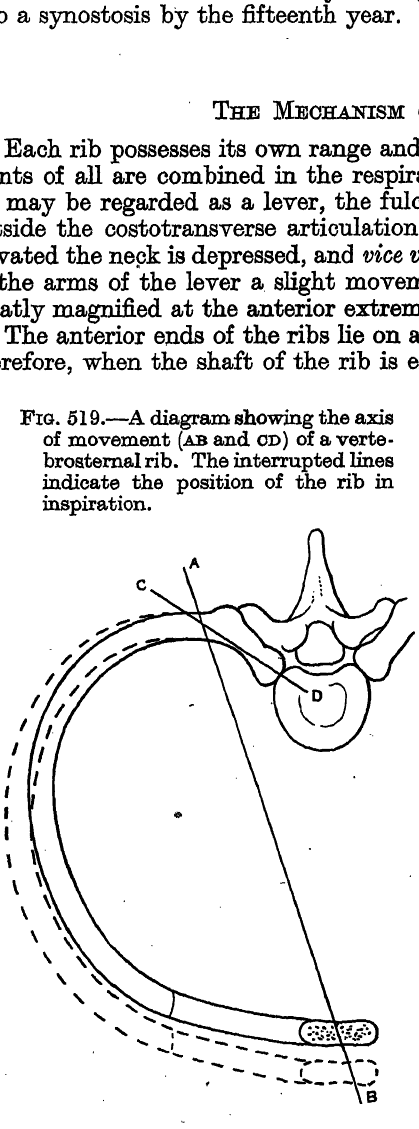
The **xiphisternal joint.**—The joint between the xiphoid process and the body of the sternum is also a secondary cartilaginous joint, but it is usually converted into a synostosis by the fifteenth year.

The Mechanism of the Thorax

Each rib possesses its own range and variety of movements, but the movements of all are combined in the respiratory excursions of the thorax. Each rib may be regarded as a lever, the fulcrum of which is situated immediately outside the costotransverse articulation, so that when the shaft of the rib is elevated the neck is depressed, and *vice versa* ; from the disproportion in length of the arms of the lever a slight movement at the vertebral end of the rib is greatly magnified at the anterior extremity.

The anterior ends of the ribs lie on a lower plane than the posterior ; and, therefore, when the shaft of the rib is elevated, the anterior extremity is also thrust forwards. Again, the middle of the shaft of the rib lies in a plane below that passing through the two extremities, so that when the shaft is elevated relatively to its ends it is at the same time carried outwards from the median plane ; further, each rib forms the segment of a curve which is greater than that of the rib immediately above. Therefore the elevation of a rib increases the transverse diameter of the thorax in the plane to which it is raised. The modifications of the rib movements at their vertebral ends have already been described (p. 447). Further modifications result from the attachments of their anterior extremities, and it is convenient therefore to consider separately the movements of the ribs of the three groups—vertebrosternal, vertebrochondral, and vertebral.

Fig. 519.—A diagram showing the axis of movement (AB and CD) of a vertebrosternal rib. The interrupted lines indicate the position of the rib in inspiration.

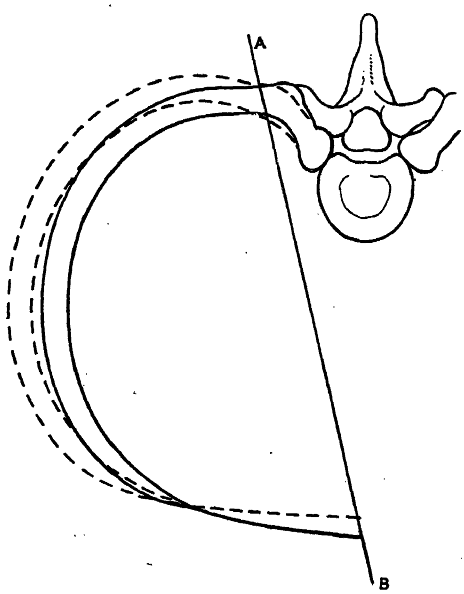


Vertebrosternal ribs (fig. 519).—The first rib differs from the others of this group in that its attachment to the sternum is a rigid one ; this is counter-balanced to some extent by the fact that its head possesses no intra-articular ligament, and is therefore more movable. The first pair of ribs with the manubrium sterni move as a single piece, the anterior portions being elevated by rotatory movements at the vertebral extremities. In normal quiet respiration the movement of this arc is practically *nil* ; when it does occur the anterior part is raised and carried forwards, increasing the anteroposterior diameter of this region of the chest. The movement of the second rib is also slight in normal respiration, as its anterior extremity is fixed to the manubrium, and therefore prevented from moving upwards. The sternocostal articulation, however, allows the middle of the shaft of the rib to be drawn up, and in this way the transverse thoracic diameter is increased. Elevation of the third, fourth, fifth, and sixth ribs raises and thrusts forwards their anterior extremities, the greater

part of the movement being effected by the rotation of the rib-neck backwards. The thrust of the anterior extremities carries forwards and upwards the body of the sternum, which moves on the joint between it and the manubrium, and thus the anteroposterior thoracic diameter is increased. This movement, however, is soon arrested, and the elevating force is then expended in raising the middle part of the shaft of the rib and everting its lower border; at the same time the costochondral angle is opened out. By these latter movements a considerable increase in the transverse diameter of the thorax is effected.

Vertebrochondral ribs (fig. 520).—The seventh rib is included with this group, as it conforms more closely to their type. While the movements of these ribs assist in enlarging the thorax for respiratory purposes, they are also concerned in increasing the upper abdominal space for viscera displaced by the action of the diaphragm. The costal cartilages articulate with one another, so that each pushes up that above it, the final thrust being directed to pushing forwards

FIG. 520.—A diagram showing the axes of movement (AB) of a vertebrochondral rib. The interrupted lines indicate the position of the rib in inspiration.



and upwards the lower end of the body of the sternum. The amount of elevation of the anterior extremities is limited on account of the very slight rotation of the rib-neck. Elevation of the shaft is accompanied by an outward and backward movement; the outward movement everts the anterior end of the rib and opens up the infracostal angle, while the backward movement pulls back the anterior extremity and counteracts the forward thrust due to its elevation; this latter is most noticeable in the lower ribs, which are the shortest. The total result is a considerable increase in the transverse and a diminution in the median anteroposterior diameter of the upper part of the abdomen; at the same time, however, the lateral anteroposterior diameters of the abdomen are increased.

Vertebral ribs.—Since these ribs have free anterior extremities and only costocentral articulations with no intra-articular ligaments, they are capable of slight movements in all directions. When the other ribs are elevated these are depressed and fixed to form points of action for the diaphragm.

Muscles producing the movements.—These are discussed with the mechanism of respiration (p. 558).

THE JOINTS OF THE UPPER LIMB

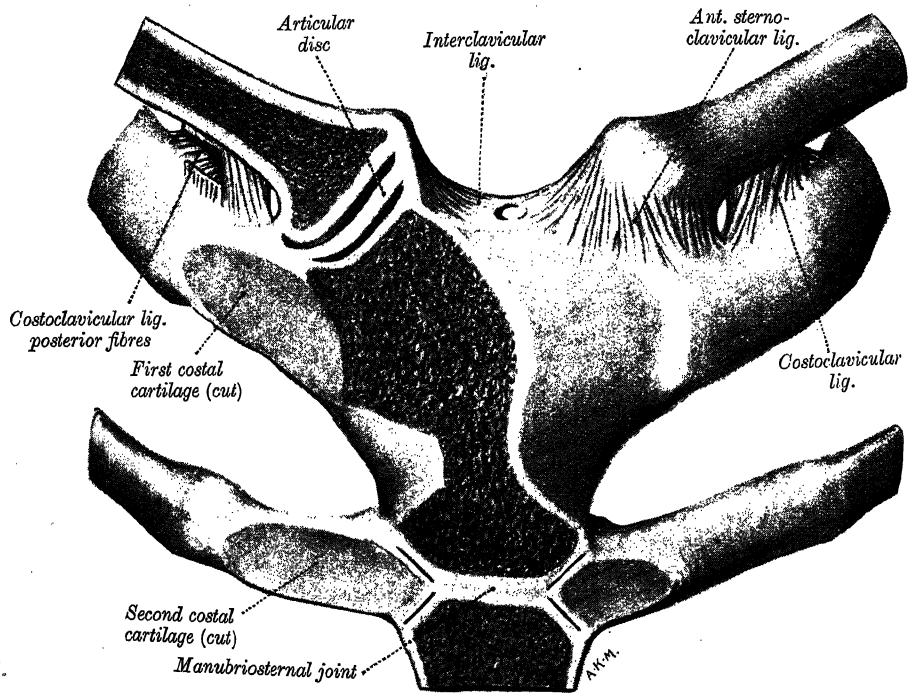
I. THE STERNOCLAVICULAR JOINT (fig. 521)

The sternoclavicular articulation is a double plane joint, the joint-cavity being subdivided by an articular disc. The parts entering into its formation are the sternal end of the clavicle, the clavicular notch of the manubrium sterni, and the cartilage of the first rib. The *articular surface* of the clavicle is much larger than that of the sternum, and is covered with a layer of fibrocartilage which is considerably thicker than that on the sternum. It is convex in its vertical diameter, and slightly concave anteroposteriorly. The clavicular notch of the sternum is reciprocally curved, but the two surfaces are not perfectly congruent and the incongruence is compensated for by the articular disc. In actual fact the joint functions rather as a ball-and-socket joint than as a saddle-joint. The ligaments of this joint are :

Capsular. Interclavicular.
Anterior sternoclavicular. Costoclavicular.
Posterior sternoclavicular.

The **capsular ligament** surrounds the articulation ; in front and behind, it is of considerable thickness, but above, and especially below, it is thin and partakes more of the character of areolar tissue than of true fibrous tissue.

FIG. 521.—The sternoclavicular joints ; viewed from in front.



The **anterior sternoclavicular ligament** is a broad band, covering the anterior surface of the joint ; it is attached above to the upper and front part of the sternal end of the clavicle, and, passing obliquely downwards and medially, is attached below to the front of the upper part of the manubrium sterni.

The **posterior sternoclavicular ligament** is a weaker band which covers the posterior aspect of the joint. It is attached to the posterior aspect of the sternal end of the clavicle and passes obliquely downwards and medially to be attached to the back of the upper part of the manubrium sterni.

The **interclavicular ligament** is continuous above with the deep cervical fascia ; it passes from the upper part of the sternal end of one clavicle to that

of the other, but gives some fibres to the upper margin of the manubrium sterni.

The **costoclavicular ligament** is short, flat, strong, and rhomboid in form. Attached below to the upper surface of the cartilage of the first rib, it is fixed above to the impression on the under surface of the medial end of the clavicle. The anterior fibres are directed upwards, backwards and laterally, the posterior fibres upwards, backwards and medially (fig. 521).

The **articular disc** is flat and nearly circular, and is interposed between the articulating surfaces of the sternum and clavicle. It is attached, above, to the upper and posterior border of the articular surface of the clavicle; below, to the cartilage of the first rib, near its junction with the sternum; and by the rest of its circumference to the capsular ligament. It is thicker at the circumference—especially at its upper and posterior part—than at the centre, and divides the joint into two cavities; each of its surfaces is clothed with synovial membrane.

The *arteries* supplying the joint are derived from the internal mammary and suprascapular (transverse scapular) arteries; the *nerves*, from the medial (anterior) supraclavicular nerves and the nerve to the subclavius muscle.

Applied Anatomy.—The strength of this joint depends upon its ligaments, and especially on the articular disc. It is owing to these, and to the fact that the force of the blow is usually transmitted along the long axis of the clavicle, that dislocation rarely occurs, and that the clavicle is broken rather than displaced. Dislocation may be either forwards, backwards or upwards. Should the clavicle be displaced backwards it may cause pressure on the trachea and great vessels of the neck. Owing to the shape of the articular surfaces, and the fact that the strength of the joint mainly depends upon the ligaments, the displacement when reduced is very liable to recur.

The joint is the fulcrum for the leverage exerted by the trapezius on the clavicle in elevation of the shoulder. If the joint is unstable, as the result of a dislocation, the effectiveness of the muscle is appreciably diminished.

II. THE ACROMIOCLAVICULAR JOINT

The acromioclavicular articulation (fig. 525) is a plane joint between the acromial end of the clavicle and the medial margin of the acromion of the scapula. The *articular surface* of the acromial end of the clavicle is covered with fibrocartilage, and forms a narrow, oval area, which is directed downwards and laterally so as to overlap the corresponding area on the medial border of the acromion. The long axis of the joint lies in an anteroposterior plane. Its ligaments are:

Capsular.	Coracoclavicular	Trapezoid part.
Acromioclavicular.		Conoid part.

The **capsular ligament** completely surrounds the articular margins, and is strengthened above by the acromioclavicular ligament.

The **acromioclavicular ligament** is a quadrilateral band, covering the superior part of the joint, and extending between the upper part of the acromial end of the clavicle and the adjoining part of the upper surface of the acromion; it is composed of parallel fibres, which interlace with the aponeuroses of the trapezius and deltoid muscles.

An **articular disc** is found sometimes in this joint; when present, it generally occupies the upper part of the articulation, and only partially separates the articular surfaces. More rarely, it divides the joint completely into two cavities.

The **coracoclavicular ligament** (fig. 522) connects the clavicle with the coracoid process of the scapula. It does not properly belong to the acromioclavicular joint, but is usually described with it since it forms a most efficient means of preventing the clavicle from losing contact with the acromion. It consists of two parts, viz. *trapezoid* and *conoid*, which are usually separated by a bursa.

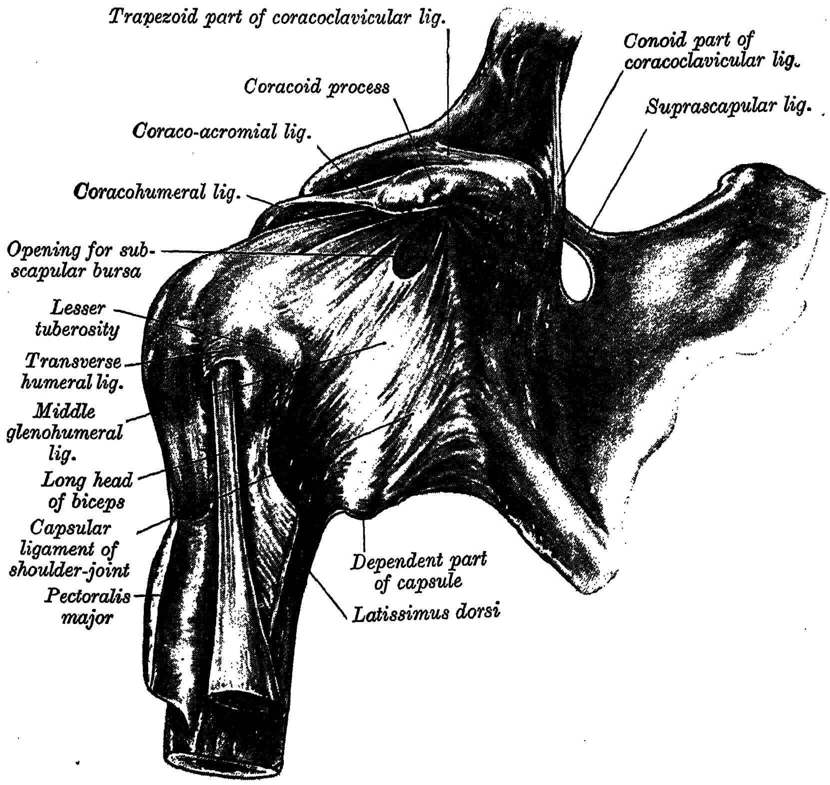
The *trapezoid part*, which forms the anterior and lateral fasciculus, is broad, thin, and quadrilateral. It is attached, below, to the upper surface of the

coracoid process; above, to the trapezoid line on the under surface of the clavicle. Its anterior border is free; its posterior is joined with the conoid part, the two forming, by their junction, an angle projecting backwards.

The *conoid part*, which forms the posterior and medial fasciculus, is a dense band of fibres, conical in form, with its base directed upwards. Its apex is attached to a rough impression at the junction of the root with the horizontal portion of the coracoid process, medial to the trapezoid part; its base is fixed to the conoid tubercle on the under surface of the clavicle, and to a line proceeding medially from it for 1·25 cm.

The *arteries* supplying the joint are derived from the suprascapular (transverse scapular) and acromiothoracic arteries; the *nerve* is a branch of the suprascapular nerve.

FIG. 522.—The right shoulder-joint. Anterior aspect.



Movements of the shoulder girdle.—The movements which occur at the sternoclavicular and acromioclavicular joints are always associated with movements of the scapula, and movements of the scapula are usually, though not invariably, associated with movements of the humerus at the shoulder joint. The movements of the scapula and clavicle *per se* are of academic interest only, but they are of great practical importance when they are considered from the point of view of their relation to the movements of the humerus. The student, therefore, is advised to keep this in mind when reading the following paragraphs, and, on their conclusion, he should turn to the paragraphs dealing with the movements at the shoulder-joint itself (p. 459).

The acromioclavicular joint allows the acromion to glide forwards and backwards, and to rotate upwards and downwards on the clavicle, but the range of these scapular movements is greatly increased by associated movements which occur at the sternoclavicular joint at the same time. The analysis of all these movements can be effected by a study of the movements of the scapula.

The following movements of the scapula are permitted: (1) elevation and

depression; (2) forward and backward movement round the chest wall; (3) rotation forwards (or upwards) and rotation backwards (or downwards).

(1) *Elevation* or *depression of the scapula*, e.g. shrugging of the shoulders, does not necessarily imply any corresponding movement at the shoulder-joint. (*a*) During elevation only a slight degree of angular movement occurs at the acromioclavicular joint, but the sternal end of the clavicle moves downwards over the surface of the articular disc. This movement at the sternoclavicular joint is checked by tension of the antagonist muscles, the costoclavicular ligament and the lower part of the capsule. It is brought about by the *trapezius* (*upper fibres*) and the *levator scapulæ*, and, as these muscles tend to rotate the scapula in opposite directions, a pure upward movement is effected.

(*b*) In the reverse movement a little angular movement occurs at the acromioclavicular joint, but at the sternoclavicular joint the clavicle rides upwards on the disc, and this movement is checked by tension of the antagonist muscles, and by the interclavicular and sternoclavicular ligaments and the articular disc. In extreme depression of the point of the shoulder, such as may occur when a heavy weight is carried on it, the sternal end of the clavicle may be supported by the first rib. As a rule this movement is carried out with the help of the force of gravity, but it can be performed actively by the *serratus anterior* (*lower fibres*) and the *pectoralis minor*.

(2) (*a*) *Forward movement of the scapula* round the chest wall occurs in all forward pushing, thrusting and punching movements, and it is usually accompanied by some degree of forward rotation. The acromion moves forwards over the clavicular facet to the limit of its range of movement, and at the same time the point of the shoulder is advanced further by a forward movement of the lateral end of the clavicle. This forward movement is associated with a backward movement of the sternal end of the bone, which moves backwards over the sternal facet, carrying the articular disc with it. Tension of the antagonist muscles, of the posterior sternoclavicular ligament and of the posterior fibres of the costoclavicular ligament checks this backward movement. The *serratus anterior* and the *pectoralis minor* are the prime movers, and this combination ensures the continuous apposition of the medial border of the scapula with the chest wall. In addition, the "strap" effect of the upper fibres of the latissimus dorsi keeps the inferior angle in close contact with the ribs, both in this movement and in forward rotation.

(*b*) In *backward movement of the scapula*, such as occurs when the shoulders are braced back, the reverse movements take place and they are checked at the sternoclavicular joint by tension of the anterior sternoclavicular ligament and of the anterior fibres of the costoclavicular ligament. When it is carried out actively or against resistance, the *trapezius* and the *rhomboid muscles* are the prime movers.

It may be noted here that when force is applied at the extremity of the outstretched arm, e.g. by a fall on the hand, the pressure transmitted to the glenoid cavity tends to drive the sloping acromial facet below the acromial end of the clavicle, but at the same time it causes tension of the trapezoid ligament, which serves to resist the displacement.

(3) (*a*) *Forward rotation of the scapula* serves to increase the range of movement of the humerus, by turning the bone so that the glenoid cavity faces almost directly upwards—the position which it assumes when the arm is raised above the head. This movement is always associated with some degree of elevation of the humerus and is accompanied by some forward movement of the scapula round the chest wall. The acromial facet rotates upwards on the clavicle and at the same time the point of the shoulder is raised. The rotation results in tension of the conoid ligament at a relatively early stage and thereafter the clavicular attachment of the ligament appears to serve as the centre around which the subsequent movement takes place. Thus throughout the greater part of the movement the conoid ligament is kept taut and it helps to bring about the upward rotation of the clavicle which usually occurs in the last stage. This rotatory movement of the clavicle is very small in extent and is checked by the tension of the articular disc, the sternoclavicular capsule and the costoclavicular ligament.

In this important movement the *trapezius* and the *serratus anterior* are the prime movers.

(*b*) The opposite rotation is usually effected under the influence of gravity, and the gradual relaxation of the trapezius and serratus anterior is sufficient to bring it about. When it is performed actively, the *levator scapulæ*, the *rhomboids*, and, in the initial stages at least, the *pectoralis minor* are the prime movers so far as the scapula is concerned.

In all the movements of the scapula the *subclavius muscle* serves to steady the clavicle by drawing it medially and downwards.

Attention should be drawn to the fact that in the movements of the scapula, muscles which are antagonists for one type of movement may nevertheless combine together and act as prime movers for another. Thus the serratus anterior and the trapezius are opposed in forward and backward movements round the chest wall, but combine together as prime movers for forward rotation.

THE LIGAMENTS OF THE SCAPULA

The ligaments of the scapula (fig. 522) are the coraco-acromial, the suprascapular (superior transverse), and the spinoglenoid (inferior transverse).

The **coraco-acromial ligament** is a strong triangular band, extending between the coracoid process and the acromion. Its apex is attached to the edge of the acromion just in front of the articular surface for the clavicle ; and its base to the whole length of the lateral border of the coracoid process. This ligament, together with the coracoid process and the acromion, forms an arch for the protection of the head of the humerus. It sometimes consists of two strong marginal bands and a thinner intervening portion.

When the pectoralis minor is inserted, as it is occasionally, into the capsule of the shoulder-joint instead of into the coracoid process, the tendon of the muscle passes between the two bands of the coraco-acromial ligament.

The **suprascapular (superior transverse) ligament** converts the suprascapular notch into a foramen, and is sometimes ossified. It is a thin and flat fasciculus, narrower at the middle than at the extremities, which are attached to the base of the coracoid process and the medial end of the suprascapular notch respectively. The suprascapular nerve runs through the foramen ; the suprascapular (transverse scapular) vessels cross over the ligament.

The **spinoglenoid (inferior transverse) ligament** is a weak, membranous band, stretching from the lateral border of the spine of the scapula to the margin of the glenoid cavity. It forms an arch under which the suprascapular nerve and vessels enter the infraspinous fossa. It is frequently absent.

III. THE SHOULDER-JOINT

The shoulder-joint (figs. 522 to 527) is a ball-and-socket joint. The bones entering into its formation are the hemispherical head of the humerus and the shallow glenoid cavity of the scapula, a construction which permits of very considerable movement but seriously affects the stability of the joint. Structurally the shoulder-joint is weak, since, for such strength as it possesses, it is dependent on the support given by the muscles which surround it and not on its bony conformation or the presence of any strong ligaments. It is, however, protected above by an arch, formed by the coracoid process, the acromion and the coraco-acromial ligament.

The *articular surfaces* are reciprocally curved, but as the head of the humerus is much larger than the glenoid cavity only a portion of it can be in contact with the cavity in any given position of the joint. The glenoid cavity is deepened somewhat by a fibrocartilaginous rim attached to its margins and termed the *glenoidal labrum*. Both articular surfaces are covered with a layer of hyaline cartilage ; that on the head of the humerus is thickest at its centre and thinner peripherally, while the reverse is the case in the glenoid cavity.

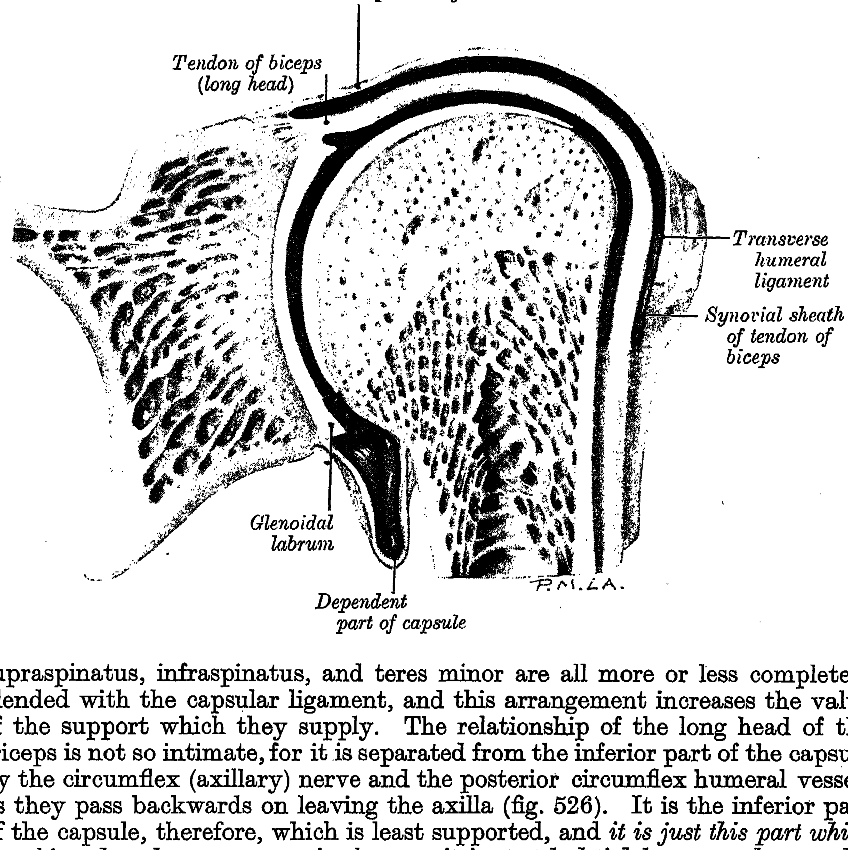
The ligaments of the articulation are :

Capsular.	The glenoidal labrum.
Coracohumeral.	Transverse humeral.

The **capsular ligament** (figs. 522, 523) envelops the joint, and is attached, medially, to the circumference of the glenoid cavity beyond the glenoidal

labrum ; above, it encroaches on to the root of the coracoid process so as to include the origin of the long head of the biceps within the joint. Laterally it is attached to the anatomical neck of the humerus, except on the medial side where it descends for rather more than 1 cm. on to the shaft of the bone. It is so remarkably loose and lax that the bones may be separated from each other for a distance of 2 or 3 cm., an evident provision for the great freedom of movement which is permitted at this articulation. *It should be noted, however, that this separation can be effected only after the superior part of the ligament has been relaxed by the movement of abduction.* The capsular ligament is strengthened, above, by the supraspinatus ; below, by the long head of the triceps ; behind, by the tendons of the infraspinatus and teres minor ; and in front, by the tendon of the subscapularis. The tendons of the subscapularis,

FIG. 523.—A section through the shoulder joint. The synovial membrane is shown in blue.



supraspinatus, infraspinatus, and teres minor are all more or less completely blended with the capsular ligament, and this arrangement increases the value of the support which they supply. The relationship of the long head of the triceps is not so intimate, for it is separated from the inferior part of the capsule by the circumflex (axillary) nerve and the posterior circumflex humeral vessels as they pass backwards on leaving the axilla (fig. 526). It is the inferior part of the capsule, therefore, which is least supported, and *it is just this part which is subjected to the greatest strain, because it is stretched tightly across the rounded head of the humerus when the arm is abducted.*

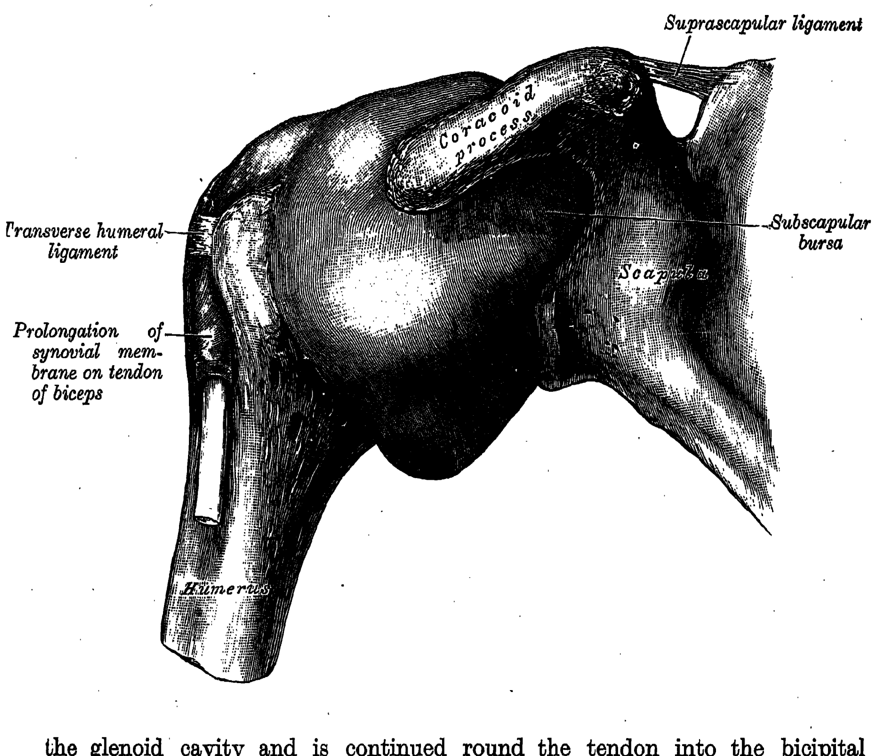
There are usually two, occasionally three, openings in the capsule. One, situated anteriorly, below the coracoid process, establishes a communication between the joint and a bursa behind the tendon of the subscapularis ; another, placed between the tuberosities of the humerus, gives passage to the long tendon of the biceps and its synovial sheath ; the third, which is not constant, is at the posterior part, between the joint and a bursal sac under the tendon of the infraspinatus.

Three supplemental bands (fig. 525), which are named the *glenohumeral ligaments,* strengthen the capsule. These are best seen by opening the posterior part of the capsule of the joint and removing the head of the humerus. At their scapular ends they are all attached to the upper part of the medial margin of the glenoid cavity and are intimately connected with the glenoidal labrum. The superior band passes along the medial edge

of the tendon of biceps and is attached to a small depression above the lesser tuberosity of the humerus; the middle band reaches to the lower part of the lesser tuberosity; the inferior band extends to the lower part of the anatomical neck of the humerus. In addition to these, the capsule is strengthened in front by two bands, one derived from the tendon of the pectoralis major, the other from the tendon of the teres major.

The *synovial membrane* is reflected from the margin of the glenoid cavity over the glenoidal labrum; it is then continued over the inner surface of the capsular ligament, and covers the lower part and sides of the anatomical neck of the humerus as far as the articular cartilage on the head of the bone. The tendon of the long head of the biceps passes through the joint and is enclosed in a tubular sheath of synovial membrane, which is reflected upon it from the summit of

FIG. 524.—The synovial cavity of the right shoulder-joint (distended). Anterior aspect. (From a specimen prepared by J. C. B. Grant.)



the glenoid cavity and is continued round the tendon into the bicipital groove (intertubercular sulcus) as far as the surgical neck of the humerus (figs. 523, 524).

The **coracohumeral ligament** (fig. 522) is a broad band which strengthens the upper part of the capsule. It is attached to the lateral border of the root of the coracoid process, and passes obliquely downwards and laterally to the front of the greater tuberosity of the humerus, blending with the tendon of the supraspinatus. The posterior and lower border of the ligament is united to the capsular ligament; its anterior and upper border is free, and overlaps the capsular ligament.

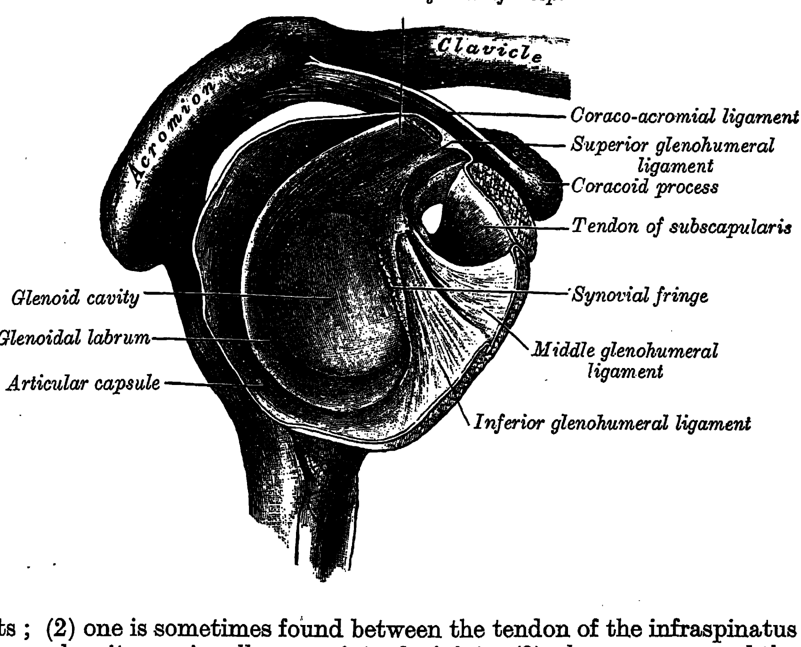
The **transverse humeral ligament** (fig. 524) is a broad band passing from the lesser to the greater tuberosity of the humerus; it converts the bicipital groove (intertubercular sulcus) into a canal, and its attachment is always limited to that portion of the bone which lies above the epiphyseal line. Although it is continuous above with the capsular ligament, the transverse humeral ligament functions simply as a retinaculum for the tendon of the long head of the biceps muscle and plays no other part in the movements of the joint.

The **glenoidal labrum** (figs. 525, 526) is a fibrocartilaginous rim attached round the margin of the glenoid cavity. It is triangular on section, the base

being fixed to the circumference of the cavity, while the free edge is thin and sharp. It is continuous above with the tendon of the long head of the biceps, which gives off two fasciculi to blend with the fibrous tissue of the labrum. It deepens the articular cavity, and protects the edges of the bone. Its attachment to the margin of the glenoid cavity is sometimes deficient in parts; the deficiency occurs most commonly at the notch on the upper part of the antero-medial margin, and a small fringe of the synovial membrane occasionally protrudes through the gap.

Bursæ.—The bursæ in the neighbourhood of the shoulder-joint are the following: (1) one is constantly found between the tendon of the subscapularis and the joint-capsule (fig. 526): it communicates with the joint cavity through an opening which is situated between the superior and the middle glenohumeral

Fig. 525.—Interior of shoulder-joint. Viewed from the lateral side.



ligaments; (2) one is sometimes found between the tendon of the infraspinatus and the capsule; it occasionally opens into the joint; (3) a large one, named the *subacromial bursa* (fig. 526), exists between the deltoid and the capsule; it does not communicate with the joint, but is prolonged under the acromion and coraco-acromial ligament, and intervenes between these structures and the supraspinatus, which covers the upper part of the capsule; (4) a large one is situated on the summit of the acromion; (5) one is frequently found between the coracoid process and the capsule; (6) one sometimes exists behind the coracobrachialis; (7) one lies between the teres major and the long head of the triceps; (8) one is placed in front of, and another behind, the tendon of the latissimus dorsi.

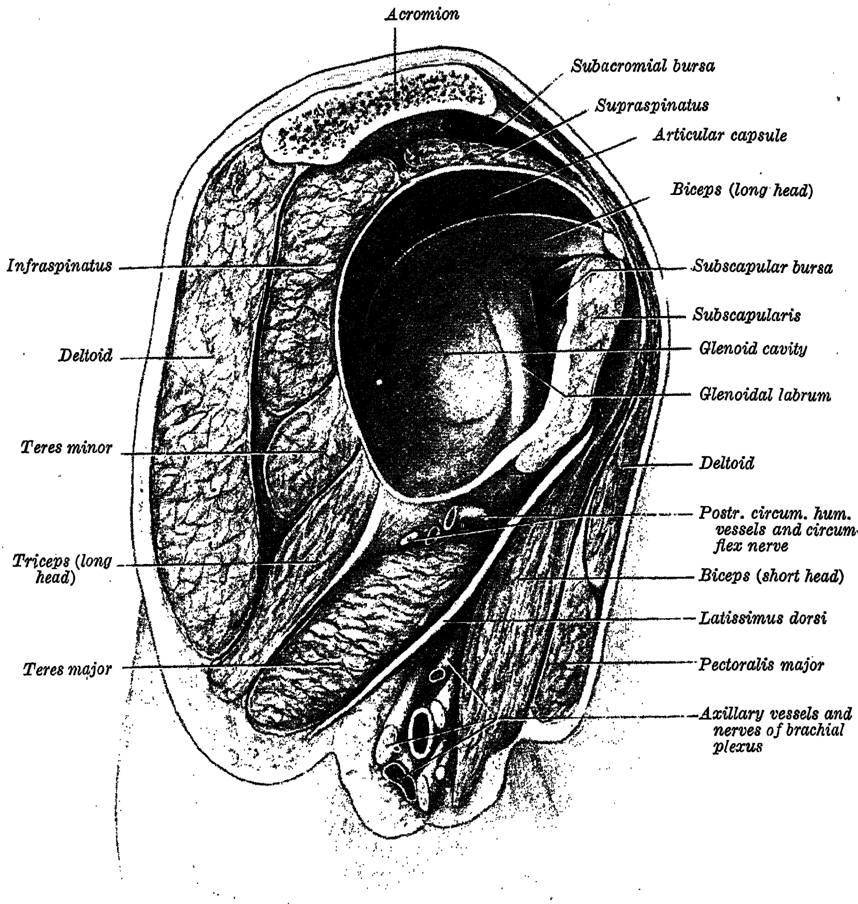
The *muscles* in relation with the joint are, above, the supraspinatus; below, the long head of the triceps; in front, the subscapularis; behind, the infraspinatus and teres minor; within, the tendon of the long head of the biceps. The deltoid covers the joint in front, behind and laterally (fig. 526).

The *arteries* supplying the joint are derived from the anterior and posterior circumflex humeral, and suprascapular (transverse scapular) arteries; the *nerves*, from the circumflex (axillary) and suprascapular nerves.

Movements.—The shoulder is a ball-and-socket joint, and therefore is capable of flexion, extension, abduction, adduction, circumduction and rotation. The laxity of its capsular ligament and the large size of the head of the humerus compared with that of the shallow glenoid cavity give to the shoulder a wider range of movement than is possible at any other joint.

When the movements at the shoulder-joint are being analysed, the humerus should be considered in its relationship to the scapula and not in its relationship to the sagittal and coronal planes of the trunk. When the arm is by the side in the resting position, the glenoid cavity faces almost equally forwards and laterally, and the position of the humerus corresponds to that of the scapula, although relative to the trunk it appears to be rotated medially (p. 346). As a result *flexion* carries the arm forwards and medially across the front of the chest, and the movement takes place around an axis which passes through the head of the humerus at right angles to the plane of the glenoid cavity at

FIG. 526.—Structures in relation with the shoulder-joint.

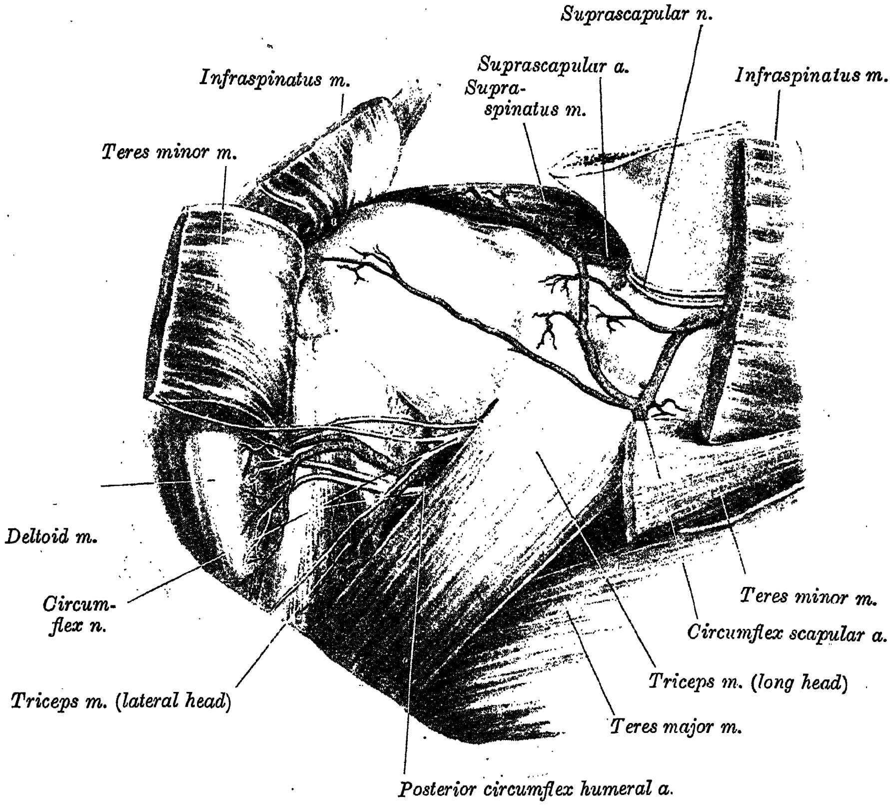


(approximately) its centre. *Abduction* and *adduction* occur in a plane at right angles to the plane of flexion and extension, and the axis passes through the head of the humerus parallel to the plane of the glenoid cavity.* Abduction therefore carries the arm forwards and laterally away from the trunk, and *the movement occurs in the plane of the body of the scapula.* At the shoulder-joint itself the movements of flexion and abduction are limited to approximately 90° ; when the arm is raised vertically above the head the additional (approximately) 90° are obtained by forward rotation of the scapula (p. 455). In flexion,

* Many writers prefer to consider flexion and extension as occurring in a paramedian plane, and abduction and adduction as occurring in a coronal plane, i.e. they prefer to regard the movements as being relative to the trunk and not to the scapula. *The reader is warned that, if he prefers to accept these definitions, he must regard the deltoid and supraspinatus muscles as producing a combination of flexion and abduction, for working as a combination they*

however, the humerus moves in a plane at right angles to the plane of the body of the scapula, and no amount of rotation of the scapula can increase the degree of elevation (90°) obtained in full flexion. If the fully flexed humerus is gradually abducted, the degree of elevation increases *pro rata*, until, when the humerus comes to lie in the plane of the body of the scapula, i.e. when the position of pure abduction is reached, the full 180° of elevation is obtained. In *rotation*, which may be medial or lateral, the humerus revolves for about one-quarter of a circle about its own long axis. The range of rotatory movement is greatest when the arm is by the side, and least when it is raised to the vertical. In *circumduction*, which results from a succession of the foregoing

FIG. 527.—The posterior aspect of the left shoulder-joint.



An oblique saw-cut has been made through the spine of the scapula and the acromion has been removed. Portions of the infraspinatus and teres minor muscles have been excised and their tendons have been turned forwards.

movements, the lower end of the humerus describes the base of a cone, the apex of which is at the head of the bone, but this movement at the shoulder-joint can be increased very substantially by the movements of the scapula, and the combination is well exemplified in the arm movements of a fast bowler in cricket.

do not raise the arm in a coronal plane. When the humerus is raised to the vertical from a position of flexion (in this sense), it undergoes a process of medial rotation, for which the deltoid (anterior fibres), the subscapularis and, probably, the supraspinatus are responsible. In the same way when the humerus is raised to the vertical from the position of abduction (in this sense), it undergoes a process of lateral rotation. In both cases the effect of the rotation is to bring the humerus into the same position relative to the scapula as it occupies when the arm is raised to the vertical in the plane of the body of the scapula, i.e. the movement described in the text as true abduction. When the arm is elevated in a natural way from the side, the humerus moves throughout in the plane of the body of the scapula and undergoes no appreciable rotation. (C. P. Martin, *British Journal of Surgery*, vol. xx. 1932, and T. B. Johnston, *British Journal of Surgery*, vol. xxv. 1937.)

When the arm is raised above the head, the movement of the humerus and the movements of the scapula and clavicle (p. 454) are combined and occur simultaneously, so that while the humerus is being raised relative to the scapula, the scapula itself is being rotated in a forward direction.*

The peculiar relation of the tendon of the long head of the biceps to the shoulder-joint appears to subserve various purposes. By its connexion with both the shoulder and elbow the muscle harmonises the action of the two joints, and acts as an elastic ligament during all the movements which occur at these articulations. It strengthens the upper part of the shoulder-joint, and prevents the head of the humerus from being pressed up against the acromion when the deltoid contracts; it thus fixes the head of the humerus as the centre of motion in the glenoid cavity. By its passage along the bicipital groove (intertubercular sulcus) it assists in steadying the head of the humerus in the various movements of the arm.

Owing to the shallowness of the glenoid cavity and the laxity of the capsule, a wide range of *accessory movements* (p. 431) is possible at the shoulder-joint. The head of the humerus can be moved backwards, forwards, upwards and downwards in relation to the glenoid cavity and, when the arm is abducted—the position in which the accessory movements are most free—it can be separated from it by traction.

Muscles producing the movements.—The muscles moving the shoulder may be divided into: (*a*) those acting on the shoulder-girdle and (*b*) those acting on the shoulder-joint.

(*a*) **Muscles acting on the shoulder-girdle.**—These muscles have already been considered in connexion with the movements of the shoulder-girdle (p. 455).

(*b*) **Muscles acting on the shoulder-joint.**

In **flexion**, the *pectoralis major* (*clavicular head*) (p. 586), the *deltoid* (*anterior fibres*) and the *coracobrachialis* are the principal muscles concerned, but they are assisted by the biceps and the subscapularis, and the *sternocostal head of the pectoralis major* plays an important part when the arm is drawn forwards to the plane of the trunk from the fully extended position.

In **extension**, the *deltoid* (*posterior fibres*) and the *teres major* are the principal muscles concerned when the movement starts with the arm by the side, but, when the fully flexed arm is extended against resistance, the *latissimus dorsi*, the infraspinatus, the teres minor, the long head of triceps, and the *sternocostal head of the pectoralis major* are powerful adjuvants until the arm reaches the plane of the body.

In **abduction**, the movement is probably initiated by the *supraspinatus* and is then carried on by the *deltoid*, which is capable of maintaining the position of abduction against very great resistance.

In **adduction** the *pectoralis major* and the *latissimus dorsi* are the principal muscles concerned, but the *teres major*, the *coracobrachialis* and, to a lesser extent, the subscapularis, the infraspinatus, the teres minor, the biceps and the triceps (long head) all participate.

Medial rotation is brought about by the *pectoralis major*, the *deltoid* (*anterior fibres*), the *latissimus dorsi*, the *teres major* and the *subscapularis*.

Lateral rotation is brought about by the *infraspinatus*, the *teres minor* and the *deltoid* (*posterior fibres*).

Applied Anatomy.—Owing to the construction of the shoulder-joint and the wide range of movement which it enjoys, as well as in consequence of its exposed situation, it is more frequently dislocated than any other joint. Dislocation occurs when the arm is abducted. In that position the head of the humerus presses against the lower and front part of the capsule, which is the thinnest and least supported part of the ligament. The rent in the capsule almost invariably takes place in this situation, and through it the head of the bone escapes, so that the dislocation in most instances is primarily subglenoid. If, after the dislocation has been reduced, abduction of the arm is prevented, the dislocation cannot recur.

* C. W. Cathcart, *Journal of Anatomy and Physiology*, vol. xviii., and R. D. Lockhart, *Journal of Anatomy*, vol. lxiv.

When the shoulder-joint is ankylosed, the loss of movement in the joint is partly compensated for by increased mobility of the scapula. In treating conditions of the shoulder-joint likely to lead to ankylosis, the humerus should be kept in the position it assumes when the palm of the hand is placed on the back of the neck, i.e. abducted, and slightly rotated laterally so as to make full use of this compensating mobility of the scapula.

IV. THE ELBOW-JOINT

The elbow-joint includes two articulations: (1) *humero-ulnar*, between the trochlea of the humerus and the trochlear notch (semilunar notch) of the ulna, and (2) *humeroradial*, between the capitulum of the humerus and the facet on the head of the radius. The joint-cavity and the articular capsule of the elbow-joint are continuous with the corresponding parts of the superior radio-ulnar joint, and these articulations are sometimes grouped together as the *cubital articulation*.

The *articular surfaces* concerned are the trochlea and capitulum of the humerus, on the one hand, and the trochlear notch of the ulna and the head of the radius, on the other. The trochlea is not a simple pulley, for its medial flange is much more extensive than its lateral flange and projects downwards to a lower level, so that the transverse axis of the joint, which lies below the level of the epicondyles, passes from the lateral side downwards and medially. In addition, the trochlea is widest where it covers the posterior aspect of the bone and in this position its lateral edge forms a salient ridge. The trochlear notch is by no means perfectly congruent with the trochlea. In full extension the medial part of its upper (olecranon) half is not in contact with the trochlea, and a corresponding strip on the lateral side loses contact on flexion. The olecranon and coronoid parts of the trochlear notch are usually separated by a narrow, roughened strip of bone, devoid of articular cartilage and covered with a little fibro-fatty tissue lined with synovial membrane. The capitulum and the head of the radius are reciprocally curved, but the best contact is obtained when the semiflexed radius is in the midprone position. The rim of the head fits into the groove between the capitulum and the trochlea.

The humero-ulnar and humeroradial articulations together form a ginglymus or hinge-joint, the ligaments of which are:

Capsular.	Anterior.	Medial.
	Posterior.	Lateral.

The **capsular ligament** (figs. 530 to 532).—The anterior part of the capsular ligament is a broad and thin fibrous layer, and constitutes the **anterior ligament** of the elbow-joint. It is attached, above, to the front of the medial epicondyle and to the front of the humerus immediately above the coronoid and radial fossæ; below, to the anterior surface of the coronoid process of the ulna and to the annular ligament (p. 468), being continuous at the sides with the medial and lateral ligaments. Its superficial fibres pass obliquely from the medial epicondyle of the humerus to the annular ligament. The middle fibres, vertical in direction, pass from the upper part of the coronoid depression and become partly blended with the preceding, but are inserted mainly into the anterior surface of the coronoid process. The deep or transverse set intersects these at right angles. Anteriorly the ligament is in relation with the brachialis and receives numerous fibres from its deep surface.

The posterior part of the capsular ligament is thin and membranous, and consists of transverse and oblique fibres, which constitute the **posterior ligament** of the elbow-joint. Above, it is attached to the humerus immediately behind the capitulum and close to the medial margin of the trochlea, to the margins of the olecranon fossa, and to the back of the lateral epicondyle some little distance from the trochlea. Below, it is fixed to the upper and lateral margins of the olecranon, to the posterior part of the annular ligament, and to the ulna behind the radial notch. It is in relation, behind, with the tendon of the triceps and the anconeus muscle.

The *synovial membrane* (figs. 528 to 530) is very extensive. It extends from the margin of the articular surface of the humerus, and lines the coronoid, radial and olecranon fossæ on that bone and covers the flattened medial surface of the trochlea (fig. 407); it is reflected over the deep surface of the capsular ligament and lines the deep surface of the annular ligament. Projecting into the joint-cavity between the radius and ulna from behind there is a crescentic fold of the synovial membrane, suggesting the division of the joint into two:

Fig. 528.—The synovial cavity of the left elbow-joint (distended). Anterior aspect. (From a specimen prepared by J. C. B. Grant.)

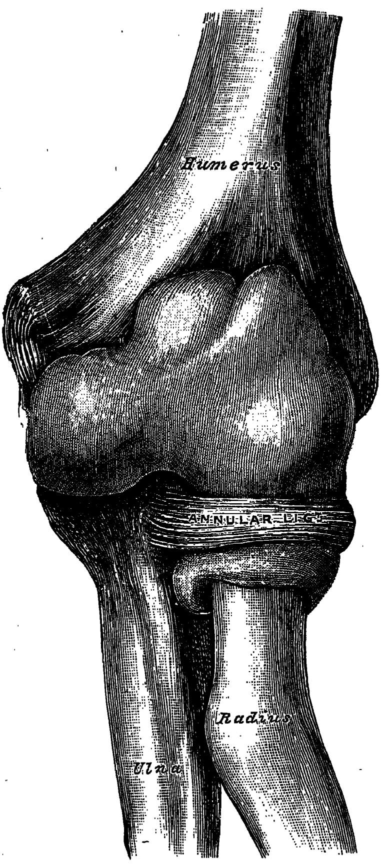


Fig. 529.—The synovial cavity of the left elbow-joint (distended). Posterior aspect of the specimen represented in fig. 528.

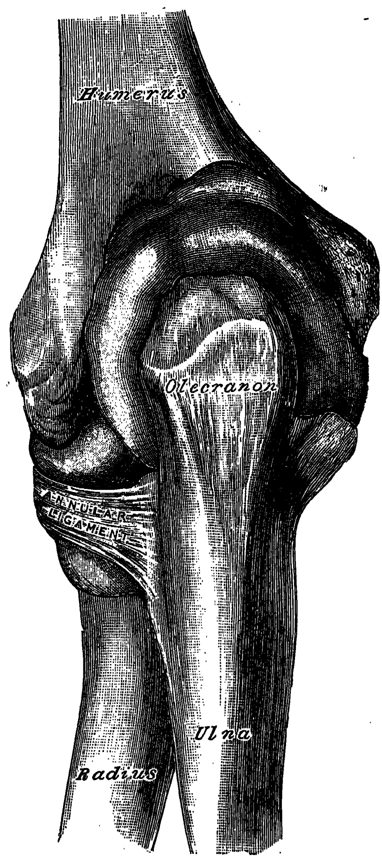


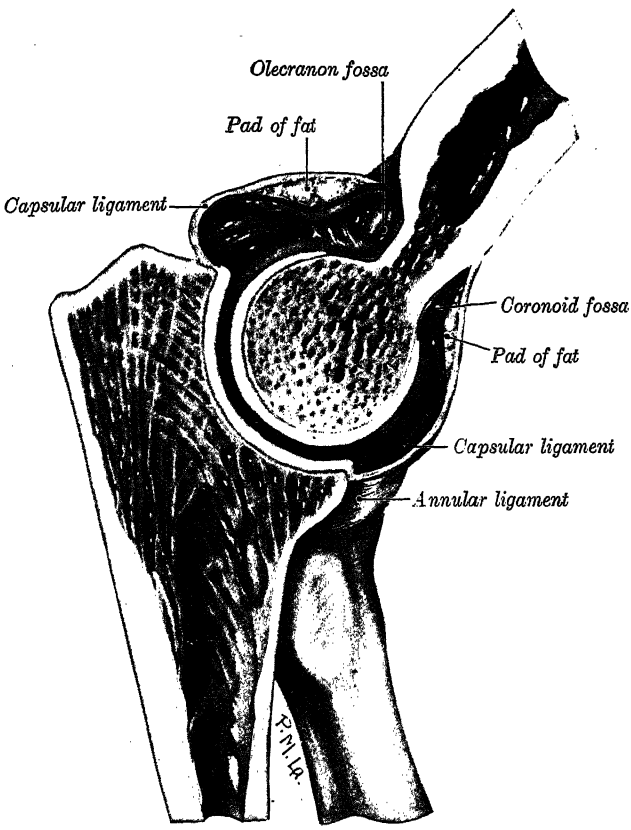
one the humeroradial, the other the humero-ulnar. This fold is irregularly triangular in outline and contains a variable quantity of extrasynovial fat.

Between the capsular ligament and the synovial membrane there are three other pads of fat. The largest, over the olecranon fossa, is pressed into the fossa by the triceps during flexion of the joint; the second, over the coronoid fossa, and the third, over the radial fossa, are pressed by the brachialis into their respective fossæ during extension. In addition, smaller tags of fat covered with synovial membrane project into the joint-cavity opposite to the constrictions on each side of the trochlear notch (p. 355), and cover the small non-articular areas of the bone in these situations.

The **medial ligament of the elbow-joint (ulnar collateral ligament)** (fig. 531) is a thick triangular band consisting of two portions, an anterior and a posterior, united by a thinner intermediate portion. The *anterior portion* is attached above, by its apex, to the front part of the medial epicondyle of the humerus; and below, by its broad base, to a tubercle on the upper part of the medial margin of the coronoid process. The *posterior portion*, also of triangular form,

is attached, above, to the lower and back part of the medial epicondyle; below, to the medial margin of the olecranon. Between these two bands a few intermediate fibres descend from the medial epicondyle to an *oblique head*—often feebly developed—which stretches between the olecranon and coronoid processes. This band converts the depression on the medial margin of the trochlear (semilunar) notch into a foramen, through which the intracapsular pad of fat is continuous with the extracapsular fat on the medial side of the joint. The medial ligament is in relation with the triceps and flexor carpi

FIG. 530.—A sagittal section through the left elbow-joint. The synovial membrane is shown in *blue*.



ulnaris *and the ulnar nerve*. Along its anterior portion the origin of the flexor digitorum sublimis extends from the medial epicondyle of the humerus downwards and laterally to the medial border of the coronoid process of the ulna.

The lateral ligament of the elbow-joint (radial collateral ligament) (fig. 532) is attached, above, to the lower part of the lateral epicondyle of the humerus, and below to the annular ligament, some of its most posterior fibres passing over that ligament to be inserted into the lateral margin of the ulna. It is intimately blended with the origins of the supinator and the extensor carpi radialis brevis.

The *muscles* in relation with the joint are, in front, the brachialis; behind, the triceps and anconeus; laterally, the supinator, and the common tendon of origin of the extensor muscles; medially, the common tendon of origin of the flexor muscles, and the flexor carpi ulnaris.

The *arteries* of supply are derived from the anastomotic network around the joint (p. 748).

The *nerves* of the joint consist of a twig from the ulnar nerve; one from the branch of the musculocutaneous nerve to the brachialis; one from the radial nerve; and two from the median nerve.

Fig. 531.—The left elbow-joint. Viewed from the medial side.

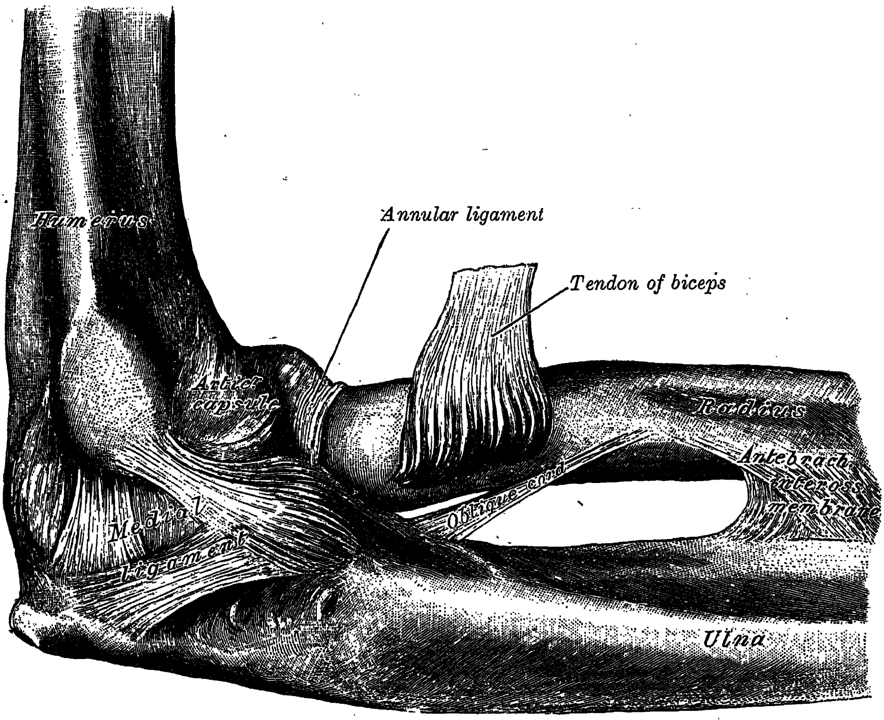


Fig. 532.—The left elbow-joint. Viewed from the lateral side.

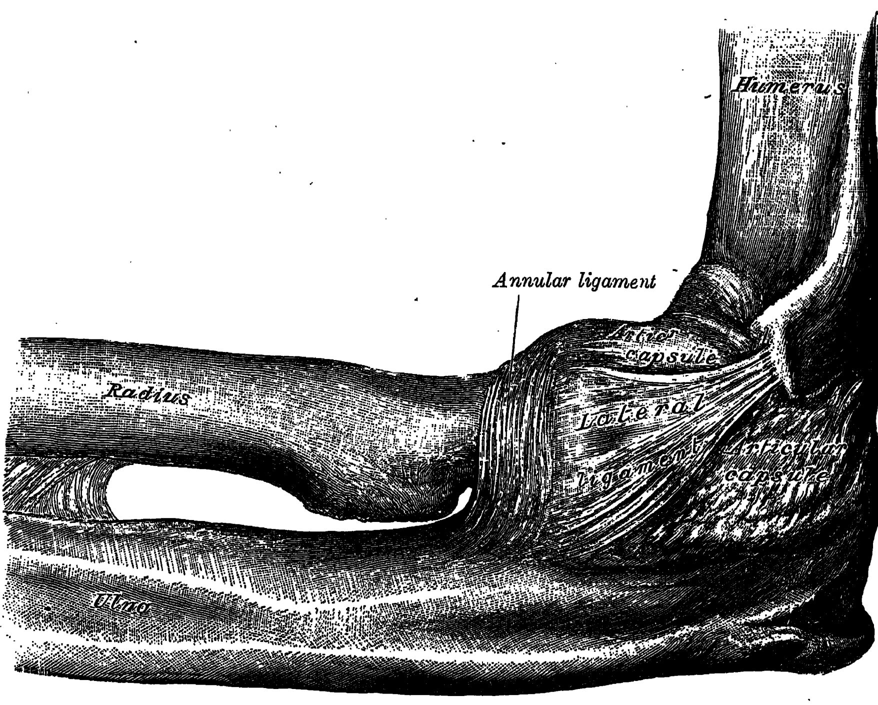
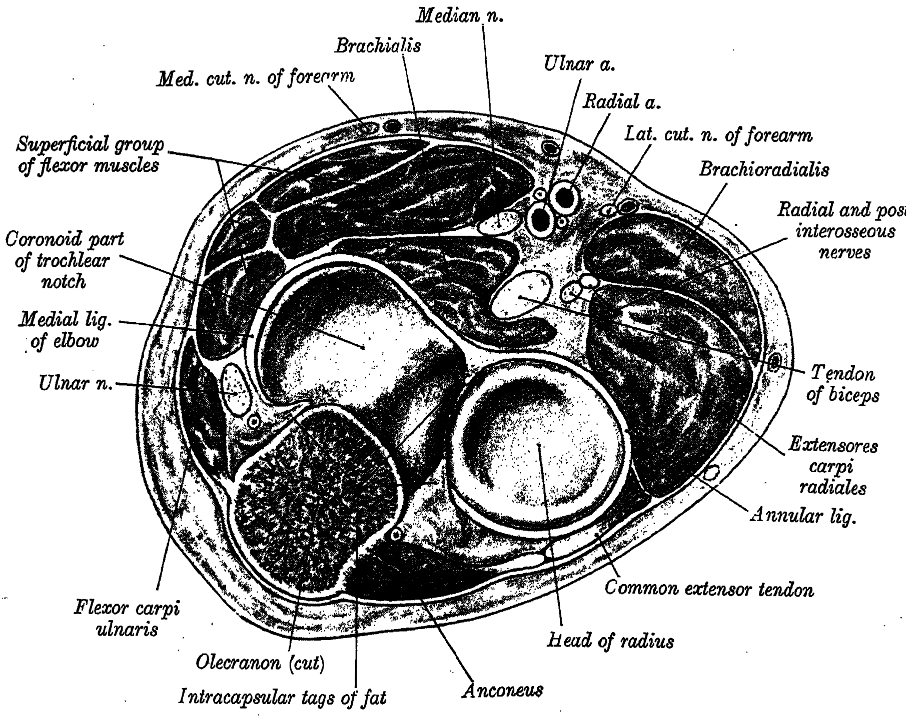


Movements.—The elbow is a hinge-joint and therefore its movements consist of flexion and extension, the ulna moving on the trochlea, and the head of the radius on the capitulum of the humerus ; as the part of the capitulum which covers the inferior surface of the lower end of the humerus is smaller than the head of the radius, the posterior edge of the head of the radius can be felt projecting at the back of the joint when the forearm is fully extended. The movement of extension is limited by the tension of the ligaments and muscles on the front of the joint ; that of flexion chiefly by the tension of the structures on the back of the joint.

When the forearm is fully extended and the hand supinated, the upper arm and forearm are not in the same line ; the forearm is directed somewhat laterally, and forms with the upper arm an angle of about 167° in the female and 173° in the male. This 'carrying angle' is caused partly by the medial edge

FIG. 533.—Transverse section of the right elbow-joint, viewed from above, to show the relations of the joint.



of the trochlea of the humerus, which projects about 6 mm. below the lateral edge,* and partly by the obliquity of the superior articular surface of the coronoid process, which is not set at right angles to the shaft of the ulna. The angles which the articular surfaces of the humerus and the ulna make with the long axes of the bones are approximately equal, and as a result the carrying angle disappears on full flexion of the forearm and the two bones come to lie in the same plane. When this movement is carried out with the arm by the side, the ulnar border of the little finger lies over the clavicle on account of the position of the resting humerus (p. 346). If the humerus is rotated laterally during the movement, the hand is carried upwards in front of the shoulder. The carrying angle is masked also in pronation of the extended forearm, and this has the effect of bringing the upper arm, the semipronated forearm and the hand into the same straight line. This arrangement increases the precision with which the hand, and any instrument or weapon held in the hand, can be controlled in full extension of the elbow or while the elbow is being extended.

* Consult articles by H. Percy Potter (*Journal of Anatomy and Physiology*, vol. xix. p. 488), and A. Ralph Thompson (*Journal of Anatomy*, vol. lviii. p. 368).

The *accessory movements* of the elbow joint are very limited in range and are restricted to abduction and adduction of the ulna, and forward and backward movement of the head of the radius on the capitulum of the humerus. In the latter movement, the head of the radius is moved on the radial notch of the ulna also, the annular ligament being slewed backwards and forwards at the same time. The extent of this movement is greatest when the elbow-joint is half-flexed.

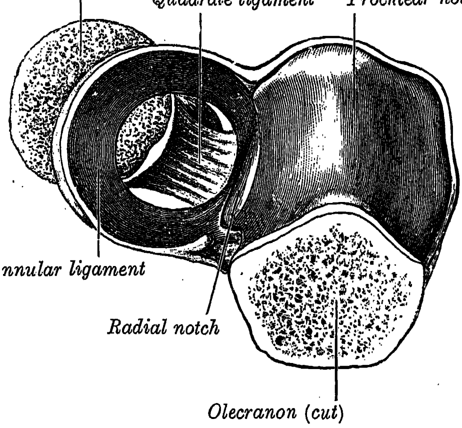
V. THE RADIO-ULNAR JOINTS

The radius and the ulna are connected at their upper and lower extremities by synovial joints, termed the superior and inferior radio-ulnar joints. In addition, the shafts of the bones are connected by an interosseous membrane and a ligament, which together constitute a middle radio-ulnar union.

1. The Superior Radio-ulnar Joint

This articulation forms a pivot-joint between the circumference of the head of the radius and the osseofibrous ring formed by the radial notch of the ulna and the annular ligament.

Fig. 534.—The annular ligament of the left radius. Superior aspect. The head of the radius has been sawn off and the bone dislodged from the ligament.



The **annular ligament** (figs. 532, 533, 534) is a strong band which encircles the head of the radius, and retains it in contact with the radial notch of the ulna. It forms about four-fifths of the osseofibrous ring and is attached to the anterior and posterior margins of the radial notch ; a few of its lower fibres are continued round below the notch and form at this level a complete fibrous ring. Its upper border blends with the lateral, anterior and posterior ligaments of the elbow-joint, while from its lower border a thin loose membrane passes to be attached to the neck of the radius. A few fibres extend from the inferior border of the radial notch to the neck of the radius, covering the synovial membrane which closes the distal aspect of the joint. They constitute the *quadrate ligament*. The *superficial surface* of the annular ligament is strengthened by the lateral ligament of the elbow, and affords origin to part of the supinator. It is related posteriorly to the anconeus and the posterior interosseous recurrent artery. On its *inner surface* the annular ligament is provided with a thin coating of cartilage where it comes into contact with the circumference of the head of the radius ; its lower part is lined with synovial membrane which is reflected upwards on to the neck of the bone.

2. The Middle Radio-ulnar Union

The shafts of the radius and ulna are connected by the oblique cord and the interosseous membrane of the forearm.

The **oblique cord** (fig. 531) is a small, flattened band, extending from the lateral side of the tuberosity of the ulna to the radius a little below the radial tuberosity. Its fibres run at right angles to those of the interosseous membrane. It is sometimes wanting.

The **interosseous membrane of the forearm** is a broad and thin sheet, the fibres of which slant obliquely downwards and medially from the interosseous border of the radius to that of the ulna; the lower part of the membrane is attached to the posterior of the two lines into which the interosseous border of the radius divides. Two or three bands are occasionally found on the posterior surface of this membrane; their fibres descend obliquely from the ulna towards the radius, i.e. at right angles to the other fibres. The membrane is deficient above, commencing about 2 or 3 cm. below the tuberosity of the radius; is broader in the middle than at either end; and presents an oval aperture a little above its lower margin, for the passage of the anterior interosseous vessels to the back of the forearm. Between its upper border and the oblique cord there is a gap, through which the posterior interosseous vessels pass. The membrane connects the bones, and increases the extent of surface for the attachment of the deep muscles of the forearm. It also transmits to the ulna and thence to the humerus any force acting upwards through the hand and radius. It is relaxed in complete pronation or supination, and is tense when the hand is midway between the prone and supine positions. *In front* the membrane is in relation, in its upper three-fourths, with the flexor pollicis longus on the radial side, with the flexor digitorum profundus on the ulnar side and between these muscles with the anterior interosseous vessels and nerve; in its lower one-fourth with the pronator quadratus; *behind*, with the supinator, abductor pollicis longus, extensor pollicis brevis, extensor pollicis longus, extensor indicis; and, near the wrist, with the anterior interosseous artery and posterior interosseous nerve.

3. The Inferior Radio-ulnar Joint

This is a pivot-joint formed between the head of the ulna and the ulnar notch of the lower end of the radius; the surfaces are enclosed in a capsular ligament and held together by an articular disc.

The capsular ligament is slightly thickened in front and behind; above it is lax, and, lined with the synovial membrane, projects upwards as a pouch (*recessus sacciformis*) in front of the lower part of the interosseous membrane.

The **articular disc** (fig. 537), triangular in shape, binds the lower ends of the ulna and radius together. Its periphery is thicker than its centre, which is occasionally perforated. It is attached by its apex to a depression between the styloid process and the inferior surface of the head of the ulna; and by its base, which is thin, to the prominent edge which separates the ulnar notch from the carpal articular surface of the radius. Its margins are united to the ligaments of the wrist-joint. Its *upper surface*, smooth and concave, articulates with the head of the ulna. Its *lower surface*, also smooth and concave, forms a part of the radiocarpal joint and articulates with the medial part of the lunate bone; when the hand is adducted, it articulates with the triquetral bone. Each of its surfaces is clothed with synovial membrane: the upper, with that of the inferior radio-ulnar articulation; the lower, with that of the radiocarpal joint.

Movements.—The movements which take place at the radio-ulnar joints result in pronation and supination of the hand. In *pronation* the radius, carrying the hand with it, is carried obliquely across the front of the ulna, its upper end being lateral, and its lower end medial, to that bone. If the forearm is semiflexed when this movement occurs, the palm of the hand faces downwards and slightly medially; if the forearm is extended, the palm faces backwards and slightly medially. In *supination* the movement is reversed, the radius lies lateral to and parallel with the ulna, and the palm faces upwards—forwards if

the forearm is extended. When the humerus is fixed and the movement is limited to the radio-ulnar joints, the hand can be turned through an angle of 160°-170°, but under normal conditions the range of the movement is very greatly increased by rotation of the humerus. The power of supination is greater than that of pronation, and thus all screw-driving instruments are made to be used in this movement.

The axis on which these movements take place is represented by a line drawn through the centre of the head of the radius above, and through the ulnar attachment of the articular disc below. The head of the radius rotates within the ring formed by the annular ligament and the radial notch of the ulna, while the lower end and the articular disc revolve on the head of the ulna. The lower end of the ulna is not stationary during these movements. It moves backwards and laterally during pronation, and forwards and medially during supination, but the range of the movement is very small and is due to the incongruence of the trochlea and trochlear notch, already noted (p. 463). It does not involve any true rotation of the ulna.

Accessory movements.—In addition to the backward and forward movement of the head of the radius on the radial notch of the ulna (p. 468), the head of the ulna can be moved backwards and forwards on the ulnar notch of the radius.

Muscles producing the movements.—These muscles may be grouped as (*a*) those acting on the elbow-joint, and (*b*) those acting on the radio-ulnar joints.

(*a*) **Muscles acting on the elbow-joint :**

In **flexion**, the *brachialis, biceps* and *brachioradialis* are the prime movers, but, owing to the position of its attachments, the brachioradialis acts to best advantage when the forearm is in the midprone position. When resistance is encountered additional help is given by the *pronator teres* and the radial extensors of the wrist.

Extension is performed by the *triceps* and *anconeus.*

(*b*) **Muscles acting on the radio-ulnar joints:**

In **pronation**, the *pronator teres* and *pronator quadratus* are the prime movers, but, in order to overcome resistance, the palmaris longus and the flexor carpi radialis may be called into play, and the brachioradialis is capable of assisting from the position of full supination to the midprone position.

In **supination**, the *supinator* is the principal agent, but *biceps* is a powerful factor when the elbow is flexed, and the brachioradialis, from the fully prone to the midprone position, and the extensors of the thumb are capable of participating in the movement.

Applied Anatomy.—Dislocations backwards and abduction dislocations are the commonest forms of dislocation at the elbow-joint. Owing to the shapes of the bones, dislocation backwards is often complicated by fracture of the coronoid process; and, owing to the strength of the collateral ligaments, the medial epicondyle is frequently torn away in abduction dislocations. Dislocation of the elbow-joint is common in children. In lesions of this joint it is often difficult to ascertain the exact nature of the injury except by *x*-ray examination.

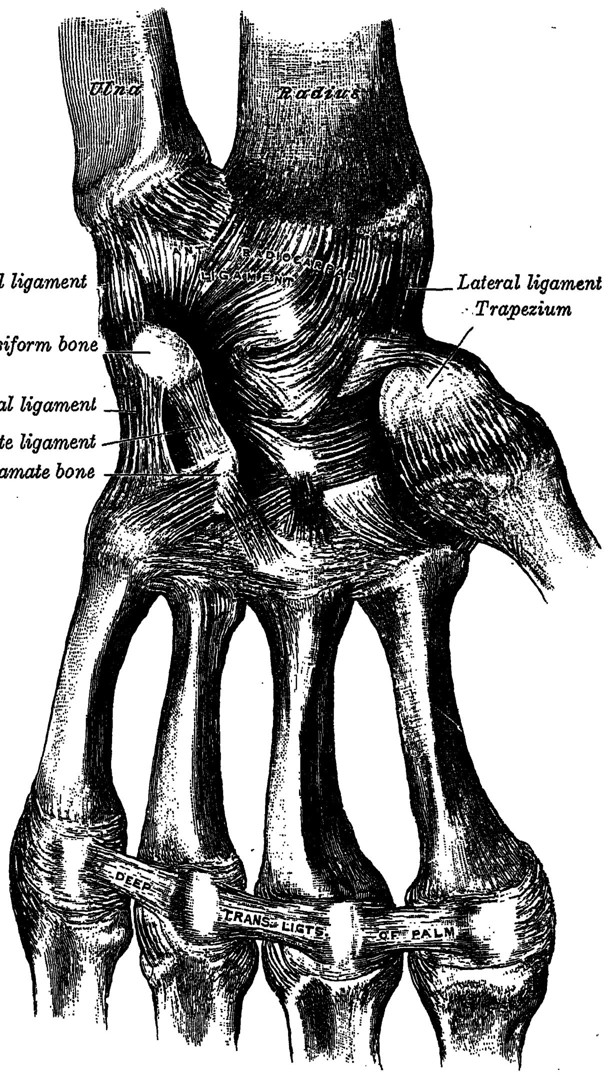
The elbow-joint is occasionally the seat of acute synovitis. The joint-cavity then becomes distended with fluid, the bulging showing itself principally around the olecranon, in consequence of the laxness of the articular capsule. Again, there is often some swelling, just above the head of the radius, in the line of the humeroradial joint, or the whole elbow may assume a fusiform appearance.

Dislocation of the head of the radius alone is a not uncommon accident, and occurs most frequently in young persons from falls on the hand when the forearm is extended and supinated, the head of the bone being displaced forward. It is attended by rupture of the annular ligament. Occasionally a peculiar injury, which is supposed to be a subluxation, occurs in young children. It is believed that the head of the radius is displaced downwards in the annular ligament, the upper border of which becomes folded over the head of the radius, between it and the capitulum of the humerus; the small size of the head of the radius in the child predisposes to this injury. The forearm becomes fixed in a position of semiflexion, midway between supination and pronation, and great pain is complained of when any attempt is made to move the joint.

VI. THE RADIOCARPAL OR WRIST-JOINT

The radiocarpal or wrist-joint (figs. 535-537) is a condyloid joint. The parts forming it are the distal end of the radius and lower surface of the articular disc, above; and the scaphoid, lunate, and triquetral bones, below. The *articular surface* of the radius and the lower surface of the articular disc form

FIG. 535.—The ligaments of the left wrist and metacarpus. Palmar aspect.



together a transversely elliptical, concave surface—the *receiving cavity*. The proximal articular surfaces of the scaphoid, lunate, and triquetral bones form a smooth convex surface, which is received into the concavity. The joint is surrounded by an articular capsule. The *synovial membrane* is usually distinct from that of the inferior radio-ulnar joint and from that of the carpal joints; the *capsular ligament* is strengthened by the following ligaments:

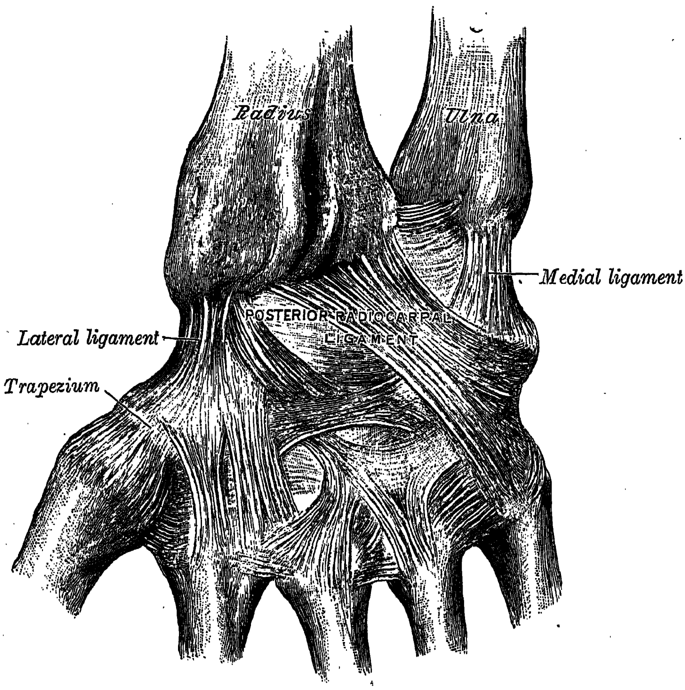
Anterior and posterior radiocarpal. Medial and lateral.

The **anterior radiocarpal ligament** (fig. 535) is a broad membranous band, attached above to the anterior margin of the lower end of the radius, to its styloid process, and to the front of the lower end of the ulna; its fibres pass

downwards and medially to be attached to the anterior surfaces of the scaphoid, lunate, and triquetral bones, some being continued to the capitate bone. In addition to this broad membrane, there is a rounded fasciculus, superficial to the rest, which reaches from the base of the styloid process of the ulna to the lunate and triquetral bones. The ligament is perforated by apertures for the passage of vessels, and is in relation, in front, with the tendons of the flexor digitorum profundus and flexor pollicis longus ; behind, it is closely adherent to the anterior border of the articular disc of the inferior radio-ulnar articulation.

The **posterior radiocarpal ligament** (fig. 536), thinner and weaker than the anterior, is attached, above, to the posterior border of the distal end of the radius ; its fibres are directed obliquely downwards and medially, and are fixed,

FIG. 536.—The ligaments of the left wrist. Posterior aspect.



below, to the posterior surfaces of the scaphoid, lunate, and triquetral bones, being continuous with those of the dorsal intercarpal ligaments. It is in relation, behind, with the extensor tendons of the wrist and fingers, their synovial sheaths and the posterior interosseous nerve ; in front, it is blended with the articular disc of the inferior radio-ulnar articulation.

The **medial (ulnar collateral) ligament** of the wrist-joint (figs. 535, 536) is attached to the end of the styloid process of the ulna ; it divides into two fasciculi, one of which is fixed to the medial side of the triquetral bone, the other to the pisiform bone.

The **lateral (radial collateral) ligament** of the wrist-joint (figs. 535, 536) extends from the tip of the styloid process of the radius to the radial side of the scaphoid bone, some of its fibres being prolonged to the trapezium (greater multangular bone). It is in relation with the radial artery, which separates the ligament from the tendons of the abductor pollicis longus and extensor pollicis brevis.

The *arteries* supplying the joint are the anterior interosseous, the anterior and posterior carpal branches of the radial and ulnar, the palmar and dorsal metacarpals, and some recurrent branches from the deep palmar arch. The *nerves* are derived from the anterior and posterior interosseous nerves.

Movements.—The active movements which can be carried out at this joint are flexion, extension, abduction, adduction, and circumduction. Flexion and extension are the most free, and of these a greater amount of extension than of

flexion is permitted, and in consequence the articulating surfaces extend farther on the posterior than on the anterior surfaces of the carpal bones. In this movement the carpal bones rotate on a transverse axis drawn between the tips of the styloid processes of the radius and ulna. The movements of flexion and extension are limited chiefly by the tension of the antagonistic muscles, and it is only when the joint is subjected to violent movement that the anterior or posterior ligament is fully stretched. In this connexion it should be noted that the range of flexion is perceptibly diminished when the fingers are flexed, owing to increased tension of the extensor muscles. Adduction or ulnar deviation, and abduction or radial deviation are also permitted. The former is considerably greater in extent than the latter, and this fact may be associated with the shortness of the styloid process of the ulna. The movements are limited by the tension of the antagonistic muscles, and in addition by the lateral and medial ligaments of the joint respectively. In this movement the carpus revolves upon an anteroposterior axis drawn through the centre of the wrist. Finally, circumduction is permitted by the combined and consecutive movements of adduction, extension, abduction and flexion. The effect of rotation is obtained by the pronation and supination of the radius on the ulna.

The *accessory movements* which can be carried out at the wrist-joint are relatively free and are more so in flexion than in extension. The carpus can be moved bodily backwards and forwards on the radius and ulna, and it can be rotated to a considerable extent. A little side to side movement can also be obtained.

Muscles producing the movements :

In **flexion,** the *flexor carpi radialis, flexor carpi ulnaris* and *palmaris longus* are the principal agents, but the flexores digitorum sublimis et profundus and the flexor pollicis longus are capable of giving assistance.

In **extension,** the *extensores carpi radialis longus et brevis,* and *extensor carpi ulnaris* are the chief muscles concerned, but the extensors of the fingers and thumb are all capable of helping.

In **adduction,** the *flexor carpi ulnaris* acts in association with the *extensor carpi ulnaris,* and in **abduction** the *flexor carpi radialis* acts in association with the *extensores carpi radialis longus et brevis,* the abductor pollicis longus and the extensor pollicis brevis. As a result of these combinations the movements can be carried out without the simultaneous occurrence of flexion or extension.

VII. THE INTERCARPAL JOINTS

The intercarpal joints connect the carpal bones to one another and may be subdivided into: (1) joints between the bones of the proximal row of the carpus; (2) joints between the bones of the distal row; and (3) a somewhat complicated and extensive joint between the two rows. Only a very slight degree of gliding movement is allowed between contiguous bones in the same row, and these joints are all of the plane variety, but a somewhat wider range of movement is allowed at the joint between the two rows, which, in its medial part at least, approaches nearer to the condyloid variety than to the plane variety of joint.

1. The Joints of the Proximal Row of Carpal Bones

The scaphoid, lunate and triquetral bones are connected by dorsal, palmar and interosseous ligaments.

The **dorsal and palmar ligaments** are placed transversely between the bones of the first row; they connect the scaphoid bone to the lunate and the lunate bone to the triquetral. The palmar ligaments are weaker than the dorsal.

The **interosseous ligaments** (fig. 537) are two narrow bundles, one connecting the lunate and scaphoid bones, the other the lunate and triquetral bones. They are on a level with the proximal surfaces of these bones, and form part of the convex articular surface of the radiocarpal joint.

The pisiform bone articulates with the palmar surface of the triquetral bone, and the ligaments of the joint are: a capsular, a pisohamate and a pisometacarpal ligament.

The **capsular ligament** is thin, and surrounds the joint; *its synovial membrane is distinct from that of the other carpal joints.*

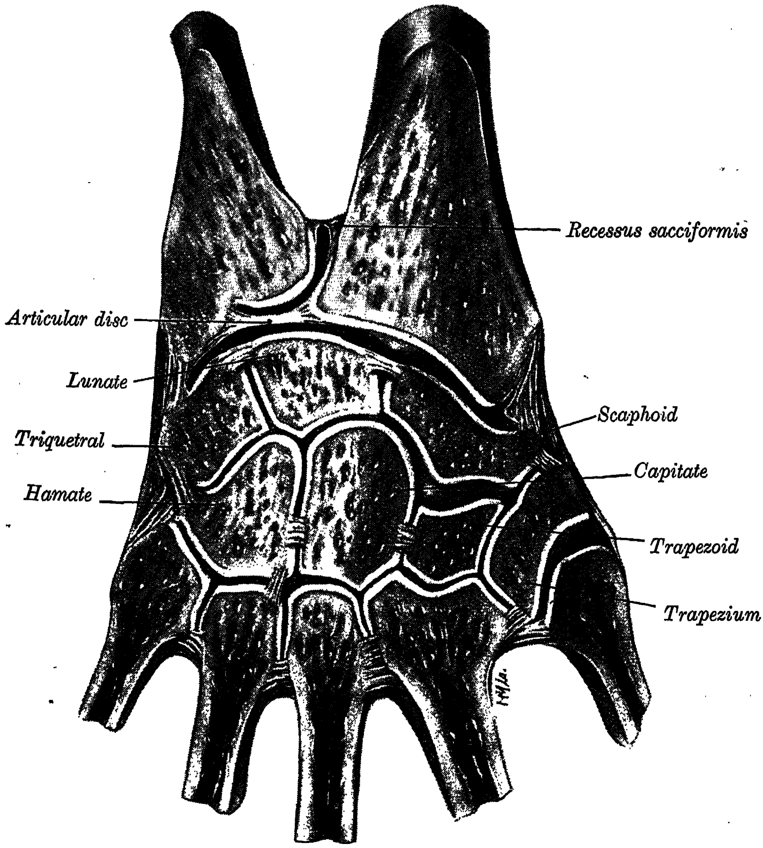
The **pisohamate ligament** connects the pisiform to the hook of the hamate bone, and the **pisometacarpal ligament** joins the pisiform to the base of the fifth metacarpal bone (fig. 535). Both ligaments are continuous with the tendon of insertion of the flexor carpi ulnaris.

2. The Joints of the Distal Row of Carpal Bones

The bones of the distal row of the carpus are connected by the dorsal, palmar and interosseous ligaments.

The **dorsal** and **palmar ligaments** extend transversely from one bone to

Fig. 537.—A coronal section through the joints at the right wrist, showing the synovial cavities.



another; one of each connects the trapezium and trapezoid (greater and lesser multangular) bones, a second the trapezoid bone and the capitate, and a third the capitate bone and the hamate.

The three **interosseous ligaments** are much thicker than those of the proximal row; one unites the capitate bone and the hamate, a second the capitate bone and the trapezoid, and a third the trapezium and trapezoid. The first is the strongest; the third is sometimes wanting.

3. The Joints of the Two Rows of Carpal Bones with each other

The joint between the scaphoid, lunate and triquetral bones on the one hand, and the second row of carpal bones on the other, is named the *mid-carpal joint,* and is made up of two portions: on the medial side the head of the capitate bone and the hamate bone articulate with the concavity formed by the scaphoid, lunate and triquetral bones, and constitute a modified condyloid

joint; on the lateral side the trapezium and trapezoid articulate with the scaphoid bone and constitute a modified plane joint.

The ligaments are: dorsal, palmar, medial and lateral.

The **dorsal and palmar ligaments** consist of short, irregular bundles passing between the bones of the first and second rows. On the palmar surface the fibres radiating from the head of the capitate bone to the surrounding bones are sometimes termed the *ligamentum carpi radiatum.*

The **lateral and medial ligaments** are very short: the one is placed on the radial, the other on the ulnar side of the carpus: the former, the stronger and more distinct, connects the scaphoid bone and the trapezium, the latter the triquetral bone and the hamate; they are continuous with the corresponding ligaments of the wrist-joint. In addition to these ligaments, a slender, interosseous band sometimes connects the capitate and scaphoid bones.

The **synovial membrane of the carpus** is very extensive (fig. 537), and bounds a cavity of very irregular shape. The proximal part of the cavity intervenes between the distal surfaces of the scaphoid, lunate and triquetral bones and the proximal surfaces of the bones of the second row. It sends two prolongations upwards—between the scaphoid and lunate bones, and between the lunate and triquetral bones—and three downwards between the four bones of the second row. The prolongation between the trapezium and the trapezoid, or that between the trapezoid and capitate bone, is, owing to the absence of the interosseous ligament, often continuous with the cavity of the carpometacarpal joints, sometimes of the second, third, fourth, and fifth metacarpal bones, sometimes of the second and third only. In the latter condition the joint between the hamate bone and the fourth and fifth metacarpal bones has a separate synovial membrane and is separated from the others (fig. 537) by the medial carpometacarpal interosseous ligament (p. 476). The synovial cavities of the carpometacarpal joints are prolonged for a short distance between the bases of the metacarpal bones. There is a separate synovial cavity between the pisiform and triquetral bones.

Movements.—The chief movements permitted in the mid-carpal joint are flexion and extension, flexion being freer than extension. A very slight amount of abduction and adduction is also permitted, the head of the capitate bone rotating round an anteroposterior axis drawn through its own centre. These movements cannot be performed actively except in association with corresponding movements of the wrist and fingers. They may therefore be regarded as *accessory movements* of the first type (p. 431).

VIII. THE CARPOMETACARPAL JOINTS

1. The Carpometacarpal Joint of the Thumb

This is a saddle-shaped joint between the base of the first metacarpal bone and the trapezium (greater multangular bone), and it enjoys great freedom of movement on account of the configuration of its articular surfaces. The joint is surrounded by a **capsular ligament**, which is thick but loose, and passes from the circumference of the base of the metacarpal bone to the rough edge bounding the articular surface of the trapezium; it is thickest laterally and dorsally. *The synovial membrane which lines the capsular ligament is distinct from that of the other carpometacarpal joints* (fig. 537).

Movements.—In this articulation the movements permitted are flexion combined with opposition, extension, abduction, adduction and circumduction. Flexion and extension take place in the plane of the palm of the hand; abduction and adduction at right angles to this plane (p. 430). Owing to the shapes of the articular surfaces concerned, flexion at this joint is not a simple movement but is accompanied by a slight degree of medial rotation of the metacarpal bone of the thumb, which enables the tip of the thumb to be brought into contact with the palmar aspects of the tips of the slightly flexed fingers. This movement is termed opposition but it cannot be dissociated from flexion and, conversely, flexion at this joint always involves the slight rotatory movement which makes opposition possible.

No *accessory movements* can be obtained at this joint with the exception of separation of the two bones; this can be effected by traction.

Muscles producing the movements :

Flexion and Opposition.—Opponens pollicis, Flexores pollicis longus et brevis.

Extension.—Extensores pollicis longus et brevis.

Adduction.—Adductor pollicis.

Abduction.—Abductores pollicis brevis et longus.

2. The Joints of the Second, Third, Fourth and Fifth Metacarpal Bones with the Carpus

The joints between the carpus and the second, third, fourth, and fifth metacarpal bones are plane joints. The bones are united by **capsular ligaments,** strengthened by dorsal, palmar and interosseous ligaments.

The **dorsal ligaments,** the strongest and most distinct, connect the carpal and metacarpal bones on their dorsal surfaces. The second metacarpal bone receives two fasciculi, one each from the trapezium and trapezoid (greater and lesser multangular) bones ; the third metacarpal receives two, one each from the trapezoid and capitate bones ; the fourth two, one each from the capitate and hamate bones ; the fifth receives a single fasciculus from the hamate bone, and this is continuous with a similar ligament on the palmar surface, forming an incomplete capsular ligament.

The **palmar ligaments** have a somewhat similar arrangement, with the exception of those of the third metacarpal bone, which are three in number : a lateral one from the trapezium (greater multangular bone), situated superficially to the sheath of the tendon of the flexor carpi radialis ; an intermediate one from the capitate bone ; and a medial one from the hamate bone.

The **interosseous ligaments** consist of short, thick fibres, and are limited to one part of the carpometacarpal articulation ; they connect the contiguous inferior margins of the capitate and hamate bones with the adjacent surfaces of the third and fourth metacarpal bones, and they may be united at their proximal ends.

The **synovial membrane** is a continuation of that of the intercarpal joints. Occasionally, the joint between the hamate bone and the fourth and fifth metacarpal bones has a separate synovial membrane, and is then bounded on its lateral side by the more medial of the two interosseous ligaments, just described, and extensions from it to the palmar and dorsal parts of the capsule (fig. 537).

Movements.—The movements permitted in the carpometacarpal articulations of the fingers are limited to slight gliding of the articular surfaces upon each other, the extent of which varies in the different joints. They are really accessory movements of the first type. The metacarpal bone of the little finger is the most movable, then that of the ring-finger ; the metacarpal bones of the index and middle fingers are almost immovable.

The *accessory movements* are limited to spiral twisting of the metacarpus as a whole on the carpus.

IX. THE INTERMETACARPAL JOINTS

The bases of the second, third, fourth and fifth metacarpal bones articulate with one another by small surfaces covered with cartilage, and are connected together by dorsal, palmar and interosseous ligaments.

The **dorsal and palmar ligaments** pass transversely from one bone to another on the dorsal and palmar surfaces. The **interosseous ligaments** connect the contiguous surfaces of the bones, just distal to their collateral articular facets.

The **synovial membrane** of these joints is continuous with that of the carpometacarpal articulations.

X. THE METACARPOPHALANGEAL JOINTS

These articulations (figs. 538, 539) are of the condyloid variety and are formed by the reception of the rounded heads of the metacarpal bones into

shallow cavities on the bases of the proximal phalanges. The metacarpophalangeal joint of the thumb is somewhat exceptional, for its movements of flexion and extension seldom exceed 60° and its side to side movements are very much restricted. Each joint has a palmar and two collateral ligaments.

The **palmar ligaments** (accessory volar ligaments) are thick, dense, fibrocartilaginous structures, placed upon the palmar surfaces of the joints in the

Fig. 538.—The metacarpophalangeal and digital joints. Palmar aspect.

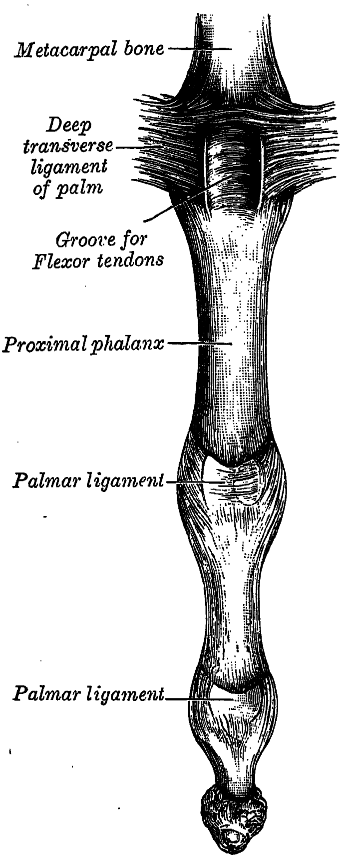


Fig. 539.—The metacarpophalangeal and digital joints. Medial aspect.

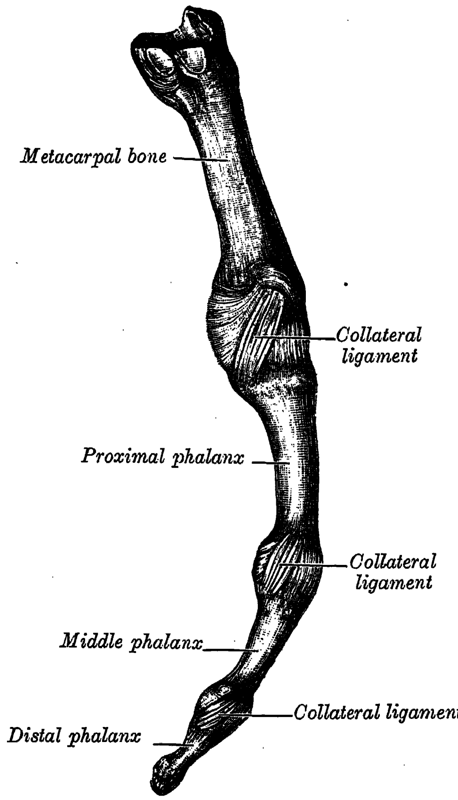


intervals between the collateral ligaments, to which they are connected; they are loosely united to the metacarpal bones, but are very firmly attached to the bases of the proximal phalanges. Their palmar surfaces are intimately blended with the deep transverse ligaments of the palm, and grooved for the flexor tendons, the fibrous sheaths of which are connected to the sides of the grooves. Their deep surfaces form parts of the articular areas for the heads of the metacarpal bones.

The **deep transverse ligaments of the palm** consist of three short, wide, flattened bands which connect the palmar ligaments of the second, third, fourth and fifth metacarpophalangeal joints to one another (fig. 538). They are related, anteriorly, to the lumbrical muscles and the digital vessels and nerves and, posteriorly, to the interosseous muscles. Offsets from the digital slips of the central portion of the palmar aponeurosis join the palmar surface (p. 614).

The **collateral ligaments** are strong, rounded cords, placed on the sides of the joints; each is attached to the posterior tubercle and adjacent depression on the side of the head of the metacarpal bone, and passes downwards and forwards to reach the side of the base of the phalanx (fig. 539).

The dorsal surfaces of these joints are covered with the expansions of the extensor tendons, together with some loose areolar tissue which connects the deep surfaces of the tendons to the bones.*

Movements.—The active movements which occur in these joints are flexion, extension, adduction, abduction, and circumduction.

Flexion is freer than extension, and both movements are limited by the tension of the opposing muscles. Abduction and adduction are less free and cannot be performed actively when the fingers are flexed (*vide infra*).

The *accessory movements* comprise rotation (which in the case of the thumb may be considerable) and gliding of the phalanx on the head of the metacarpal bone forwards, backwards and from side to side. In addition the articular surfaces can be separated by traction.

Muscles producing the movements :

In **flexion,** the *flexores digitorum sublimis et profundus* are assisted by the *lumbricals* and the interossei (p. 619) and, in the case of the little finger, by the *flexor digiti minimi.* In the thumb, the *flexores pollicis longus et brevis* are assisted by the first *palmar interosseous muscle.*

In **extension** of the middle and ring fingers at the metacarpophalangeal joints, the *extensor digitorum* is the only muscle concerned, but the *extensor indicis* and the *extensor digiti minimi* take part in extension of the index and little fingers, respectively. In the thumb the *extensores pollicis longus et brevis* are the only muscles concerned.

Adduction of the extended fingers is performed by the *palmar interossei,* but during flexion the long flexors of the fingers play the principal part. The slight degree of this movement in the thumb is attributable to the *adductor pollicis* and the *first palmar interosseous muscle.*

Abduction of the extended fingers is performed by the *dorsal interossei* assisted by the *long extensors.* In the little finger the *abductor digiti minimi* is the principal agent, and the *abductor pollicis brevis* produces the slight movement possible in the thumb. When the fingers are in the flexed position, abduction cannot be performed actively, but, provided that the long flexors of the fingers are not in active contraction, it can easily be carried out passively. The inability to perform the movement actively in this position is presumably due to the fact that the dorsal interossei and the abductor digiti minimi are so relaxed by flexion that they are unable to function ; the inability is certainly not to be ascribed to tension of the collateral ligaments.

XI. THE DIGITAL JOINTS (figs. 538, 539)

The digital or interphalangeal articulations are hinge-joints, and each has a palmar and two collateral ligaments. The arrangement of these ligaments is similar to those in the metacarpophalangeal joints (p. 477). The extensor tendons supply the places of dorsal ligaments.

Movements.—The only active movements which occur at the interphalangeal joints are flexion and extension ; these movements are freer between the proximal and middle phalanges than between the middle and distal. The amount of flexion is very considerable, but extension is limited by tension of the digital flexors and, in violent movements, by the palmar ligaments.

The *accessory movements* comprise a limited range in each case of rotation, abduction, adduction and gliding forwards and backwards. They permit the fingers to adapt themselves to the shape of any object gripped in the hand, and they provide against the stresses and strains which occur during the ordinary use of the hand.

Muscles producing the movements :

In **flexion** of the proximal joint both the flexor digitorum sublimis and the flexor digitorum profundus are concerned ; in the distal joint, the latter muscle is the sole agent. At the interphalangeal joint of the thumb, the *flexor pollicis longus* is the only muscle available.

* Consult an article on "The Nerve Supply of the Interphalangeal and Metacarpophalangeal joints," by J. S. B. Stopford, *Journal of Anatomy,* vol. lvi. 1921.

In **extension**, which takes place simultaneously at both joints, the *lumbricals* and the *interossei*, both palmar and dorsal, are the active agents, owing to their insertion into the expansion of the extensor tendon (p. 619). The extensor digitorum does not take part in the movement, owing to its fixation at the base of the proximal phalanx. In the thumb, the *extensor pollicis longus* is the only muscle concerned.

Attention should be drawn at this point to the combined movements of flexion at the metacarpophalangeal joint and extension at the interphalangeal joints which are carried out simultaneously and are of such importance in the fine movements executed in writing, drawing, painting, etc. The *lumbricals* are the principal agents in producing the movements, and they are enabled to do so by virtue of their anterior relationship to the transverse axes of the metacarpophalangeal joints and their attachment to the extensor tendon distal to that joint. The interossei are unable to initiate the movement, but they help to steady the metacarpophalangeal joints and assist the movement as soon as the lumbricals have caused the necessary degree of flexion.

THE JOINTS OF THE PELVIS

I. THE SACRO-ILIAC JOINT

The sacro-iliac articulation is a synovial joint between the auricular surfaces of the sacrum and ilium. Although the joint is to be regarded as of the plane variety, the *articular surfaces* are not flat, but are marked by a number of irregular elevations and depressions. These irregularities fit in to one another and provide a locking device which restricts movements to a minimum in order to ensure stability, for the sacro-iliac joint interrupts the line of weight transmission from the vertebral column to the lower limb. This mechanism permits the body weight to be transmitted through the joint without causing tension of the ligaments. In the adult male a large number of short but strong bundles of fibres enter into the constitution of the sacro-iliac ligaments and, as a result, only a very small amount of anteroposterior rotatory movement is possible. In the female, after puberty, the range is appreciably greater and it is increased temporarily in the later months of pregnancy.* In the elderly it is usual to find that the joint cavity is at least partly obliterated by the presence of fibrous or fibrocartilaginous adhesions. The ligaments of the joints are :

Anterior sacro-iliac. Interosseous sacro-iliac.
Posterior sacro-iliac.

The **anterior sacro-iliac ligament** (fig. 540) covers the anterior and inferior surfaces of the joint and consists of numerous thin bands. The superior fibres of the ligament connect the ala of the sacrum to the adjoining part of the iliac fossa ; the inferior fibres are placed below the arcuate line, and unite the lateral parts of the three upper sacral vertebræ to the pre-auricular sulcus (p. 374) and adjacent part of the ilium.

The **interosseous sacro-iliac ligament** is very strong, and forms the chief bond of union between the two bones. It fills the irregular space immediately above and behind the joint-cavity (figs. 543, 544) and is covered by the posterior sacro-iliac ligament. It consists of bundles of short fibres which connect the iliac and sacral tuberosities.

The **posterior sacro-iliac ligament** is oblique in direction ; it connects the posterior superior iliac spine to the upper four transverse tubercles of the sacrum. Its lower fibres are long and partly blended with the upper end of the sacrotuberous ligament. Its upper fibres are short and nearly horizontal.

The Vertebropelvic Ligaments

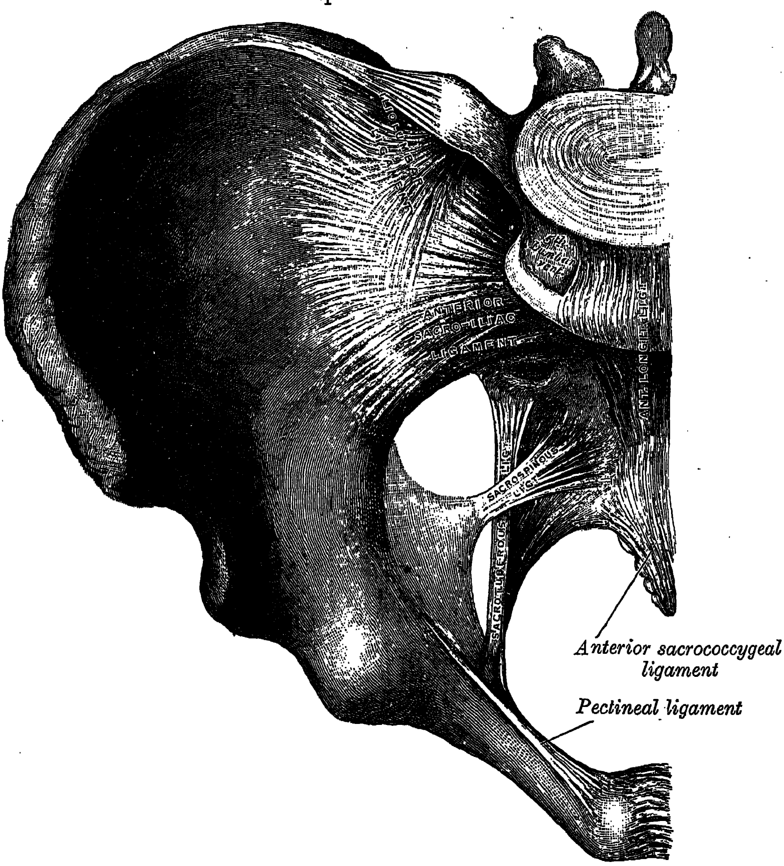
The ilium is connected to the fifth lumbar vertebra by the *iliolumbar ligament*, and the sacrum to the ischium by the *sacrotuberous* and *sacrospinous ligaments*.

* R. Brooke, *Journal of Anatomy*, 1924.

The **iliolumbar ligament** (fig. 540) is attached above to the lower and front part of the transverse process of the fifth lumbar vertebra, and occasionally has an additional, weak attachment to the transverse process of the fourth. It radiates as it passes laterally and is attached by two main bands to the pelvis. The lower band runs to the ala of the ilium and the base of the sacrum, blending with the anterior sacro-iliac ligament; the upper, which gives partial origin to the quadratus lumborum muscle, is attached to the crest of the ilium immediately in front of the sacro-iliac joint and is continuous above with the lumbar fascia.

The **sacrotuberous ligament** (figs. 540, 541) is placed at the lower and posterior part of the pelvis. It is attached by a broad base to the posterior

FIG. 540.—The joints and ligaments of the right side of the pelvis. Antero-superior aspect.



iliac spines (where it is partly blended with the posterior sacro-iliac ligament), to the third, fourth and fifth transverse tubercles of the sacrum, and to the lateral margin of the lower part of the sacrum and upper part of the coccyx. Its fibres run obliquely downwards and laterally, and converge to form a thick, narrow band; this band widens out below and is fixed to the medial margin of the ischial tuberosity, and is continued along the ramus of the ischium under the name of the *falciform process,* the free concave edge of which gives attachment to the fascia of the obturator internus muscle. On its posterior surface the ligament gives origin to the lowest fibres of the gluteus maximus, and some of the superficial fibres of its lower part are continued into the tendon of origin of the long head of the biceps femoris. The ligament is pierced by the coccygeal branches of the inferior gluteal artery, by the perforating cutaneous nerve and by minute filaments of the coccygeal plexus.

The **sacrospinous ligament** (fig. 540) is thin, and triangular in form; it is attached by its apex to the spine of the ischium, and, medially, by its broad

base, to the lateral margins of the sacrum and coccyx, in front of the sacrotuberous ligament, with which its fibres are intermingled. It is in relation in front with the coccygeus muscle, to which it is closely connected, and of which it may represent a degenerated part.

These two ligaments convert the sciatic notches into foramina. The *greater sciatic foramen* is bounded, in front and above, by the greater sciatic notch; behind by the sacrotuberous ligament; and below by the sacrospinous ligament and the spine of the ischium. It is partially filled up, in the recent state, by the piriformis muscle, which emerges from the pelvis through it. Above this muscle, the superior gluteal vessels and nerve pass out of the pelvis; and below it, the inferior gluteal vessels and nerve, the internal pudendal vessels and nerve, the sciatic and the posterior femoral cutaneous nerves, and the nerves to the obturator internus and quadratus femoris make their exit from the pelvis. The *lesser sciatic foramen* is bounded, in front, by the body of the ischium; above, by the

FIG. 541.—The joints and ligaments of the right side of the pelvis. Posterior aspect.

body of the ischium and the sacrospinous ligament; behind, by the sacrotuberous ligament. It transmits the tendon of the obturator internus, the nerve to this muscle, and the internal pudendal vessels and nerve.

The sacrotuberous and, to a lesser extent, the sacrospinous ligaments would oppose any tendency of the lower part of the sacrum to tilt upwards under the downward thrust which is imparted to the upper end of the bone by the weight of the trunk (p. 483).

II. THE PUBIC SYMPHYSIS (fig. 542)

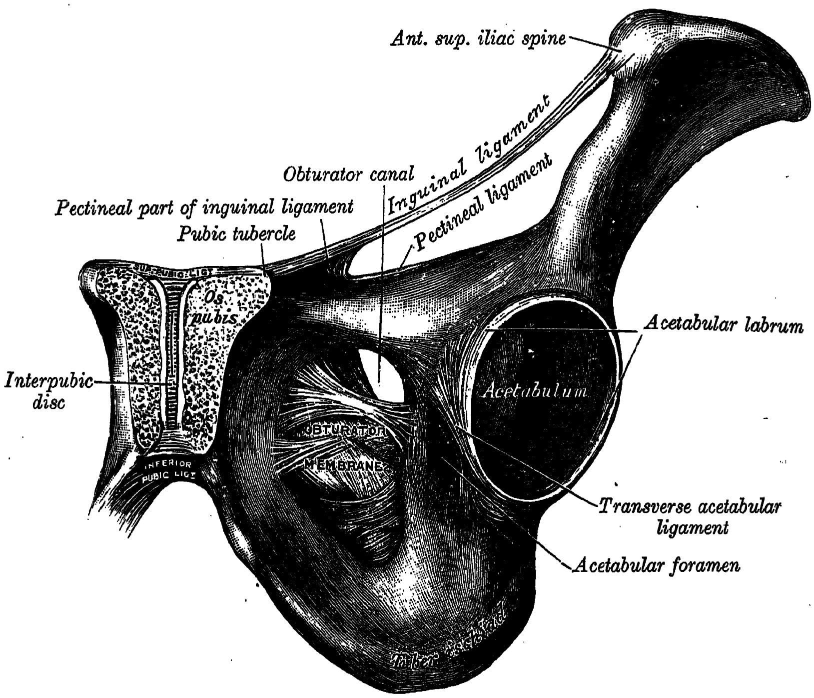
The pubic bones meet each other in the median plane, where they form a secondary cartilaginous joint which receives the special name of the pubic symphysis. The two bones are connected by a superior and an inferior pubic ligament, and by an interpubic disc of fibrocartilage.

The **superior pubic ligament** connects the pubic bones superiorly, and extends as far as the pubic tubercles.

The **inferior (arcuate) pubic ligament** is a thick, triangular arch of fibres, connecting the two pubic bones below, and forming the upper boundary of the pubic arch. Above, it is blended with the interpubic disc ; laterally, it is attached to the inferior rami of the pubic bones ; its base is free, and is separated from the perineal membrane (inferior fascia of the urogenital diaphragm) by an opening through which the deep dorsal vein of the penis (or clitoris) enters the pelvis.

The **interpubic disc** connects the opposed surfaces of the pubic bones. Each of these surfaces is covered with a thin layer of hyaline cartilage firmly joined

FIG. 542.—A coronal section through the pubic symphysis. Anterior aspect.



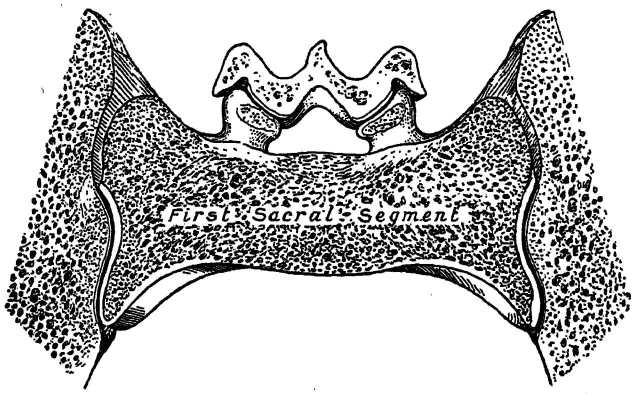
to the bone by a series of nipple-like processes which fit accurately into corresponding depressions on the osseous surface. These opposed cartilaginous surfaces are connected by a lamina of fibrocartilage, which varies in thickness in different subjects. It often contains a cavity in its interior, probably formed by the softening and absorption of the fibrocartilage, since it rarely appears before the tenth year of life and is not lined with synovial membrane. This cavity is usually limited to the upper and back part of the joint ; it occasionally reaches the front, and may extend the entire length of the cartilage. When present it may be demonstrated by making a coronal section of the symphysis pubis near its posterior surface (fig. 542). In front the disc is strengthened by several superimposed layers of fibres, which pass obliquely from one bone to the other, decussating and forming an interlacement with the fibres of the external oblique aponeuroses and the medial tendons of origin of the recti abdominis.

THE MECHANISM OF THE PELVIS

The pelvic girdle supports and protects the contained viscera and affords surfaces for the attachments of the muscles of the trunk and lower limb. Its most important mechanical function, however, is to transmit the weight of the trunk and upper limbs to the lower extremities.

It may be divided into two arches by a vertical plane passing through the acetabular cavities; the posterior of these arches is the one chiefly concerned in the function of transmitting the weight of the trunk. Its essential parts are the upper three sacral vertebræ and two strong pillars of bone running from the sacro-iliac joints to the acetabular fossæ (p. 378). The anterior of these arches is formed by the pubic bones and their superior rami. It connects the bases of the lateral pillars of the posterior arch and so acts as a tie-beam to prevent their separation and consequent collapse of the arch. The sacrum forms

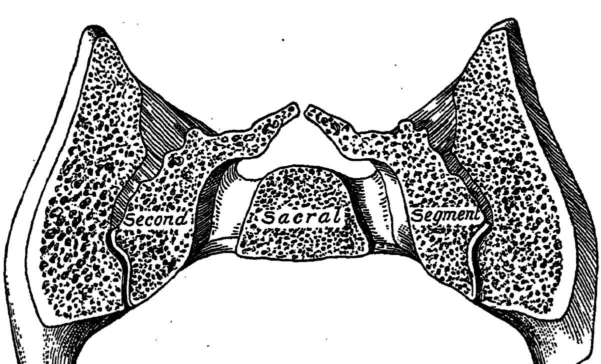
Fig. 543.—A coronal section through the anterior sacral segment.



the summit of the posterior arch; the weight transmitted falls on it at the lumbosacral joint and, theoretically, has a component in each of two directions. One component of the force is expended in driving the sacrum downwards and backwards between the iliac bones, while the other thrusts the upper end of the sacrum downwards and forwards towards the pelvic cavity.

The movements of the sacrum are regulated by its form. Viewed as a whole, it presents the shape of a wedge with its base upwards and forwards. The first component of the force is therefore acting against the resistance of the wedge,

Fig. 544.—A coronal section through the middle sacral segment.



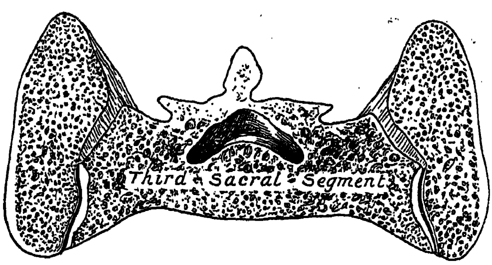
and its tendency to separate the iliac bones is resisted by the sacro-iliac and iliolumbar ligaments and by the ligaments of the symphysis pubis.

If a series of coronal sections be made through the sacro-iliac joints, it will be found possible to divide the articular portion of the sacrum into three segments: anterior, middle, and posterior. In the *anterior segment* (fig. 543), which involves the first sacral vertebra, the articular surfaces show slight sinuosities and are almost parallel to one another. In the *middle segment* (fig. 544) the width between the dorsal margins of the sacral articular surfaces is greater than that between the ventral margins, and in the centre of each surface there is a concavity into which a corresponding convexity of the iliac

articular surface fits. This forms an interlocking mechanism which prevents the strain of the body-weight from falling on the ligaments. In the *posterior segment* (fig. 545) the ventral width of the sacrum is greater than the dorsal, and the articular surfaces are only slightly concave.

Dislocation downwards and forwards of the sacrum by the second component of the force applied to it is prevented therefore by the middle segment, which interposes the resistance of its wedge-shape and that of the interlocking mechanism on its surfaces; a rotatory movement, however, is produced by which the anterior segment is tilted downwards and the posterior upwards: the axis of this rotation passes through the dorsal part of the middle segment. The movement of the anterior segment is slightly limited by its wedge-form, but chiefly by the posterior and interosseous sacro-iliac ligaments; that of the posterior segment is checked to a slight extent by its wedge-form, but the chief limiting factors are the sacrotuberous and sacrospinous ligaments. In all these movements the effect of the sacro-iliac and iliolumbar ligaments and the ligaments of the symphysis pubis in resisting the separation of the iliac bones must be recognised.

FIG. 545.—A coronal section through the posterior sacral segment.



Applied Anatomy.—During pregnancy the pelvic joints and ligaments are relaxed and capable therefore of more extensive movements. This relaxation of the ligaments renders the locking mechanism of the sacro-iliac joint less efficient and permits a rotation of the hip-bones to take place. This rotation has the effect of increasing the capacity of the pelvis. The less efficient the locking mechanism, the more the strain of weight bearing falls on the ligaments, leading to the frequent occurrence of sacro-iliac strain after pregnancy. During involution the ligaments become tightened up again and the locking mechanism is restored, but, in some cases, the locking may occur in the position of rotation of the hip-bones which was adopted during the pregnancy. This so-called subluxation of the sacro-iliac joint causes pain by the tension which it imposes on the ligaments, and reduction by forcible manipulation is required. The common position found in this condition is believed to be backward rotation of the hip-bone on the sacrum; it is usually unilateral.

THE JOINTS OF THE LOWER LIMB

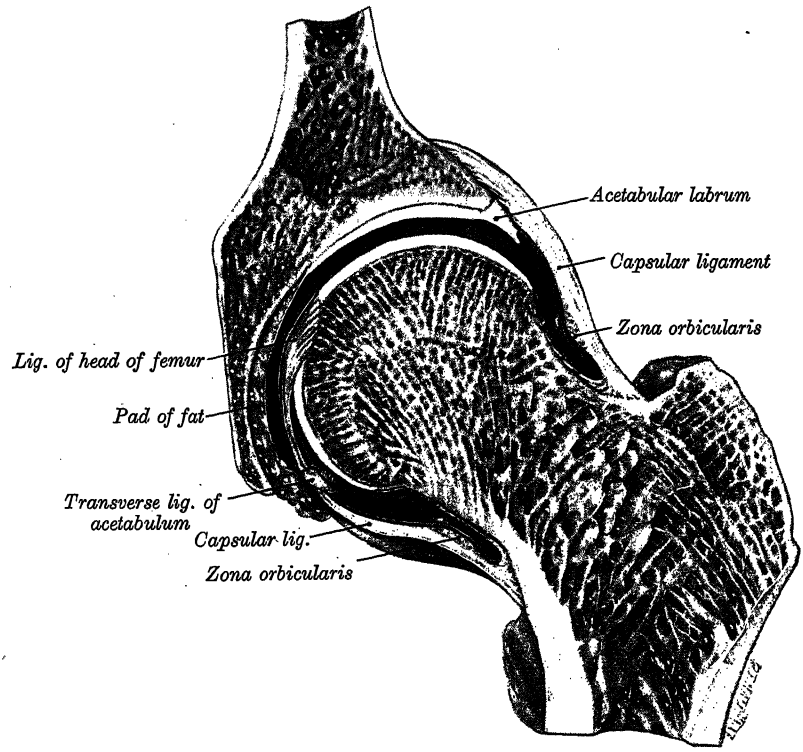
I. THE HIP-JOINT

The hip-joint is a ball-and-socket articulation, formed by the reception of the head of the femur into the cup-shaped fossa of the acetabulum. The *articular surfaces* are reciprocally and regularly curved, but are not co-extensive. The head of the femur is completely covered with articular cartilage, except over the small, roughened pit to which the ligament of the head is attached. In front, the cartilage extends laterally to cover a small area on the adjoining part of the neck of the femur. The cartilage is thickest at the centre of the head and thinner towards its periphery. The articular surface of the acetabulum forms an incomplete ring, broadest at its upper part where the pressure of the body weight falls in the erect attitude and narrowest where it covers the pubic constituent. The ring is deficient below opposite the acetabular notch. It is covered with articular cartilage which is thickest where the ring is broadest, but the floor of the acetabular fossa within the ring is devoid of articular cartilage and lodges a mass of fat covered with synovial membrane. The depth of the acetabulum is appreciably increased by a fibrocartilaginous rim, termed the *acetabular labrum*. The ligaments of the joint are:

The capsular.	Pubofemoral.
Iliofemoral.	Ligament of the head of the femur.
Ischiofemoral.	The acetabular labrum.
Transverse acetabular.	

The **capsular ligament** (figs. 548, 549) is strong and dense. Above, it is attached to the margin of the acetabulum, 5 or 6 mm. beyond the acetabular labrum ; in front, it is attached to the outer margin of the labrum, and, opposite the acetabular notch, to the transverse acetabular ligament and the edge of the obturator foramen. It surrounds the neck of the femur, and is attached in front to the trochanteric line ; above, to the base of the neck ; behind, to the neck about 1 cm. above the trochanteric crest ; below, to the lower part of the neck close to the lesser trochanter. From its attachment to the front of the neck of the femur many of the fibres are reflected upwards along the neck as longitudinal bands, termed *retinacula.* The capsular ligament is much thicker at the upper and fore part of the joint, where the greatest amount of resistance is required ; behind and below, it is thin and only loosely connected to the bone. It consists of two sets of fibres, circular and longitudinal. The circular

FIG. 546.—A section through the hip-joint. The synovial membrane is shown in *blue.*



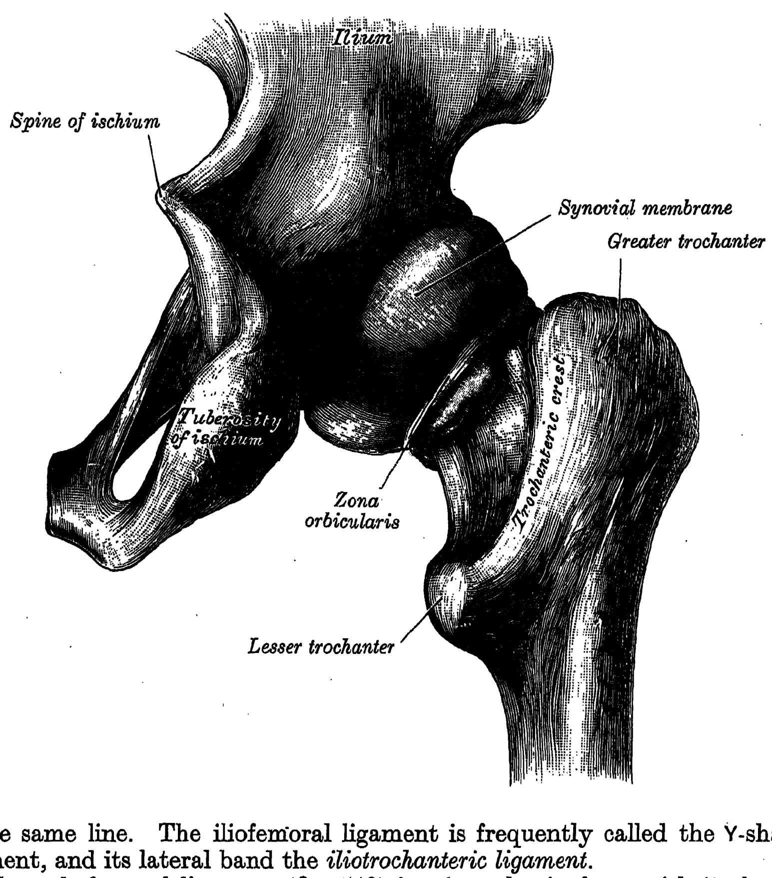
fibres (*zona orbicularis*) are the deeper (fig. 546) and form a collar or ring round the neck of the femur (fig. 547). Although partially blended with the pubo- and ischio-femoral ligaments, these fibres have no direct attachment to bone. The longitudinal fibres are greatest in number at the upper and front part of the capsule, where they are reinforced by the *iliofemoral ligament.* The articular capsule is also strengthened by the *pubofemoral* and the *ischiofemoral ligaments.* The external surface of the capsule is rough, covered by numerous muscles, and separated in front from the psoas major and iliacus by a bursa.

The **synovial membrane** is very extensive. Commencing at the margin of the cartilaginous surface of the head of the femur, it covers the portion of the neck which is contained within the joint ; from the neck it is reflected on the internal surface of the capsular ligament, covers both surfaces of the acetabular labrum, ensheathes the ligament of the head of the femur, and covers the mass of fat contained in the acetabular fossa. It is absent, however, from the deep surface of that part of the iliofemoral ligament which is compressed against the head

of the femur in the erect attitude. The joint-cavity communicates sometimes with the bursa of the psoas major tendon through a circular aperture which is situated between the pubofemoral ligament and the vertical band of the iliofemoral ligament.

The **iliofemoral ligament** (fig. 548), triangular in shape and of great strength, lies in front of the joint and is intimately connected with the capsule. Its apex is attached to the lower part of the anterior inferior iliac spine, its base to the trochanteric line of the femur. The medial and lateral parts of the ligament are strong bands, while the central part is relatively thin and weak; the medial band is vertical in direction and is fixed to the lower part of the trochanteric line; the lateral band is oblique and is attached to the tubercle at the upper part

FIG. 547.—The synovial cavity of the right hip-joint (distended). Posterior aspect. (From a specimen prepared by J. C. B. Grant.)



of the same line. The iliofemoral ligament is frequently called the Y-shaped ligament, and its lateral band the *iliotrochanteric ligament.*

The **pubofemoral ligament** (fig. 548) is triangular in form with its base at the hip-bone, where it is attached to the iliopubic (iliopectineal) eminence, the superior ramus of the os pubis, the obturator crest and obturator membrane; below, it blends with the capsule and with the deep surface of the medial band of the iliofemoral ligament.

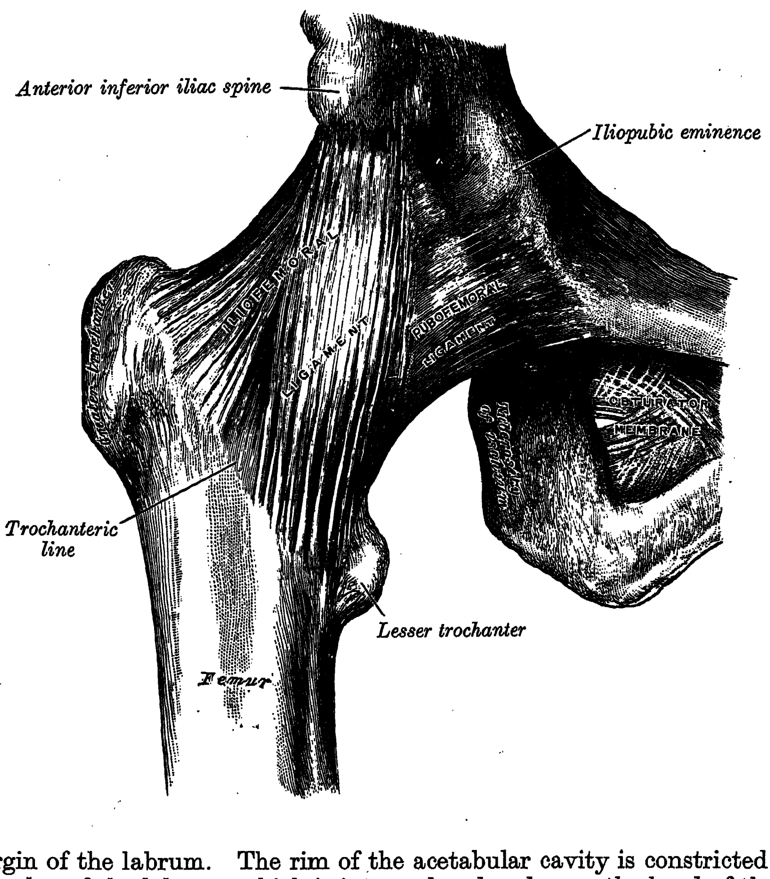
The **ischiofemoral ligament** (fig. 549) has a somewhat spiral disposition on the back of the joint. From its attachment to the ischium below and behind the acetabulum, it is directed upwards and laterally over the back of the neck of the femur. Some of its fibres are continuous with those of the zona orbicularis, others are fixed to the base of the greater trochanter.

The **ligament of the head of the femur (ligamentum teres femoris)** (fig. 550) is a triangular, somewhat flattened band implanted by its apex on the antero-superior part of the pit on the head of the femur; its base is attached by two bands, one into each side of the acetabular notch, and between these bony attachments it blends with the transverse ligament. It is ensheathed by

synovial membrane, and varies greatly in strength in different subjects; occasionally only its synovial sheath exists, and in rare cases even this is absent. The ligament is made tense when the thigh is semiflexed and then adducted; it is relaxed when the limb is abducted.

The **acetabular labrum** (**glenoidal labrum**) (fig. 542) is a fibrocartilaginous rim attached to the margin of the acetabulum, the cavity of which it deepens. It bridges the acetabular notch as the *transverse ligament of the acetabulum*, and thus forms a complete circle. It is triangular on cross-section; the base is attached to the edge of the acetabulum, and the apex corresponds with the free

FIG. 548.—The right hip-joint. Anterior aspect.



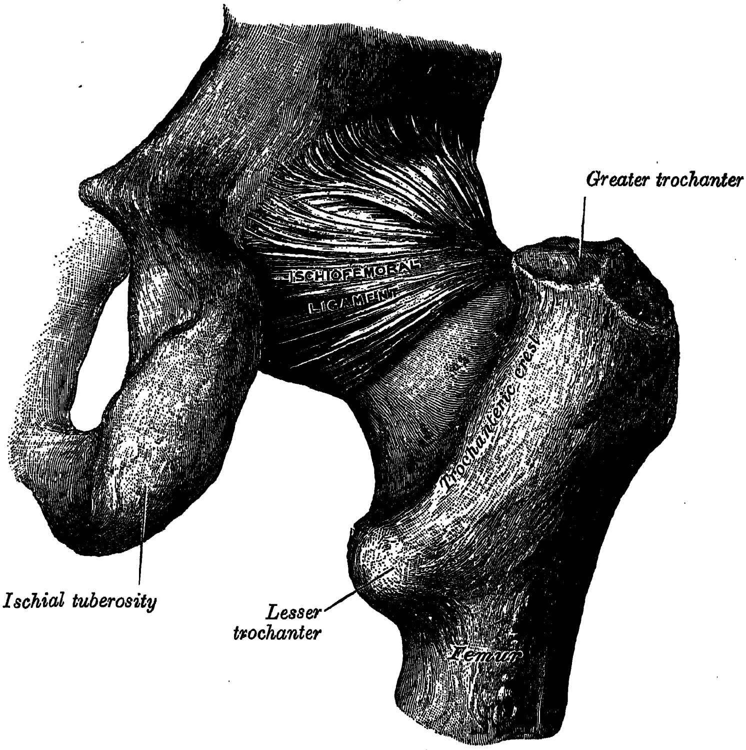
margin of the labrum. The rim of the acetabular cavity is constricted by the free edge of the labrum, which is inturned and embraces the head of the femur closely so as to assist in holding it in its socket.

The **transverse ligament of the acetabulum** (fig. 542) is in reality a portion of the acetabular labrum, though differing from it in having no cartilage-cells among its fibres. It consists of strong, flattened fibres, which cross the acetabular notch, and convert it into a foramen through which vessels and nerves enter the joint.

Relations of the hip-joint.—The capsule is surrounded by muscles on all sides (fig. 551). *Anteriorly*, the lateral fibres of the pectineus intervene between the most medial part of the capsule and the femoral vein. Lateral to the pectineus the tendon of the psoas major, with the iliacus on its lateral side, runs downwards across the front of the capsule, partly separated from it by a bursa. In this situation the femoral artery is lying on the psoas tendon and the femoral nerve lies deeply in the groove between the tendon and the iliacus. More laterally the straight head of the rectus femoris crosses the joint and, under its lateral border, the deep layer of the iliotibial tract blends with the capsular ligament.

Superiorly, the reflected head of the rectus femoris is in contact with the medial part of the capsule ; the gluteus minimus covers the lateral part and is closely adherent to it. *Inferiorly*, the lateral fibres of the pectineus lie on the capsule as they incline backwards and, more posteriorly, the obturator externus crosses obliquely to gain the posterior aspect of the joint. *Posteriorly*, the lower part of the capsule is covered with the tendon of the obturator externus, which separates it from the quadratus femoris and is accompanied by the ascending branch of the medial circumflex femoral artery. Above that, the tendon of the obturator internus with the two gemelli is in intimate relation with the joint

Fig. 549.—The right hip-joint. Posterior aspect.



and intervenes between it and the sciatic nerve. The nerve to the quadratus femoris lies deep to the obturator internus tendon and descends on the most medial part of the capsule. The uppermost part of the posterior surface of the capsular ligament is crossed by the piriformis.

The *arteries* supplying the joint are derived from the obturator, medial circumflex femoral, and superior and inferior gluteal arteries.

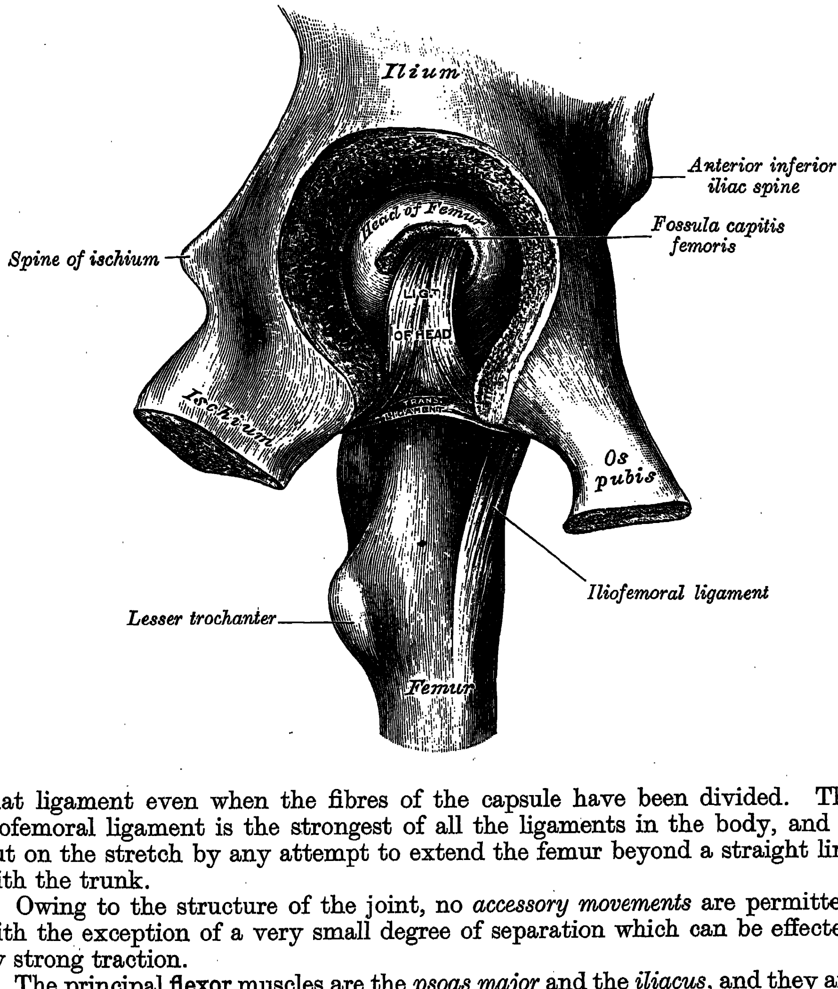
The *nerves* are articular branches from the sacral plexus, the sciatic, obturator, and accessory obturator nerves, a branch from the nerve to the quadratus femoris, and a filament from the branch of the femoral nerve supplying the rectus femoris.

Movements.—The *active movements* of the hip-joint are flexion, extension, adduction, abduction, circumduction, and rotation.

The length of the neck of the femur and its inclination to the body of the bone have the effect of converting the angular movements of flexion, extension, adduction, and abduction partially into rotatory movements in the joint. Thus when the thigh is flexed or extended, the head of the femur rotates within the acetabulum around a transverse axis. Rotation of the thigh takes place around a vertical axis which passes through the centre of the head of the femur and the intercondylar notch. The movements of abduction and adduction occur around an anteroposterior axis which passes through the centre of the head of the femur.

The hip-joint presents a very striking contrast to the shoulder-joint as regards the mechanical arrangements for its security and for the limitation of its movements. In the shoulder, as has been seen, the head of the humerus is not adapted in size to the glenoid cavity, and its ordinary movements are restrained but little by the capsule. In the hip-joint, on the contrary, the head of the femur is closely fitted to the acetabulum for an area extending over nearly half a sphere, and at the margin of the bony cup it is embraced still more closely by the acetabular labrum, so that the head of the femur is held in its place by

FIG. 550.—The left hip-joint, opened by the removal of the floor of the acetabulum from within the pelvis.



that ligament even when the fibres of the capsule have been divided. The iliofemoral ligament is the strongest of all the ligaments in the body, and is put on the stretch by any attempt to extend the femur beyond a straight line with the trunk.

Owing to the structure of the joint, no *accessory movements* are permitted with the exception of a very small degree of separation which can be effected by strong traction.

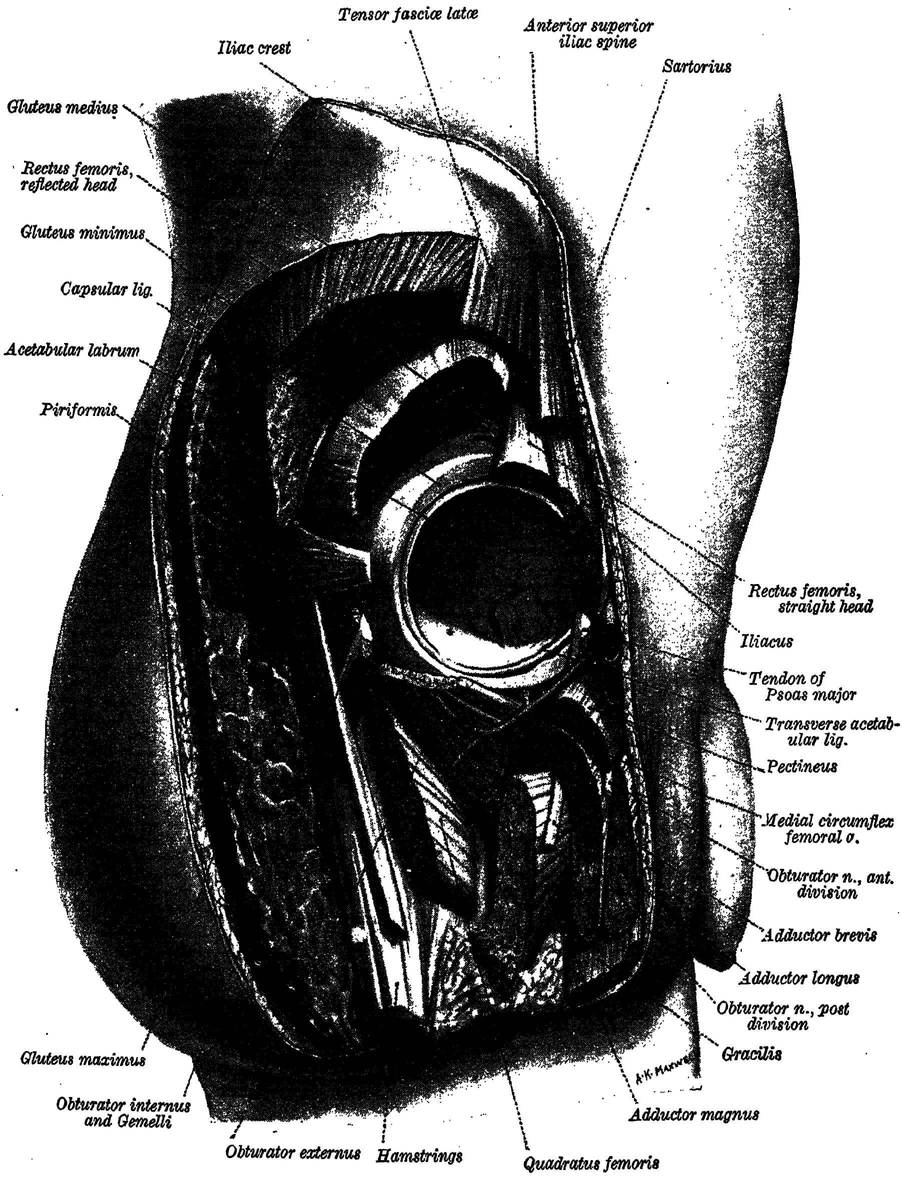
The principal **flexor** muscles are the *psoas major* and the *iliacus*, and they are assisted by the pectineus, rectus femoris and sartorius. The adductors may participate in the movement when it is performed against strong resistance. When the knee is flexed, flexion of the hip-joint is arrested by contact of the front of the thigh with the anterior abdominal wall. When extension of the knee is maintained, flexion of the hip-joint is limited at an earlier stage by the tension of the hamstring muscles.

The principal **extensor** muscle is the *gluteus maximus*, which is the true antagonist of the psoas major and iliacus. The hamstring muscles share in the production of the movement, when strong resistance is encountered. In the erect posture a vertical line passing through the centre of gravity of the trunk falls behind the line joining the centres of the femoral heads, and therefore the pelvis tends to fall backwards, but it is kept in position by the balanced tone

of the flexor and extensor muscles. The iliofemoral ligaments prevent hyperextension.

The principal **abductor** muscles are the *gluteus medius* and the *gluteus minimus*, and they are assisted by the tensor fasciæ latæ and the sartorius. Abduction is a free movement and it is limited by the tension of the adductor

Fig. 551.—The structures surrounding the right hip-joint.



muscles, the pubofemoral ligament and the medial band of the iliofemoral ligament. The principal **adductor** muscles are the *adductores longus, brevis et magnus,* assisted by the pectineus and the gracilis. Adduction is limited by contact with the opposite limb, but a wider range of movement can be obtained when the thigh is flexed. Adduction of the flexed thigh is limited by the tension of the abductor muscles, the lateral band of the iliofemoral ligament and the ligament of the head of the femur.

Medial rotation is a relatively weak movement and no great force is required to prevent it. The principal muscles concerned are the *tensor fasciæ latæ* and the *anterior fibres of the glutei minimus et medius*. The movement is limited by the tension of the lateral rotator muscles, the ischiofemoral ligament and the posterior part of the capsular ligament. **Lateral rotation** can be effected with considerable power. The principal muscles concerned are the *obturatores*, the *gemelli* and the *quadratus femoris*, assisted by the *piriformis*, the gluteus maximus, the sartorius and the adductors. The movement is limited by the tension of the medial rotator muscles and by the lateral band of the iliofemoral ligament.

Applied Anatomy.—In dislocation of the hip, " the head of the thigh-bone may rest at any point around its socket " (Bryant); but whatever position it assumes ultimately, the primary displacement is generally downwards and medially, the capsule giving way at its weakest—that is, its lower and medial—part. The situation subsequently assumed by the head of the bone is determined by the degree of flexion or extension, and of lateral or medial rotation of the thigh at the moment of dislocation, influenced, no doubt, by the iliofemoral ligament, which is not easily ruptured.

The iliofemoral ligament is rarely torn in dislocations of the hip, and this fact is taken advantage of by the surgeon in reducing these dislocations by manipulation. It is made to act as the fulcrum to a lever, of which the long arm is the body of the femur, and the short arm the neck of the bone.

Congenital dislocation is met with more commonly in the hip-joint than in any other articulation. The displacement usually takes place on to the dorsum ilii, the upper part of the rim of the acetabulum being deficient.

IV. THE KNEE-JOINT

The knee-joint is a ginglymus or hinge-joint. It consists of three articulations: two condyloid joints between the condyles of the femur and the semilunar cartilages (menisci) and condyles of the tibia; and a third between the patella and the femur, partly plane, but not completely so, since the articular surfaces are not mutually adapted to each other, so that the movement is not a simple gliding one. This view of the construction of the knee-joint receives confirmation from a study of the articulation in some of the lower mammals, where, corresponding to these three subdivisions, three synovial cavities are found, either distinct from one another or connected by small communications.

The joint is partly subdivided by two semilunar fibrocartilages, which are placed between the femur and the tibia.

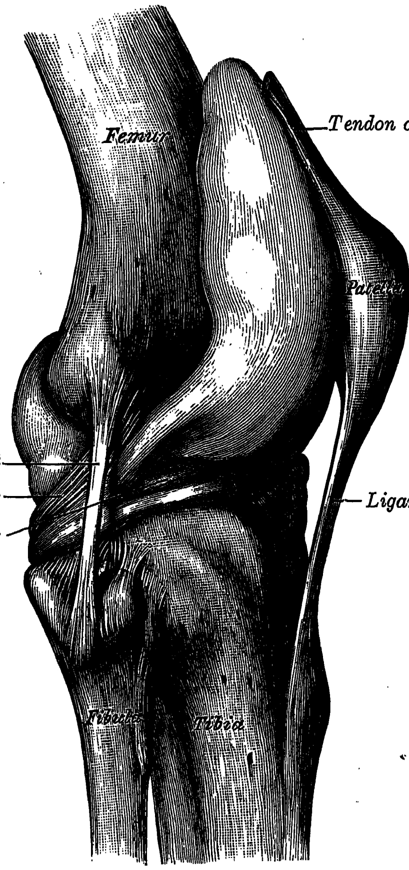
The *articular surfaces* (pp. 390, 395 and 396) are not perfectly congruent. The femoral condyles are convex from side to side and from before backwards, the curvature being accentuated posteriorly (fig. 458). Each tibial articular surface, on the other hand, though gently hollowed out centrally, is flattened around its periphery where it is covered with the corresponding semilunar cartilage. The opposing femorotibial surfaces are adapted to one another more closely by the semilunar cartilages, which are shaped so as to render the inferior articular surface concave both from side to side and from before backwards. The articular surface of the lateral femoral condyle is marked in front by a faint groove (fig. 457) which rests on the peripheral border of the lateral semilunar cartilage in full extension of the joint. A similar groove marks the articular surface of the medial condyle, but it does not reach the lateral border of the condyle, where a narrow strip is marked off which comes into contact with the medial part of the patellar articular surface in full flexion of the knee.

The articular surface of the patella is adapted in a general way to the patellar surface of the femur. The vertical ridge which divides it into a larger, lateral part and a smaller, medial part fits into the corresponding groove on the femur, but the lateral and medial parts are only imperfectly congruent with the corresponding parts of the femur. The articular surface of the patella is divided still further by two faint, horizontal ridges which, with the vertical ridge map out three pairs of facets.* On the medial side a second vertical ridge

* In many patellæ only one horizontal ridge can be made out. It is better marked on the lateral area, and the upper and lateral facet differs from the others in being more deeply hollowed out.

cuts off a narrow, elongated, semilunar strip from the medial border of the surface. This strip comes into contact with the lateral part of the anterior end of the medial femoral condyle in full flexion, and in that position of the joint the uppermost lateral facet on the patella is in contact with the anterior part of the lateral condyle. As the knee is extended the middle facets of

Fig. 552.—The synovial cavity of the right knee-joint (distended). Lateral aspect. (From a specimen prepared by J. C. B. Grant.)



the patella come into contact with the lower half of the femoral patellar surface, and in full extension only the lowest patellar facets are in contact with the femur.

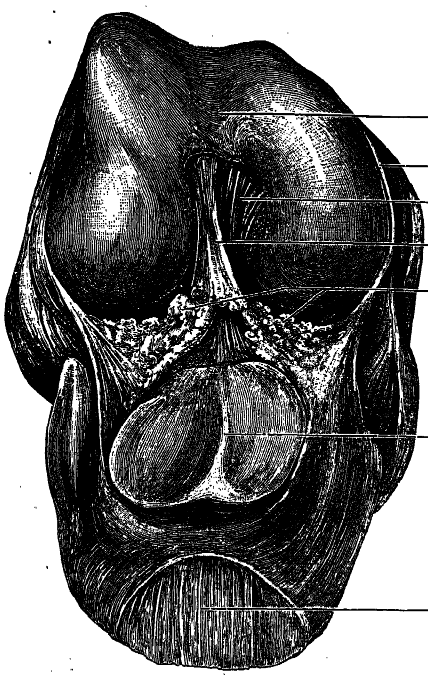
The ligaments of the joints are :

The capsular.	Anterior and posterior cruciate.
Ligamentum patellæ.	Transverse.
Oblique posterior and arcuate.	Coronary.
Medial and lateral.	

The **capsular ligament** is a very complicated structure, for in part it is deficient and in part it is replaced by strong expansions from the tendons of the muscles which surround the joint. Posteriorly, it consists of vertically running fibres which are attached above to the margins of the femoral condyles and the posterior margin of the intercondylar notch, and below to the posterior margins of the tibial condyles and the posterior border of the intercondylar area. This part of the capsule is blended above on each side with the origin of the corresponding head of the gastrocnemius and centrally it is strengthened by the oblique posterior ligament with which its fibres interlace. On the medial side the fibres are attached to the medial surfaces of the femoral and tibial condyles

beyond the articular margins. In this situation the capsular ligament blends with the deep fibres of the medial (tibial collateral) ligament. On the lateral side the fibres are attached to the femur above the origin of the popliteus and they descend to the lateral condyle of the tibia covering the muscle. The lateral (fibular collateral) ligament stands clear of the capsule and is separated from it by a little fat and the inferior lateral genicular vessels and nerve. Anteriorly, the capsule is entirely awanting above the patella and over the patellar area. Elsewhere it blends indistinguishably with expansions from the vastus medialis and vastus lateralis. These expansions are attached to the margins of the patella and ligamentum patellæ and extend backwards on each side as far as the corresponding collateral ligament and downwards to the condyles of the tibia. They form the *medial* and *lateral patellar retinacula,*

FIG. 553.—The right knee-joint. Opened from the front.

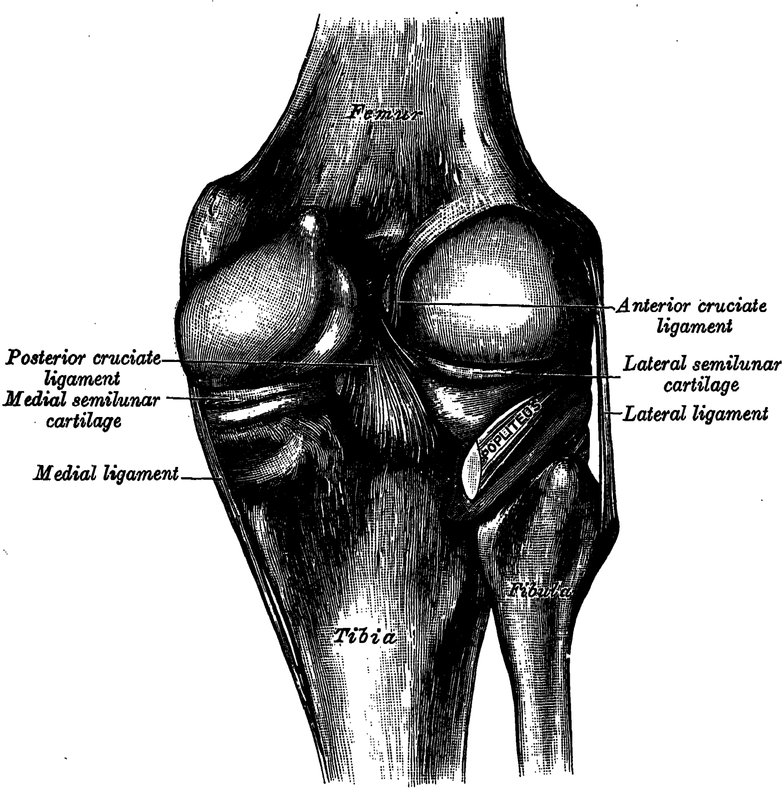


and the latter is further strengthened by the iliotibial tract, which partially covers and blends with the expansion from the vastus lateralis. Above the patella the deficiency of the capsule allows the suprapatellar bursa (p. 498) to communicate freely with the cavity of the joint. Posteriorly, the attachment of the capsule to the posterior surface of the lateral tibial condyle is interrupted, and in this situation the popliteus emerges from within the capsule (fig. 556). The oblique posterior ligament, which is augmented by fibres derived from the tendon of the semimembranosus, strengthens the posterior aspect of the capsule. Laterally, a prolongation from the iliotibial tract fills the interval between the oblique posterior and the lateral (fibular collateral) ligaments, and partly covers the latter. Medially, expansions from the sartorius and semimembranosus pass upwards to the medial (tibial collateral) ligament and strengthen the capsule.

The **synovial membrane** of the knee-joint is the most extensive in the body. Commencing at the upper border of the patella, it forms a large pouch under cover of the quadriceps femoris on the lower part of the front of the femur (figs. 552, 560), and usually communicates with a bursa interposed between the tendon and the front of the bone. The pouch between the quadriceps and front of the femur is upheld, during the movements of the knee, by a small muscle,

named the articularis genu, which is inserted into it. On either side of the patella, the synovial membrane extends beneath the aponeuroses of the vasti, and more especially beneath that of the vastus medialis. Below the patella it is separated from the ligamentum patellæ by a considerable quantity of fat, known as the *infrapatellar pad*. Opposite the medial and lateral borders of the lower part of the articular surface of the patella, the synovial membrane covering the infrapatellar pad is projected into the interior of the joint in the form of two fringe-like folds termed the *alar folds*; behind, these folds converge and are continued as a single band, named the *infrapatellar fold*, to the front of the intercondylar notch of the femur (fig. 553). By its position, attachments and

FIG. 554.—The synovial cavity of the right knee-joint (distended). Posterior aspect of the specimen represented in fig. 552.



structure the infrapatellar fold may be identified as a vestige of the inferior boundary of the originally separate femoropatellar joint (p. 491).

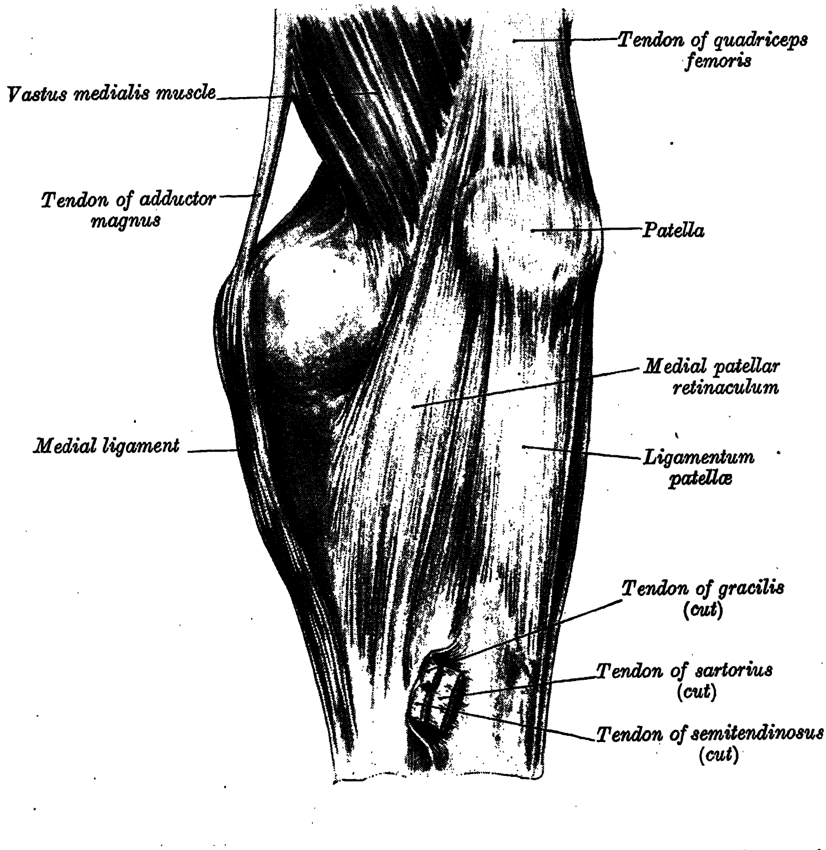
At the sides of the joint the synovial membrane passes downwards from the femur, lining the capsular ligament as far as its attachment to the semilunar cartilages. In the fœtus it may then be traced over the upper surfaces of these to their free borders, and thence along their under surfaces to the tibia, but, in the adult, owing to the pressure to which they have been subjected, the fibro-cartilages are devoid of a synovial investment. At the back part of the lateral semilunar cartilage the synovial membrane forms a cul-de-sac between the groove on the surface of the cartilage and the tendon of the popliteus.

The **ligamentum patellæ** (fig. 555) is the central portion of the common tendon of the quadriceps femoris, which is continued from the patella to the tubercle of the tibia. It is a strong, flat, ligamentous band, about 8 cm. in length, attached, above, to the apex and adjoining margins and to the rough depression on the lowest part of the posterior surface of the patella; and below, to the upper part of the tubercle of the tibia; its superficial fibres are con-

tinuous over the front of the patella with those of the tendon of the quadriceps femoris. The medial and lateral portions of the tendon of the quadriceps pass down, one on each side of the patella, to be inserted into the upper extremity of the tibia, one on each side of the tubercle; these portions merge into the capsular ligament, as stated above, forming the medial and lateral patellar retinacula. The posterior surface of the ligamentum patellæ is separated from the synovial membrane by a large infrapatellar pad of fat, and from the tibia by a bursa.

The **oblique posterior ligament** (oblique popliteal ligament) (fig. 556) is a broad, flat, fibrous band, formed of fasciculi separated from one another by apertures for the passage of vessels and nerves. It is attached, above, to the lateral part of the intercondylar line and to the lateral condyle of the femur, and

Fig. 555.—The left knee-joint. Anteromedial aspect.



below, it gradually blends with the capsular ligament, which constitutes its principal connexion. It consists of a strong fasciculus which is derived from the tendon of the semimembranosus close to its insertion into the tibia, and it becomes partially blended with the capsule as it passes upwards and laterally across its posterior part. The oblique posterior ligament forms part of the floor of the popliteal fossa, and the popliteal artery rests upon it.

The **arcuate ligament of the knee** (arcuate popliteal ligament) (fig. 556) is an arched bundle of fibres which varies somewhat in strength and appearance. It is attached to the lateral condyle of the femur and passes downwards to fuse with the capsular ligament. Two bands, an anterior and a posterior, converge from the upper and lower extremities of the arcuate ligament; they unite below to form the *retinaculum* of the ligament, which is fixed to the styloid process of the head of the fibula. The anterior band of this retinaculum is sometimes described as the *short lateral (fibular collateral) ligament* and the

popliteus emerges from under cover of the posterior band (fig. 556). In fig. 556 the oblique upper border of the arcuate ligament shows an upward concavity, but in many cases it is straight and blended with the capsule. Some anatomists describe the ligament as a Λ-shaped band, consisting of femorotibial and femoro-fibular parts, which straddle the emerging tendon of the popliteus muscle.

The **medial** (tibial collateral) **ligament** (figs. 555, 561) is a broad, flat band, situated nearer to the back than to the front of the joint. It is attached, above, to the medial epicondyle of the femur immediately below the adductor tubercle; below, to the medial condyle and medial surface of the shaft of the tibia. The fibres of the posterior part of the ligament are short and incline backwards

Fig. 556.—The right knee-joint. Posterior aspect.

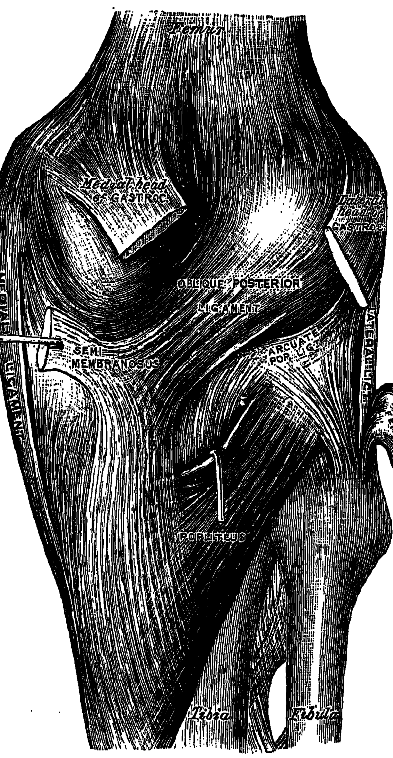


Fig. 557.—The right knee-joint. Dissected from the front.

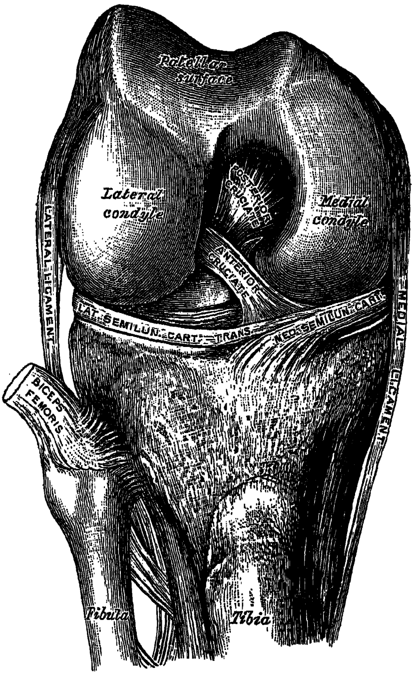


as they descend; they are inserted into the tibia above the groove for the semimembranosus. The anterior part of the ligament, about 10 cm. long, inclines forwards as it descends; it is inserted into the medial margin and the posterior part of the medial surface of the shaft of the tibia (fig. 468). It is crossed, at its lower part, by the tendons of the sartorius, gracilis, and semitendinosus, a bursa being interposed. Its deep surface covers the inferior medial genicular vessels and nerve, and the anterior portion of the tendon of the semimembranosus with which it is connected by a few fibres; *its upper part is intimately adherent to the periphery of the medial semilunar cartilage.*

The **lateral** (fibular collateral) **ligament** (fig. 557) is a strong, rounded cord, attached, above, to the lateral epicondyle of the femur, immediately above the groove for the tendon of the popliteus; below, to the lateral side of the head of the fibula, in front of the styloid process. The greater part of it is hidden by the tendon of the biceps femoris, but the tendon divides at its insertion into two parts, which are separated by the ligament. Deep to the ligament are the tendon of the popliteus and the inferior lateral genicular vessels and nerve. *The ligament has no attachment to the lateral semilunar cartilage.*

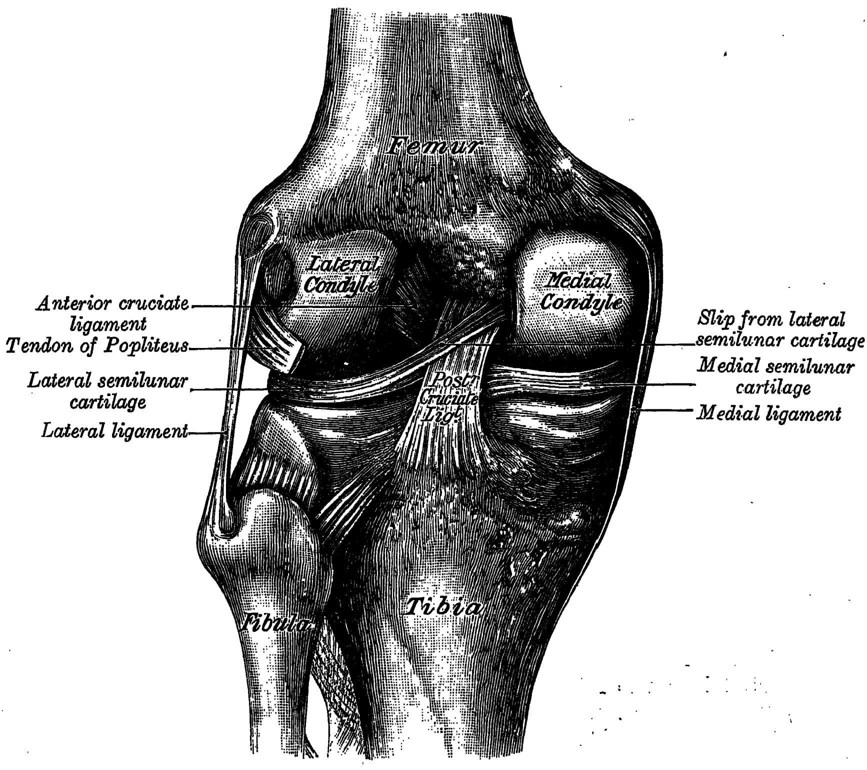
The **cruciate ligaments** are of considerable strength, and are situated in the

middle of the joint, nearer to its posterior than its anterior surface. They are called *cruciate* because they cross each other somewhat like the limbs of the letter X; and have received the names *anterior* and *posterior*, from the position of their attachments to the tibia. Their position within the joint justifies their identification as collateral ligaments of the originally separate medial and lateral femorotibial joints (p. 491).

The **anterior cruciate ligament** (fig. 559) is attached to the medial part of the anterior portion of the intercondylar area of the tibia, being partly blended with the anterior end of the lateral semilunar cartilage; it passes upwards, backwards and laterally, and is attached to the posterior part of the medial surface of the lateral condyle of the femur.

The **posterior cruciate ligament** (fig. 558) is stronger, but shorter and less oblique in its direction, than the anterior. It is attached to the posterior part

FIG. 558.—The left knee-joint. Dissected from behind.



of the intercondylar area of the tibia, and to the posterior extremity of the lateral semilunar cartilage; it passes upwards, forwards and medially, to be attached to the lateral surface of the medial condyle of the femur.

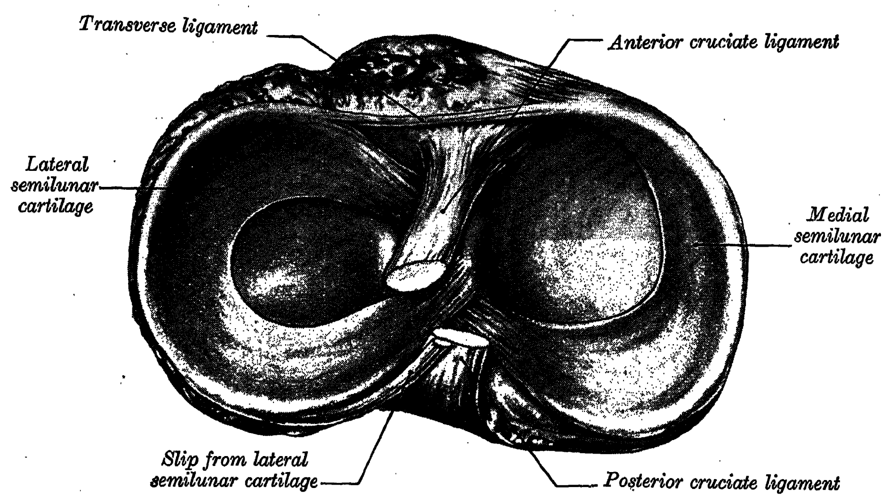
The **semilunar cartilages** (menisci) (fig. 559) are two crescentic lamellæ, which serve to deepen the surfaces of the upper end of the tibia for articulation with the condyles of the femur. The peripheral border of each cartilage is thick and convex; the opposite border is thin, concave, and free. The upper surfaces of the cartilages are smooth and concave, and in contact with the condyles of the femur; their lower surfaces are smooth and flat, and rest upon the tibia. Each covers approximately the peripheral two-thirds of the corresponding articular surface of the tibia.

The **medial semilunar cartilage** is nearly semicircular in form, and is broader behind than in front; its anterior end is attached to the anterior part of the intercondylar area of the tibia, in front of the anterior cruciate ligament, its posterior fibres being continuous with the transverse ligament; its posterior end is fixed to the posterior part of the intercondylar area of the tibia, between

the attachments of the lateral semilunar cartilage and the posterior cruciate ligament. Its peripheral border is attached to the capsular ligament and *is firmly adherent to the deep surface of the medial ligament of the knee-joint.*

The lateral semilunar **cartilage** is nearly circular and covers a larger portion of the articular surface than the medial cartilage. It is of the same breadth throughout its extent, and is grooved posteriorly by the tendon of the popliteus, which separates it from the lateral ligament of the knee-joint. Its anterior end is attached in front of the intercondylar eminence of the tibia, behind and lateral to the anterior cruciate ligament, with which it partly blends; the posterior end is attached behind the intercondylar eminence of the tibia, in front of the posterior end of the medial cartilage. The anterior attachment of the lateral semilunar cartilage is twisted so that its free margin looks backwards and upwards, its anterior end resting on a sloping shelf of bone on the front of the lateral intercondylar tubercle. Close to its posterior attachment it sends off a strong fasciculus (figs. 558, 559), which passes upwards and medially, to be inserted into the medial condyle of the femur, immediately behind the attachment of

FIG. 559.—The upper end of the left tibia, showing the semilunar cartilages and the lower ends of the cruciate ligaments.



the posterior cruciate ligament. Occasionally a small fasciculus passes forwards to be inserted into the lateral part of the anterior cruciate ligament. *The tendon of the popliteus muscle intervenes between the lateral semilunar cartilage and the lateral ligament of the knee-joint.*

The **transverse ligament** (fig. 559) connects the anterior convex margin of the lateral to the anterior end of the medial semilunar cartilage; its thickness varies considerably in different subjects, and it is sometimes absent.

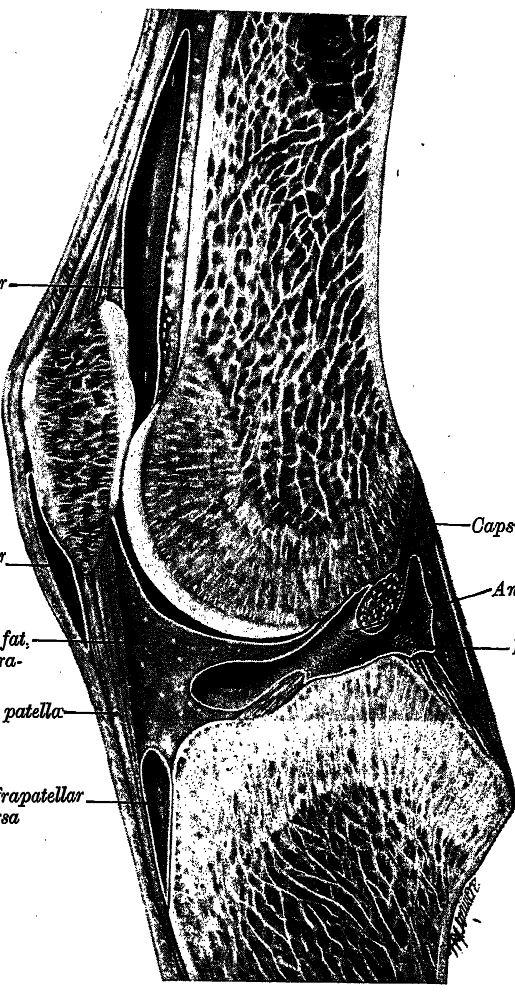
The **coronary ligaments** are merely portions of the capsule, connecting the periphery of each semilunar cartilage with the margin of the head of the tibia.

Bursæ.—The bursæ near the knee-joint are the following:

In front there are four bursæ: a large one (*subcutaneous prepatellar bursa*) is interposed between the lower part of the patella and the skin, a small one (*deep infrapatellar bursa*) between the upper part of the tibia and the ligamentum patellæ, a third (*subcutaneous infrapatellar bursa*) between the lower part of the tubercle of the tibia and the skin, and a fourth, of large size (*suprapatellar bursa*), which usually communicates with the knee-joint, between the anterior surface of the lower part of the femur and the deep surface of the quadriceps femoris (fig. 560). Laterally there are four bursæ: (1) one (which sometimes communicates with the joint) between the lateral head of the gastrocnemius and the capsule; (2) one between the lateral ligament and the tendon of the biceps femoris; (3) one between the same ligament and the tendon of the popliteus (this is sometimes only an expansion from the next bursa); (4) one between the

tendon of the popliteus and the lateral condyle of the femur, usually an extension from the synovial membrane of the joint. Medially, there are five bursæ: (1) one between the medial head of the gastrocnemius and the capsule: this sends a prolongation between the tendon of the medial head of the gastrocnemius and the tendon of the semimembranosus and often communicates with the joint; (2) one (*tibial intertendinous bursa*) superficial to the medial ligament, between it and the tendons of the sartorius, gracilis, and semitendinosus; (3) one deep to the medial ligament, between it and the tendon of the semi-

FIG. 560.—A sagittal section through the right knee-joint. Lateral aspect. The synovial membrane is shown in colour.



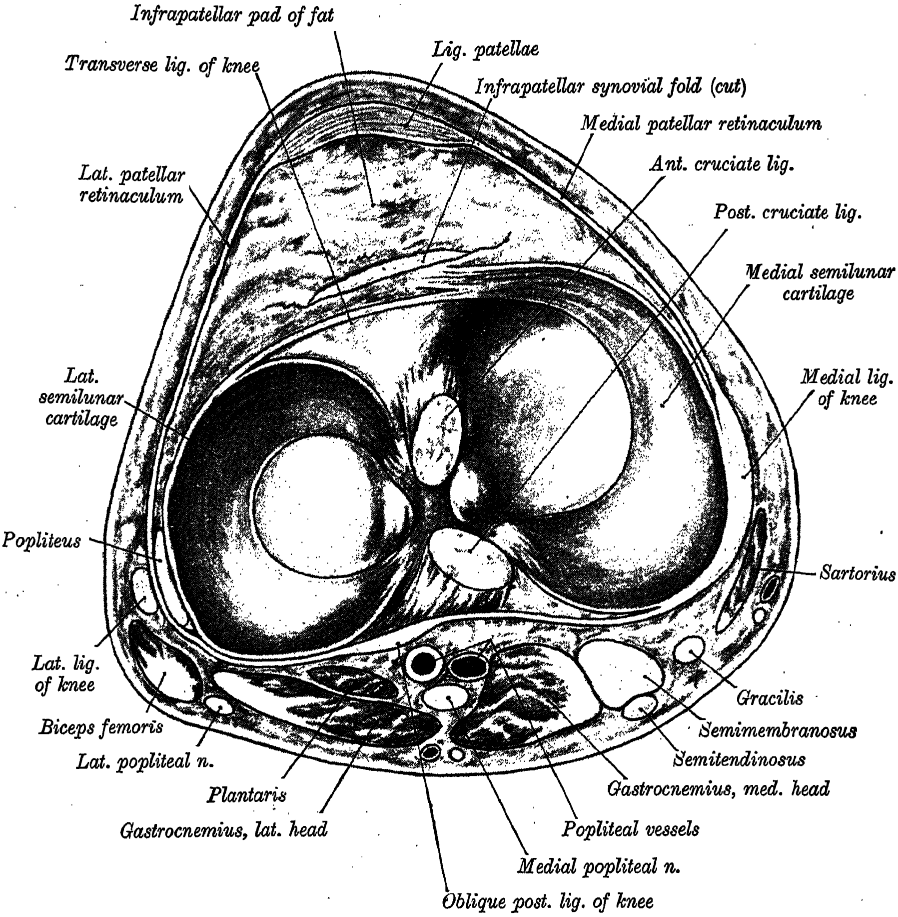
membranosus (this is sometimes only an expansion from the next bursa); (4) one between the tendon of the semimembranosus and the medial condyle of the tibia; (5) occasionally there is a bursa between the tendons of the semimembranosus and semitendinosus.

Structures around the joint.—*Anteriorly*, the quadriceps femoris covers the joint, and tendinous expansions from the vastus medialis and vastus lateralis extend backwards from its margins over the *anteromedial* and *anterolateral* aspects of the capsule, respectively, forming the patellar retinacula. On the *posteromedial* side the sartorius, with the gracilis tendon lying along its posterior border, descends across the joint; on the *posterolateral* side the biceps tendon, with the lateral popliteal nerve on its medial side, is in contact with the capsule, which separates it from the popliteus (fig. 561). The *posterior* relations are the most numerous and the most important. The popliteal artery, with its

associated lymph glands, lies on the posterior ligament; the popliteal vein is posteromedial, or medial, to the artery; and the medial popliteal nerve is posterior to both vessels. The nerve and vessels are overlapped by the adjoining edges of the two heads of the gastrocnemius and, on the lateral side, by the plantaris. On each side of the vessels the corresponding head of the gastrocnemius comes into intimate relation with the capsule, and on the medial side of the medial head the semimembranosus intervenes between the capsule and the semitendinosus.

The *arteries* supplying the joint are the descending genicular (a. genu suprema), the genicular branches of the popliteal, the recurrent branches of

FIG. 561.—A transverse section of the left knee-joint, viewed from above, to show the relations of the joint.



the anterior tibial, and the descending branch from the lateral circumflex femoral branch of the arteria profunda femoris.

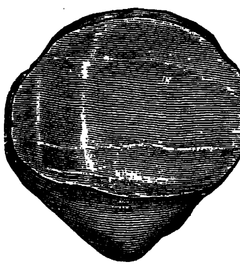
The *nerves* are derived from the obturator, femoral, medial and lateral popliteal (tibial and common peroneal).

Movements.—The active movements which can be carried out at the knee-joint are flexion, extension, medial rotation and lateral rotation. The movements of flexion and extension differ from those of a typical hinge-joint, such as the elbow, in two ways. Firstly, the axis around which the movement occurs is not fixed, but shifts forwards during extension of the leg on the thigh and backwards during flexion. Secondly, extension is associated with a minor degree of lateral rotation of the leg, and flexion with a corresponding degree of medial rotation. In full flexion the posterior parts of the tibial articular surfaces are in contact with the posterior parts of the articular surfaces of the

femoral condyles. During extension the tibia and its semilunar cartilages glide forwards on the femoral condyles and the axis around which the movement takes place gradually shifts forwards. As a result the point of contact between the two bones moves forwards also, carrying the semilunar cartilages with it. As the movement progresses the flatter curve of the femoral condyles makes contact with the tibia, and the curves of the semilunar cartilages are opened out, the net result being that the anterior ends of the cartilages move forwards, while their posterior ends suffer little change in position. In flexion the reverse movement occurs, so that the cartilages adapt their outline to the curve of the parts of the femoral condyles which are making contact with the tibia.

The movement of lateral rotation* of the tibia which is associated with extension of the bone on the femur constitutes a locking mechanism which is of importance when the fully extended knee is subjected to strain. The axis of rotation passes vertically through the lateral condyle medial to its centre, and on this account the medial tibial condyle has a longer traverse than the lateral, and the articular surfaces of both the tibia and the femur reflect this fact. It is usually stated that the lateral rotation referred to occurs at the last stage of extension and has the effect of screwing the joint home and locking it. It must be observed, however, that the rotation is not necessary to ensure stability in the erect posture, for in that position the joint is not fully extended, and it can be extended voluntarily still further until the limit of the movement is reached. This is due to the fact that although the weight of the trunk falls behind the line joining the centres of the femoral heads, it falls in front of the transverse axis of the knee-joint and tends to cause hyperextension of the joint. This is prevented by the tension of the hamstring muscles, so that the quadriceps is partially relaxed in the erect attitude and, as a result, the patella lies loosely on the front of the lower end of the femur.

FIG. 562.—The posterior surface of the right patella, showing diagrammatically the areas of contact with the femur in different positions of the knee-joint.



In addition to the rotatory movements associated with extension and flexion, medial and lateral rotation of the leg can be effected when the joint is partly flexed; these movements are freest when the leg is bent at right angles with the thigh.

At the limit of flexion the ligamentum patellæ and part of the posterior cruciate ligament are stretched, while the oblique posterior and collateral ligaments and, to a slight extent, the anterior cruciate ligament are relaxed. Flexion is checked during life by the contact of the leg with the thigh. When the knee-joint is fully extended the oblique posterior, collateral and anterior cruciate ligaments and the posterior fibres of the posterior cruciate ligament are tense; in the act of extending the knee the ligamentum patellæ is tightened by the quadriceps femoris, but in the erect attitude it is relaxed for reasons already stated. Medial rotation is checked by the anterior cruciate ligament and the tension of the biceps femoris; lateral rotation tends to uncross and relax the cruciate ligaments, but is checked by the collateral ligaments and the tension of the medial rotators. The main function of the cruciate ligaments is to act as a direct bond between the tibia and femur and to prevent the former bone from being carried too far backwards or forwards. They also assist the collateral ligaments in resisting any bending of the joint to either side. The semilunar cartilages ensure that perfect contact is maintained between the articular surfaces in all positions of the joint. They move with the femur on the tibia in gliding and rotatory movements, but with the tibia on the femur in flexion and extension. The patella is a great defence to the front of the knee-joint; it also affords leverage to the quadriceps femoris.

Accessory movements.—A wider range of rotation can be obtained by passive movements than can be performed actively when the joint is semiflexed, and in

* The actual mechanism whereby this rotation is effected is very difficult to explain, and none of the theories hitherto advanced is really satisfactory.

this position the tibia can be made to glide backwards and forwards on the femur. When the knee is slightly flexed a limited amount of adduction and abduction can be obtained, and it may be noted that these movements can be performed actively, provided that the foot is on the ground. A slight amount of separation of the femur and tibia can be obtained on strong traction.

Muscles producing the movements :

In **flexion**, the *biceps femoris, semitendinosus* and *semimembranosus* are the principal muscles concerned, but they receive assistance from the gracilis, sartorius and popliteus. When the foot is on the ground, the gastrocnemius and the plantaris are capable of participating in the movement.

In **extension**, the *quadriceps femoris* is the chief muscle concerned, but it receives some assistance from the tensor fasciæ latæ.

In **medial rotation of the flexed leg**, the *popliteus, semimembranosus* and *semitendinosus* are the chief agents, but they may be assisted by the sartorius and the gracilis.

In **lateral rotation of the flexed leg**, the biceps femoris is the only muscle concerned.

Applied Anatomy.—From a consideration of the construction of the knee-joint, it would at first sight appear to be one of the least secure joints in the body. It is formed between the two longest bones, and therefore the amount of leverage which can be brought to bear upon it is considerable; the articular surfaces are but ill-adapted to each other, and the range of motion which it enjoys is great. All these circumstances tend to render the articulation insecure; nevertheless, on account of the powerful ligaments which bind the bones together and the strength of the muscles concerned, the joint is one of the strongest in the body, and dislocation from traumatism is a rare occurrence.

One or other of the semilunar cartilages may be torn or detached, tearing being the commoner accident; when a cartilage is torn it is the thin, central portion which is separated. The torn part projects into the interior, and leads to locking of the joint in the semiflexed position. The accident is produced by a twist of the leg when the knee is slightly flexed, and is accompanied by a sudden pain, and often by fixation of the knee in the flexed position. The torn part of the cartilage may be displaced either towards the tibial intercondylar eminence, so that it becomes lodged in the intercondylar notch, or to one side, so that it projects beyond the margin of the two articular surfaces. The medial semilunar cartilage is much more commonly affected than the lateral because it is more securely attached to neighbouring structures (p. 497) and is therefore less able to adapt itself to sudden changes of position. Further, during the slight rotation of the joint it moves through a greater interval than the lateral cartilage.

The cruciate ligaments are sometimes ruptured, but great violence is necessary to produce this injury. When the anterior is torn the tibia can be pushed forwards; when the posterior is torn the tibia can be pulled backwards.

Acute synovitis, the result of traumatism, is of frequent occurrence in the knee-joint. When the cavity is distended with fluid, the swelling shows itself above and at the sides of the patella, reaching about 2·5 cm., occasionally 5 cm. or more, above the patellar surface of the femur, and extending a little higher under the vastus medialis than under the vastus lateralis. The lower level of the synovial membrane is just below the upper end of the tibia.

The bursæ about the knee-joint are sometimes the seat of enlargement. The bursa between the front of the patella and the skin is frequently affected in those who are in the habit of kneeling, and the condition is known as 'housemaid's knee.' The bursa beneath the semimembranosus tendon also occasionally becomes enlarged, and forms a fluctuating swelling at the back of the knee. During extension the swelling is firm and tense; but during flexion it becomes soft, and, as the bursa often communicates with the synovial cavity of the joint, the fluid it contains can be made to disappear by pressure when the knee is flexed.

III. THE TIBIOFIBULAR JOINTS

The tibia and the fibula are connected at their extremities by (1) the superior and (2) the inferior tibiofibular joints. (3) In addition, the shafts of the bones are connected by the crural interosseous membrane.

1. The Superior Tibiofibular Joint

This articulation (fig. 558) is a plane joint between the lateral condyle of the tibia and the head of the fibula. The *articular surfaces* of the bones present flat, oval facets covered with cartilage, and the bones are connected by a capsular ligament and by anterior and posterior ligaments.

The **capsular ligament** is attached to the margins of the articular facets on the tibia and fibula ; it is much thicker in front than behind. Not infrequently the synovial membrane of the joint is continuous with that of the knee-joint through the popliteus bursa.

The **anterior ligament** consists of two or three flat bands, which pass obliquely upwards from the front of the head of the fibula to the front of the lateral condyle of the tibia.

The **posterior ligament** is a thick band, which passes obliquely upwards from the back of the head of the fibula to the back of the lateral condyle of the tibia. It is covered by the tendon of the popliteus.

2. The Crural Interosseous Membrane

The **crural interosseous membrane** connects the interosseous borders of the tibia and fibula, and separates the muscles on the front from those on the back of the leg. The anterior tibial artery passes to the front of the leg through a large oval opening in the uppermost part of the membrane, and the perforating branch of the peroneal artery pierces its lower part. It consists of oblique fibres, which for the most part run downwards and laterally; a few, however, pass downwards and medially, including a bundle which forms the upper border of the opening for the anterior tibial artery. The membrane is continuous below with the interosseous ligament of the inferior tibiofibular joint. It is in relation, in front, with the tibialis anterior, extensor digitorum longus, extensor hallucis longus, peroneus tertius, and the anterior tibial vessels and anterior tibial (deep peroneal) nerve; behind, with the tibialis posterior and flexor hallucis longus.

3. The Inferior Tibiofibular Joint (Tibiofibular Syndesmosis)

This syndesmosis is formed by the rough, convex surface on the medial side of the lower end of the fibula, and a rough, concave surface (the fibular notch) on the lateral side of the tibia. Below, to the extent of about 4 mm., these surfaces are smooth, and covered with cartilage continuous with that of the ankle-joint. The ligaments are : anterior, posterior, inferior transverse and interosseous.

The **anterior inferior tibiofibular ligament** (fig. 567) is a flattened band, which extends obliquely downwards and laterally between the adjacent margins of the tibia and fibula, on the front of the syndesmosis.

The **posterior inferior tibiofibular ligament** (fig. 564), smaller than the preceding, is disposed in a similar manner on the posterior surface of the syndesmosis. Its lower and deep portion forms the **inferior transverse ligament**—a strong, thick band of yellowish fibres which passes transversely from the upper part of the malleolar fossa of the fibula to the posterior border of the articular surface of the tibia, almost as far as the medial malleolus. The inferior transverse ligament projects below the margins of the bones, and forms part of the articulating surface for the talus.

The **interosseous ligament** is continuous, above, with the crural interosseous membrane and consists of numerous, short, strong bands which pass between the adjacent rough surfaces of the tibia and fibula, and constitute the chief bond of union between the lower ends of the bones.

IV. THE ANKLE-JOINT

The ankle-joint is a ginglymus, or hinge-joint. The lower end of the tibia and its malleolus, the malleolus of the fibula, and the inferior transverse tibiofibular ligament enter into its formation, and together form a mortise for the reception of the body of the talus. The *articular surfaces* are covered with hyaline cartilage. The trochlear surface of the talus, which is convex from before backwards and gently concave from side to side, is *wider in front than behind*, and the inferior articular surface of the tibia is reciprocally shaped. The articular surface for the medial malleolus is restricted to the upper part of the medial surface of the talus. It is flat and comma-shaped, being deeper in

front than behind. The lateral surface of the talus, which is triangular in outline, is concave from above downwards and adapts itself to the articular surface of the lateral malleolus, which is convex from above downwards.

Fig. 563.—The synovial cavity of the left ankle-joint (distended). Lateral aspect. (From a specimen prepared by J. C. B. Grant.)

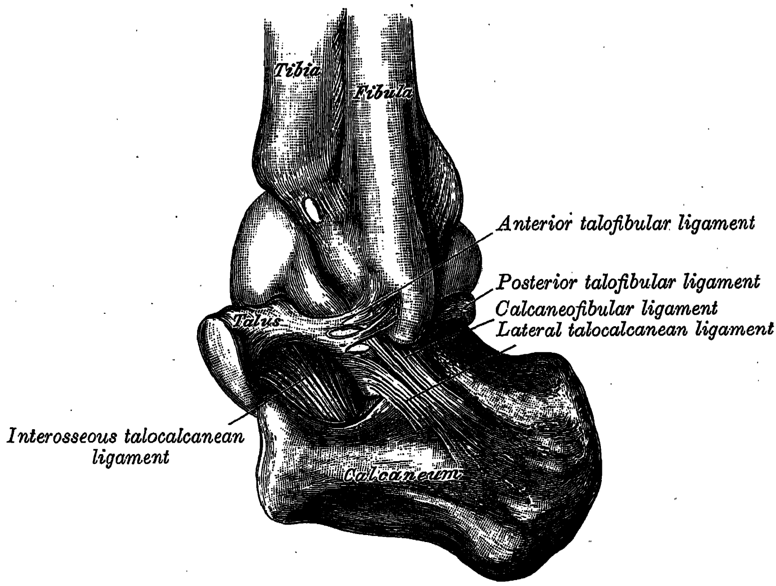


Fig. 564.—The left ankle-joint. Posterior aspect.

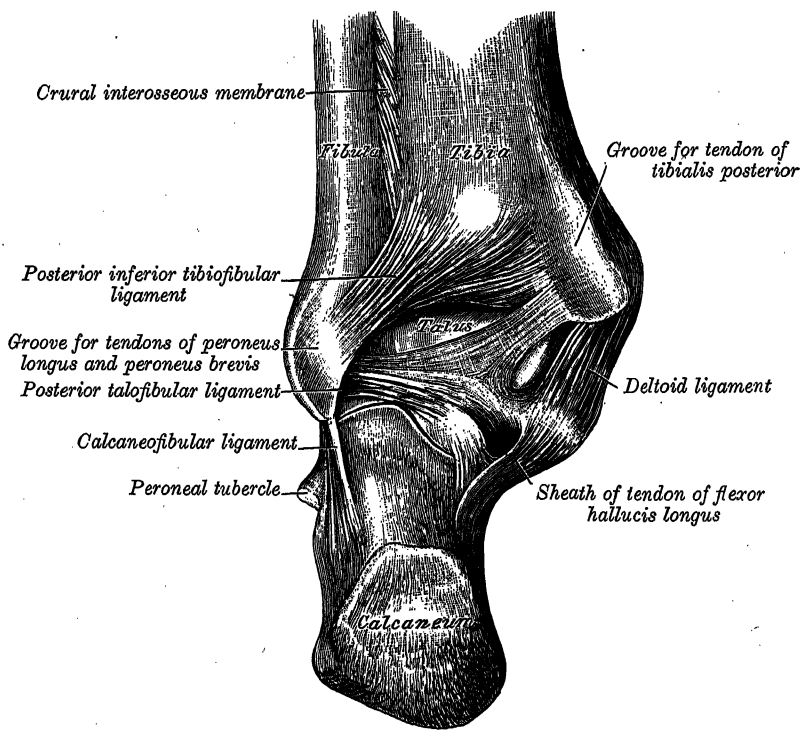


The bones are connected by the following ligaments :

Capsular.	Lateral.
Anterior and posterior.	Anterior and posterior talofibular.
Deltoid.	Calcaneofibular.

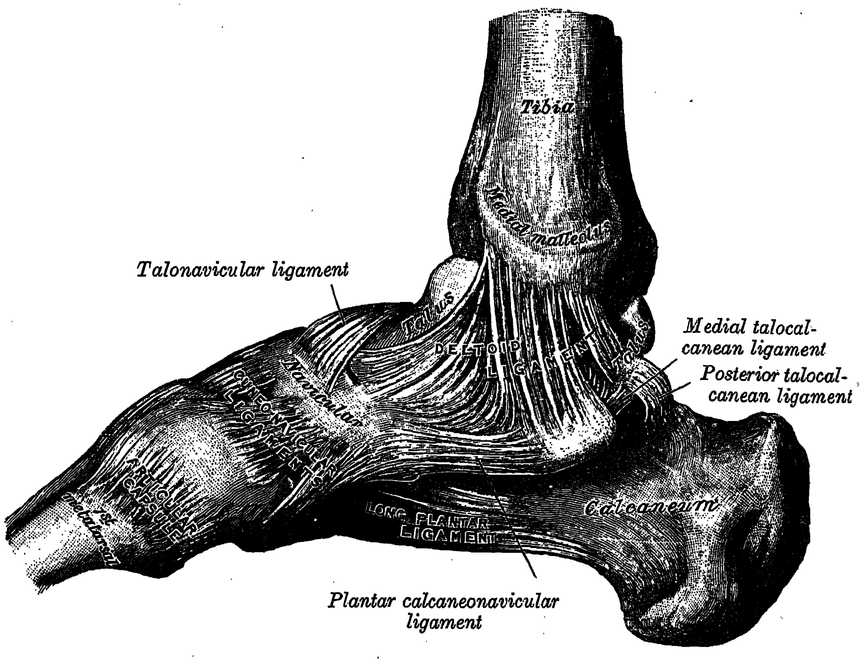
The **capsular ligament** (fig. 565) surrounds the joint, and is attached, above, to the borders of the articular surfaces of the tibia and malleoli. Below, it is attached to the dorsum of the neck of the talus a little in front of the trochlear surface, and elsewhere it is attached close to the margins of the articular surfaces.

The **anterior ligament** is a broad, thin, membranous layer attached, above, to the anterior margin of the lower end of the tibia, and below to the talus, a little in front of its superior articular surface.

The **posterior ligament** is very thin and consists principally of transverse fibres. It is attached, above, to the posterior margin of the articular surface of the tibia, blending with the inferior transverse ligament, and below, to the talus behind its superior articular facet. Laterally, it is somewhat thickened and reaches as far as the malleolar fossa of the fibula.

A synovial membrane lines the capsular ligament, and the joint-cavity ascends for a short distance between the tibia and fibula (fig. 568).

Fig. 565.—The ligaments of the right ankle and tarsus. Medial aspect.



The **deltoid ligament** (figs. 565, 568) is a strong, triangular band, attached, above, to the apex and anterior and posterior borders of the medial malleolus. It consists of two sets of fibres, superficial and deep. Of the superficial fibres the anterior (*tibionavicular*) pass forwards to be attached to the tuberosity of the navicular bone, and immediately behind this they blend with the medial margin of the plantar calcaneonavicular ligament; the middle fibres (*calcaneotibial*) descend almost perpendicularly and are fixed to the whole length of the sustentaculum tali of the calcaneum; the posterior fibres (*posterior talotibial*) pass backwards and laterally to be attached to the medial side of the talus, and to its medial tubercle. The deep fibres (*anterior talotibial*) are fixed above, to the tip of the medial malleolus, and, below, to the non-articular part of the medial surface of the talus. The deltoid ligament is crossed by the tendons of the tibialis posterior and flexor digitorum longus.

The **lateral ligament** consists of three separate bands, termed the anterior talofibular, the posterior talofibular and the calcaneofibular.

The **anterior talofibular ligament** (fig. 567) passes from the anterior margin of the fibular malleolus, forwards and medially, to the talus, where it is attached in front of the lateral articular facet and to the lateral aspect of the neck.

The **posterior talofibular ligament** (fig. 564), strong and deeply seated, runs

FIG. 566.—Transverse section through the lower part of the ankle-joint.

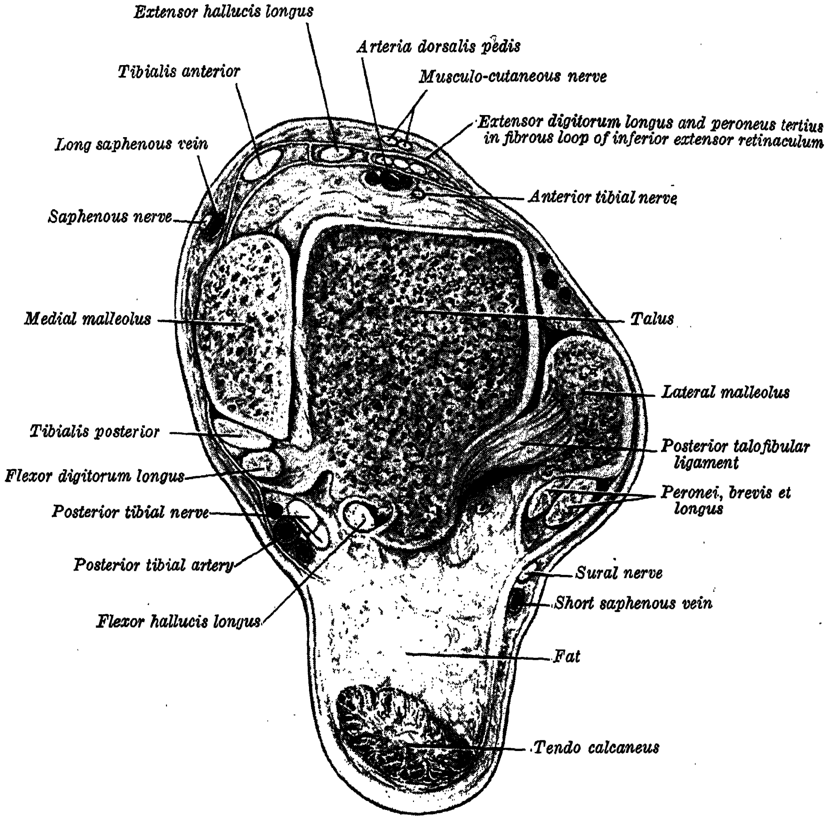


FIG. 567.—The ligaments of the right ankle and tarsus. Lateral aspect.

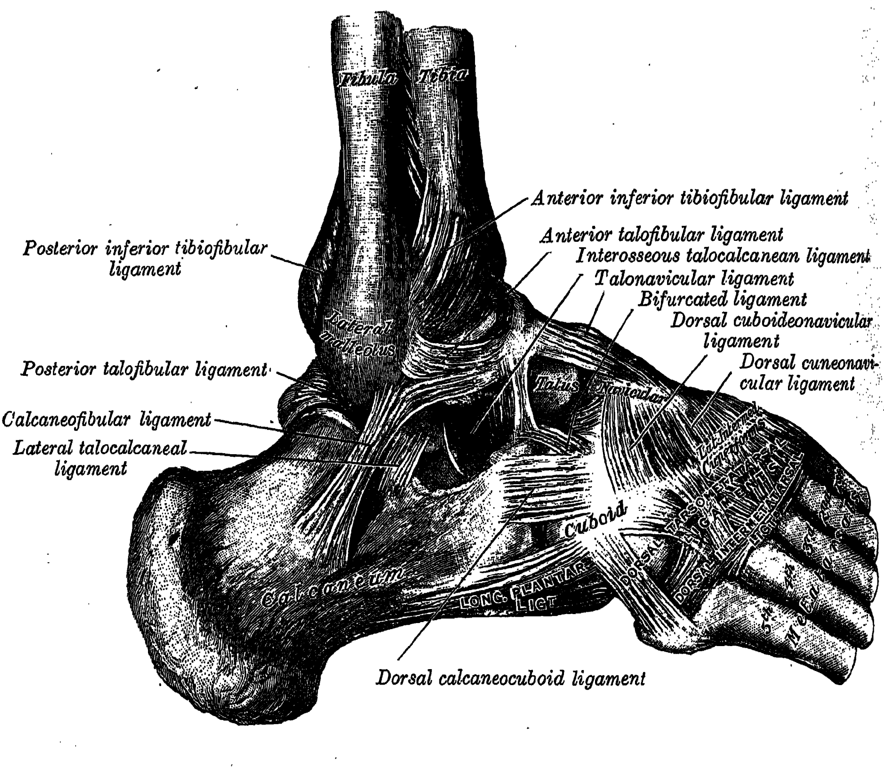


almost horizontally from the lower part of the malleolar fossa to the posterior tubercle of the talus.

The **calcaneofibular ligament** (fig. 567) is a long rounded cord, running from the depression in front of the apex of the fibular malleolus downwards and slightly backwards to a tubercle on the lateral surface of the calcaneum. It is crossed by the tendons of the peroneus longus and brevis.

Relations.—The tendons, vessels, and nerves in relation with the joint are: in front, from the medial side, the tibialis anterior, extensor hallucis longus, anterior tibial vessels, anterior tibial (deep peroneal) nerve, extensor digitorum longus, and peroneus tertius; behind, from the medial side, the tibialis posterior, flexor digitorum longus, posterior tibial vessels, posterior tibial nerve (tibial nerve), flexor hallucis longus; and, in the groove behind the fibular malleolus, the tendons of the peroneus longus and brevis (fig. 566).

The *arteries* supplying the joint are derived from the malleolar branches of the anterior tibial and from the peroneal.

The *nerves* are derived from the anterior and posterior tibial (deep peroneal and tibial).

Movements.—When the body is in the erect position the foot is at right angles to the leg. The *active movements* of the ankle-joint are those of dorsiflexion and plantar-flexion; in dorsiflexion the angle between the front of the leg and the dorsum of the foot is diminished; in plantar-flexion the angle is increased, the heel being raised and the toes pointed downwards. The malleoli embrace the talus in the position of rest, and no appreciable degree of side-to-side movement can occur without stretching of the ligaments of the inferior tibiofibular joint, and slight bending of the fibula. The superior articular surface of the talus is broader in front than behind. In dorsiflexion, therefore, greater space is required between the two malleoli. This is obtained by a slight separation of the lower ends of the tibia and fibula and is consequent on slight movement at the inferior tibiofibular joint; this movement is facilitated by a minor degree of gliding at the superior tibiofibular joint. The deltoid ligament is exceedingly strong—so much so, that it usually resists a force which fractures the process of bone to which it is attached. Its middle portion, together with the calcaneofibular ligament, binds the bones of the leg firmly to the foot, and resists displacement in every direction. The posterior talofibular ligament assists the calcaneofibular in resisting the displacement of the foot backwards, and deepens the cavity for the reception of the talus. The anterior talofibular ligament is a security against the displacement of the foot forwards. Plantar-flexion of the foot is limited by the tension of the opposing muscles, by the anterior fibres of the deltoid and by the anterior talofibular ligament. Dorsiflexion of the foot is limited by the tension of the tendo calcaneus, by the posterior fibres of the deltoid and by the calcaneofibular ligament.

Accessory movements.—Slight amounts of side to side gliding movement, rotation, abduction and adduction are permitted, when the foot is in plantar flexion.

Muscles producing the movements :

In **dorsiflexion** the *tibialis anterior* is the most important factor, but it receives appreciable assistance from the extensor digitorum longus, the extensor hallucis longus and the peroneus tertius.

In **plantar-flexion,** the *gastrocnemius* and the *soleus* are the chief agents, assisted to a lesser degree by the peroneus longus and brevis, the plantaris, the tibialis posterior, the flexor hallucis longus and the flexor digitorum longus.

Applied Anatomy.—Owing to the protection afforded to the talus by the tibiofibular mortise, the ankle-joint is a very stable articulation and dislocation is rare unless one of the malleoli is fractured. So-called sprains of the ankle-joint are almost always abduction sprains of the subtalar joints, although some of the fibres of the deltoid ligament also are torn. True sprains of the ankle-joint are usually caused by forced plantar flexion and result in tearing of the capsular ligament on the front of the joint and bruising by impaction of the structures at the back of the joint.

When disease or injury of the ankle-joint is likely to lead to ankylosis, the joint is kept dorsiflexed to rather less than a right angle.

V. THE INTERTARSAL JOINTS

1. The Talocalcanean Joint

There are two articulations between the calcaneum and talus, an anterior and a posterior; the anterior forms part of the talocalcaneonavicular joint, and is described with it (p. 509). The posterior or talocalcanean joint is formed between the convex, posterior calcanean facet on the inferior surface of the talus, and the concave, posterior facet on the superior surface of the calcaneum. It is a plane joint, and the two bones are connected by a capsular ligament and by anterior, posterior, lateral, medial and interosseous talocalcanean ligaments.

The **capsular ligament** envelops the joint, and consists for the most part of

Fig. 568.—A coronal section through the left ankle and talocalcaneal joints.

short fibres; it is split into slips, and between these there is only a weak fibrous investment. It is lined with synovial membrane, and the joint-cavity does not communicate with any of the other tarsal joints.

The **anterior talocalcanean ligament** (fig. 570) extends from the inferior and lateral surfaces of the neck of the talus to the superior surface of the calcaneum. It is identical with the posterior part of the interosseous talocalcanean ligament.

The **posterior talocalcanean ligament** (fig. 565) connects the posterior tubercle of the talus with the upper surface of the calcaneum close to the posterior facet; it is a short band, and its fibres radiate from their narrow attachment on the talus.

The **lateral talocalcanean ligament** (fig. 567) is a short, flattened fasciculus, which passes downwards and backwards from the lateral tubercle of the talus to be attached to the lateral surface of the calcaneum, above and in front of the calcaneofibular ligament.

The **medial talocalcanean ligament** connects the medial tubercle on the

posterior surface of the talus with the back of the sustentaculum tali. Its fibres blend with those of the deltoid ligament.

The **interosseous talocalcanean ligament** (figs. 568, 570) forms the chief bond of union between the bones and is attached, above, to the sulcus tali ; below, to the sulcus calcanei. It comprises the posterior ligament of the talocalcaneo-navicular joint and the anterior ligament of the talocalcanean joint. Medially, these two ligaments are fused, but laterally they are separated by a band of fibres derived from the fibrous loop which encloses the tendons of the peroneus tertius and the extensor digitorum longus in front of the ankle-joint (p. 650). The lateral part of the anterior portion of the talocalcanean interosseous ligament is especially strengthened and extends between the inferolateral aspect of the neck of the talus and the upper surface of the calcaneum (fig. 570). It is rendered taut when the foot is inverted and prevents the occurrence of too great a degree of this movement.

Movements.—The movements permitted between the talus and calcaneum are closely associated with the movements at the talocalcaneonavicular joint and will be described with them.

2. The Talocalcaneonavicular Joint

This articulation is a restricted form of ball-and-socket joint : the rounded head of the talus being received into the concavity formed by the posterior surface of the navicular, the anterior upper articular surface of the calcaneum, and the upper surface of the plantar calcaneonavicular ligament. The bones forming the joint are connected by a capsular ligament, and by the talonavicular, the plantar calcaneonavicular and the lateral calcaneonavicular ligaments.

The **capsular ligament** is imperfectly developed except posteriorly, where it is considerably thickened and forms the anterior part of the interosseous ligament, which fills the sinus tarsi formed by the opposing grooves on the calcaneum and talus, as mentioned above.

The **talonavicular ligament** (fig. 565) is a broad, thin band, connecting the neck of the talus to the dorsal surface of the navicular bone ; it is covered with the extensor tendons. The plantar calcaneonavicular ligament (p. 511) is the plantar, and the lateral calcaneonavicular (*vide infra*) the lateral ligament for this joint.

Movements.—A considerable range of gliding and rotatory movement is permitted at both the talocalcanean and the talocalcaneonavicular joints. The calcaneum and the navicular, carrying the foot with them, can be moved medially on the talus in a combination of gliding movement and rotation.* This movement results in the elevation of the medial border and a corresponding depression of the lateral border of the foot, so that the plantar aspect of the foot faces medially. This is the position of *inversion*, which is in reality a combination of adduction and partial 'supination'. The range of the movement is appreciably increased in plantar flexion of the foot, for in this position the narrow part of the trochlear surface of the talus occupies the tibiofibular mortise and a slight amount of lateral movement of the talus in the mortise gives an increased range of adduction to the front part of the foot. The opposite movement, which is much more limited in range, is termed *eversion*. The chief factor in the limitation of inversion is the tension of the peronei and the strong lateral part of the interosseous talocalcanean ligament (p. 499). The other tarsal interosseous ligaments and the calcaneofibular ligament are less important factors. Eversion is arrested by the tension of the tibialis anterior and tibialis posterior and the deltoid ligament.

Muscles producing the movements:

Inversion.—Tibialis anterior and posterior.
Eversion.—Peroneus longus and brevis.

3. The Calcaneocuboid Joint

The articular surfaces of the calcaneocuboid joint are somewhat saddle-shaped. The ligaments of the joint are : the capsular, the dorsal calcaneo-

* For a full analysis of these movements, consult a paper by Philip Wiles : "Flat-Feet," *The Lancet*, 1934.

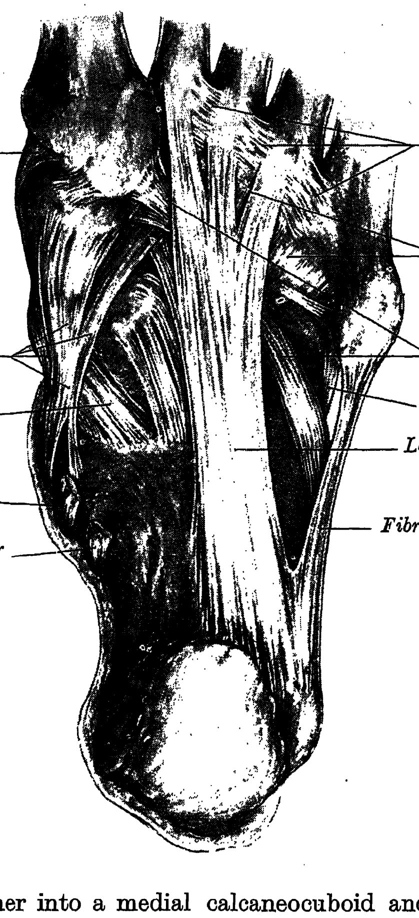
cuboid, the calcaneocuboid portion of the bifurcated ligament, the long plantar and the short plantar (plantar calcaneocuboid).

The **capsular ligament** contains certain bands which form the other ligaments of the joint. Its synovial membrane is distinct from that of the other tarsal articulations (fig. 571).

The **dorsal calcaneocuboid ligament** (fig. 567) is a thin but broad fasciculus, which passes between the contiguous surfaces of the calcaneum and the cuboid bone, on the dorsal surface of the joint.

The **bifurcated ligament** (figs. 567, 570) is a strong band attached behind to the anterior part of the upper surface of the calcaneum and dividing in front

FIG. 569.—The ligaments of the plantar surface of the left foot.



in a Y-shaped manner into a medial calcaneocuboid and a lateral calcaneonavicular ligament. The *medial calcaneocuboid ligament* is fixed to the dorsal part of the medial side of the cuboid bone and forms one of the principal bonds between the first and second rows of the tarsal bones. The *lateral calcaneonavicular ligament* is attached to the dorsilateral aspect of the navicular bone.

The **long plantar ligament** (fig. 569), which is the longest of the tarsal ligaments, is attached posteriorly to the plantar surface of the calcaneum in front of the medial and lateral tubercles, and anteriorly to the ridge and tuberosity on the plantar surface of the cuboid bone, the more superficial fibres being continued forwards to the bases of the second, third, and fourth metatarsal bones. This ligament converts the groove on the plantar surface of the cuboid bone into a tunnel for the tendon of the peroneus longus. It possesses great strength and is an important factor in resisting flattening of the lateral longitudinal arch of the foot (p. 517).

The **short plantar (plantar calcaneocuboid) ligament** (fig. 569) lies nearer to the bones than the preceding ligament, from which it is separated by a little

areolar tissue. It is a short but wide band of great strength, and stretches from the anterior tubercle of the calcaneum and the depression in front of it, to the adjoining part of the plantar surface of the cuboid bone. Like the preceding ligament, it resists flattening of the lateral longitudinal arch of the foot.

Movements.—The movements permitted between the calcaneum and the cuboid bone are limited to slight gliding and rotation of the bones upon each other, and occur during the movements of inversion and eversion.

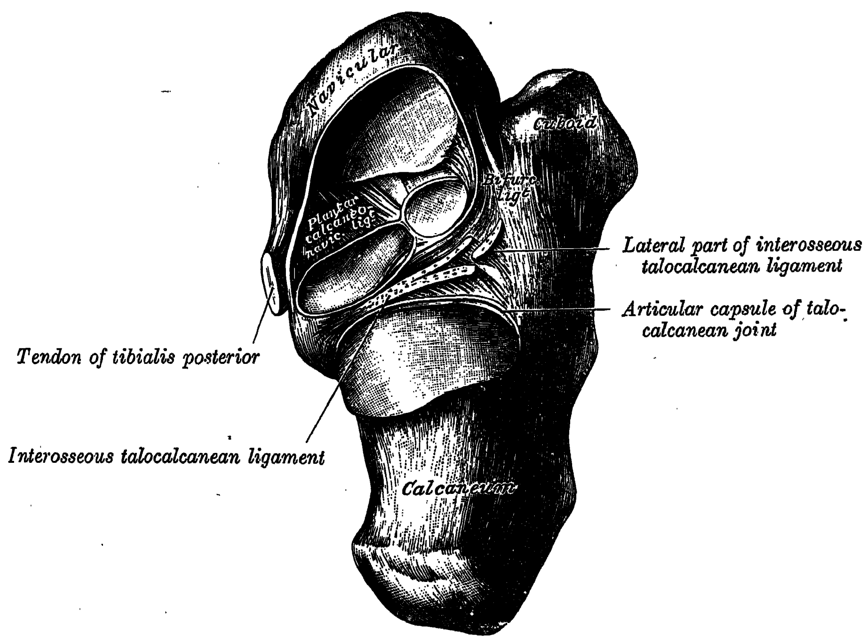
The calcaneocuboid and talonavicular articulations together form what is known as the *transverse tarsal joint*.

4. The Ligaments connecting the Calcaneum and Navicular

Though the calcaneum and the navicular bone do not articulate directly, they are connected by two ligaments: the lateral calcaneonavicular and the plantar calcaneonavicular.

The **lateral calcaneonavicular ligament** has been described above; it forms the medial band of the bifurcated ligament.

Fig. 570.—The right talocalcanean and talocalcaneonavicular joints exposed by removal of the talus.



The **plantar calcaneonavicular** or '**spring**' **ligament** (fig. 569) is a broad, thick band connecting the anterior margin of the sustentaculum tali of the calcaneum to the plantar surface of the navicular bone. This ligament unites the calcaneum with the navicular bone, and lies below the head of the talus, forming part of the articular cavity in which the head is received; it resists flattening of the medial longitudinal arch of the foot (p. 516). The *dorsal surface* of the ligament presents a fibrocartilaginous facet upon which a portion of the head of the talus rests (fig. 570). Its *plantar surface* is supported by the tendon of the tibialis posterior, medially; and by the tendons of the flexor hallucis longus and the flexor digitorum longus, laterally; its *medial border* is blended with the anterior fibres of the superficial part of the deltoid ligament of the ankle-joint.

5. The Cuneonavicular Joint

The navicular bone articulates in front with the three cuneiform bones. The joint is of the plane variety and its *capsular ligament* is continuous with the capsular ligaments of the intercuneiform and the cuneocuboid joints. Its synovial cavity is continuous with the synovial cavities of these joints and with the synovial cavities of the second and third cuneometatarsal joints and of the intermetatarsal joints between the bases of the second and third, and third and fourth metatarsal bones.

Dorsal and plantar ligaments connect the navicular bone to each of the cuneiform bones.

The **dorsal ligaments** are three small fasciculi, one attached to each of the cuneiform bones. The fasciculus connecting the navicular bone with the medial cuneiform bone is continuous round the medial side of the joint with the plantar ligament which unites these two bones.

The **plantar ligaments** have a similar arrangement to the dorsal, and are strengthened by slips from the tendon of the tibialis posterior.

6. The Cubonavicular Joint

The cubonavicular joint is usually a syndesmosis, and the two bones are connected by dorsal, plantar and interosseous ligaments.

The **dorsal ligament** extends obliquely forwards and laterally, while the **plantar** passes nearly transversely from the cuboid bone to the navicular bone.

The **interosseous ligament** consists of strong transverse fibres, and connects the rough non-articular portions of the adjacent surfaces of the two bones.

Not infrequently the syndesmosis is replaced by a synovial joint. In that event the joint is of the plane variety and its capsular ligament and synovial cavity are continuous with those of the cuneonavicular joint.

7. The Intercuneiform and Cuneocuboid Joints

The intercuneiform joints and the joint between the lateral cuneiform bone and the cuboid are all synovial in character and of the plane variety. Their capsular ligaments and synovial cavities are continuous with those of the cuneonavicular joint.

The bones are connected together by dorsal, plantar, and interosseous ligaments.

The **dorsal** and **plantar ligaments** each consist of three transverse bands: one connects the medial and intermediate cuneiform bones, another the intermediate and lateral cuneiform bones, and another the lateral cuneiform and cuboid bones. The plantar ligaments are strengthened by slips from the tendon of the tibialis posterior.

The **interosseous ligaments** connect the rough non-articular portions of the adjacent surfaces of the bones and possess considerable strength; they resist depression of the transverse arch of the foot (p. 517).

Movements.—The movements permitted at the cuneonavicular, cubonavicular, intercuneiform and cuneocuboid joints are limited to a slight amount of gliding on each other of the bones concerned, and cannot be performed voluntarily when the foot is raised from the ground. They occur when load is taken by the anterior part of the foot, *e.g.* in starting to run or jump, etc., and greatly increase the suppleness of the foot.

VI. THE TARSOMETATARSAL JOINTS

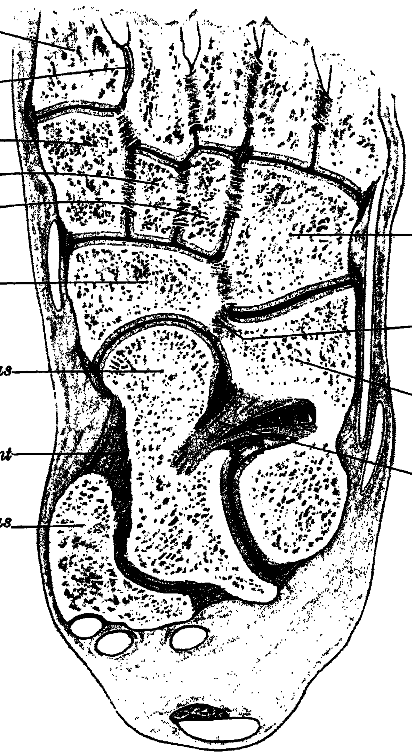
These are synovial joints of the plane variety. The first metatarsal bone articulates with the medial cuneiform bone; the second is dovetailed in between the medial and lateral cuneiform bones, articulating by its base with the intermediate cuneiform bone; the third articulates with the lateral cuneiform bone; the fourth, with the cuboid and lateral cuneiform bones; and the fifth with

the cuboid bone. The first joint possesses an independent capsular ligament and synovial cavity. The capsular ligaments and synovial cavities of the second and third joints are continuous with those of the intercuneiform and cuneonavicular joints, but are shut off from those of the fourth and fifth joints by an interosseous ligament which passes between the lateral cuneiform bone and the base of the fourth metatarsal. The bones are connected by dorsal, plantar, and interosseous ligaments.

The **dorsal ligaments** are strong, flat bands. The first metatarsal is joined to the medial cuneiform bone by a capsular ligament; the second metatarsal receives three bands, one from each cuneiform bone; the third, one from the lateral cuneiform bone; the fourth, one from the lateral cuneiform bone, and another from the cuboid bone; and the fifth, one from the cuboid bone.

The **plantar ligaments** consist of longitudinal and oblique bands, disposed

Fig. 571.—An oblique section through the right foot, showing the synovial cavities of the intertarsal and tarsometatarsal joints. Viewed from above.



N.B.—The section passed below the joint between the medial cuneiform bone and the base of the second metatarsal; no synovial joint was present between the navicular and cuboid bones.

with less regularity than the dorsal ligaments. Those for the first and second metatarsal bones are the strongest; the second and third metatarsal bones are joined by oblique bands to the medial cuneiform bone; the fourth and fifth metatarsal bones are connected by a few fibres to the cuboid bone.

The **interosseous ligaments** are three in number. The first is the strongest and passes from the lateral surface of the medial cuneiform bone to the adjacent angle of the second metatarsal bone (fig. 571). The second connects the lateral cuneiform bone with the adjacent angle of the second metatarsal bone. The third connects the lateral angle of the lateral cuneiform bone with the adjacent side of the base of the third metatarsal bone.

Movements.—The movements permitted between the tarsal and metatarsal bones are limited to gliding of the bones upon each other. This movement is very limited in range except in the case of the joint between the medial cuneiform bone and the first metatarsal, where an appreciable amount both of up

and down movement and of rotation of the metatarsal bone can be obtained passively when the muscles concerned are relaxed. These movements are carried out actively in standing and walking and form part of the mechanism by which the foot is kept plantigrade whether it is inverted or everted.

In order that the inverted foot may remain plantigrade on a flat surface, the elevation of its medial border, which is a necessary accompaniment of inversion, is corrected by medial (or downward) rotation and depression of the first metatarsal and medial cuneiform bones, brought about by the action of the peroneus longus muscle (p. 649). Conversely, in the case of eversion, the elevation of the lateral border of the foot is corrected by lateral (or upward) rotation and elevation of the first metatarsal and medial cuneiform bones, brought about passively by pressure on the ground. As a result of these movements the transverse arch of the foot (p. 517) is accentuated in inversion and flattened in eversion.

VII. THE INTERMETATARSAL JOINTS

The base of the first metatarsal bone is not connected with that of the second by any ligaments; in this respect the great toe resembles the thumb. A small bursa is often interposed between the lateral side of the base of the first metatarsal bone and the medial side of the shaft of the second (fig. 571).

The bases of the second, third, fourth, and fifth metatarsal bones are connected by dorsal, plantar, and interosseous ligaments.

The heads of all the metatarsal bones are connected indirectly by the deep transverse ligaments of the sole.

The **dorsal** and **plantar ligaments** pass transversely between the bases of the adjacent bones.

The **interosseous ligaments** consist of strong transverse fibres which connect the rough non-articular portions of the adjacent surfaces (fig. 571).

Movements.—The movements permitted between the tarsal ends of the metatarsal bones are limited to a slight gliding of the articular surfaces one upon another when the anterior part of the foot is working under load (*cf.* movements of the intercuneiform joints, etc., p. 512).

THE SYNOVIAL CAVITIES OF THE TARSUS AND METATARSUS

The **synovial cavities** (fig. 571) present in the joints of the tarsus and metatarsus are six in number: one for the talocalcanean; a second for the talocalcaneonavicular; a third for the calcaneocuboid; a fourth for the cuneonavicular, intercuneiform, and cuneocuboid articulations, the articulations of the intermediate and lateral cuneiform bones with the bases of the second and third metatarsal bones, and the adjacent surfaces of the bases of the second, third, and fourth metatarsal bones; a fifth for the medial cuneiform bone with the metatarsal bone of the great toe; and a sixth, for the articulation of the cuboid bone with the fourth and fifth metatarsal bones. A small synovial cavity is sometimes found between the contiguous surfaces of the navicular and cuboid bones; it usually communicates with that between the cuboid and lateral cuneiform bones.

VIII. THE METATARSOPHALANGEAL JOINTS

The metatarsophalangeal joints are of the condyloid variety and are formed by the reception of the rounded heads of the metatarsal bones in shallow cavities on the bases of the proximal phalanges.

The *articular surfaces* cover the distal and plantar surfaces of the heads of the metatarsal bones but do not extend on to their dorsal surfaces. The plantar part of the head of the first metatarsal presents two longitudinal grooves separated by an intervening ridge. Each groove articulates with a sesamoid bone imbedded in the plantar ligament of the joint. The articular surface of the base of the proximal phalanx is concave in all diameters.

The ligaments of the joint are the capsular, plantar and collateral.

The **capsular ligaments** surround the joints and are attached to the margins of the articular surfaces. Dorsally, they are blended with the deep surfaces of the tendons of the long extensors, and they are inseparable from the deep surfaces of the plantar and collateral ligaments.

The **plantar (accessory plantar) ligaments** are thick, dense, fibrous structures. They are placed on the plantar surfaces of the joints in the intervals between the collateral ligaments, to which they are connected ; they are loosely united to the metatarsal bones, but are firmly fixed to the bases of the proximal phalanges. Their margins are continuous with the deep transverse ligaments of the sole, and their plantar surfaces are grooved for the flexor tendons, the fibrous sheaths of which are connected to the sides of the grooves ; the deep surfaces of the ligaments form parts of the articular facets for the heads of the metatarsal bones.

The **deep transverse ligaments of the sole** (ligamenta capitulorum transversa) consist of four short, wide, flattened bands which connect the plantar ligaments of adjoining metatarsophalangeal joints to one another. Their dorsal surfaces are related to the interosseous muscles and their plantar aspects to the lumbricals and the digital vessels and nerves. They correspond closely to the deep transverse ligaments of the palm (p. 477), but, in addition, they are connected to the plantar ligament of the first metatarsophalangeal joint.

The **collateral ligaments** are two strong, rounded cords, placed on the sides of the joints ; each is attached by one end to the dorsal tubercle on the side of the head of the metatarsal bone, and runs obliquely forwards and downwards to reach the corresponding side of the base of the phalanx.

The extensor tendons supply the place of *dorsal ligaments*.

Movements.—The active movements possible at the phalangeal joints are very similar to those permitted at the corresponding joints in the hand but are more limited in their range. Flexion is a much freer movement than extension and is usually associated with adduction. Abduction is possible only when the toes are extended (*cf.* p. 478). As in the hand, the *accessory movements* comprise gliding movements and rotation of the phalanges around their long axes.

Muscles producing the movements.—In **flexion,** the *flexor digitorum brevis*, the *lumbricals* and the *interossei* are the active agents, assisted by the flexor digitorum longus and the accessorius (quadratus plantæ). In the case of the little toe the *flexor digiti minimi brevis* assists, and in the case of the great toe the *flexores hallucis longus et brevis* are the only muscles concerned.

In **extension,** the *extensores digitorum longus et brevis* and the *extensor hallucis longus* are the only active agents.

In **adduction** and **abduction,** the line of reference passes through the second toe. The great toe is adducted by the *adductor hallucis*, and abducted by the *abductor hallucis*. The second toe is abducted to the medial side by the first dorsal interosseous muscle, and to the lateral side by the second. The third and fourth toes are abducted by the corresponding dorsal interossei and adducted by the first and second plantar interossei, respectively. The little toe is abducted by the abductor digiti minimi and adducted by the third plantar interosseous muscle.

IX. THE JOINTS OF THE DIGITS

The digital or interphalangeal joints are hinge-joints, and each has a capsular, a plantar and two collateral ligaments. The arrangement of these ligaments is similar to that in the metatarsophalangeal joints. The extensor tendons supply the places of dorsal ligaments.

Movements.—The only active movements permitted in the joints of the digits are flexion and extension ; these movements are freer between the proximal and middle phalanges than between the middle and distal. The amount of flexion is very considerable, but extension is limited by the tension of the flexor muscles and by the plantar ligaments.

The *accessory movements* comprise abduction, adduction and rotation.

Muscles producing the movements:

Flexion.—Flexores digitorum longus, brevis et accessorius (Quadratus plantæ), Flexor hallucis longus.

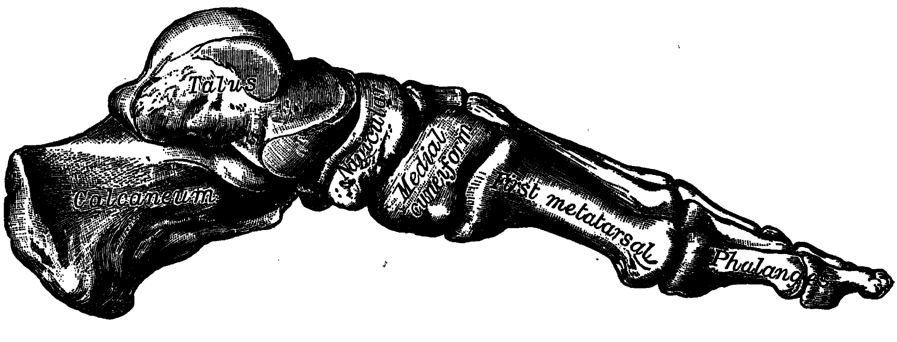
Extension.—Lumbricales, Interossei dorsales et plantares, Extensor hallucis longus.

The Arches of the Foot

The foot has two important functions to perform. (1) It must support the weight of the body in standing. (2) It must act as a lever to propel the body forwards in walking.

To fulfil the first function perfectly, the foot should lie flat on the ground and should be pliable enough to adapt itself to uneven surfaces. In actual

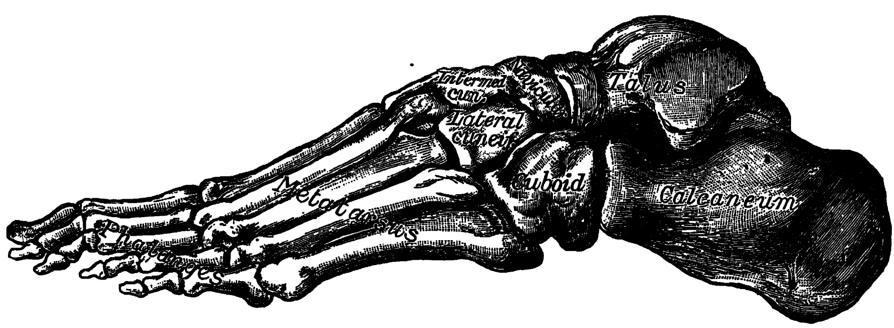
Fig. 572.—The skeleton of the left foot. Medial aspect.



fact, the foot of the child approaches this ideal much more nearly than the foot of the adult, which is, to a certain extent, permanently arched.

To fulfil its second function the foot must be capable of transformation into a rigid lever which will not collapse under the body weight. A segmented

Fig. 573.—The skeleton of the left foot. Lateral aspect.



lever, such as the foot, can only withstand stress if it is built up into an arch form, and in active use, therefore, the muscles acting on the foot convert it into a complex but rigid, arched lever. The arches thus formed comprise a longitudinal arch, which is divisible into a medial and a lateral portion, and a transverse arch. In the average adult these arches do not flatten out completely when the muscles are relaxed, and they are therefore to that extent permanent. They vary in height in different subjects.

The *medial arch* (fig. 572) is made up of the calcaneum, the talus, the navicular, the three cuneiform bones, and the first, second and third metatarsals. Its summit is at the superior articular surface of the talus, and its two extremities or piers, on which it rests on standing, are the tubercles on the plantar surface of the calcaneum posteriorly, and the heads of the first, second and

third metatarsal bones anteriorly. The chief characteristic of this arch is its resilience, due to its height and to the number of joints between its component parts. The arch is dependent for its maintenance on the tibialis posterior, the flexor digitorum longus and flexor hallucis longus muscles, assisted by the small muscles in the sole of the foot. Flattening of the arch is resisted by the tension of these muscles and by the plantar aponeurosis and the plantar ligaments of all the joints concerned, including the plantar calcaneonavicular or 'spring' ligament (p. 511).

The *lateral arch* (fig. 573) is composed of the calcaneum, the cuboid, and the fourth and fifth metatarsal bones. Its summit is at the talocalcanean articulation, and its chief joint is the calcaneocuboid, which allows only a limited movement. The most marked features of this arch are its solidity and its slight elevation; it is supported by the peroneus longus and the short muscles of the little toe, and its integrity is preserved by the long and short plantar ligaments.

In addition to the longitudinal arches the foot presents a series of *transverse arches*. At the posterior part of the metatarsus and the anterior part of the tarsus the arches are complete, but in the middle of the tarsus they present more the characters of half-domes the concavities of which are directed downwards and medially, so that when the medial borders of the feet are placed in apposition a complete tarsal dome is formed. The transverse arches are supported by the short muscles of the first and fifth toes (especially the transverse head of the adductor hallucis), and by the peroneus longus, the tendon of which stretches between the piers of the arches, and are strengthened by the interosseous and plantar ligaments.

It should be observed that in a normal foot the arches become flattened when the erect posture is assumed, and are restored when the weight of the body is taken off the feet. This resilience accounts for the suppleness of the normal foot and enhances the value of the arches by rendering possible such rapid and sudden movements as running and jumping.

In the resting upright posture the feet take up the position of eversion, but the first metatarsal and medial cuneiform bones are elevated and rotated upwards relative to the rest of the foot (p. 514). The latter movement is essential to allow the lateral border of the everted foot to remain in contact with the ground, and it results in a flattening of the transverse arch of the foot. The medial longitudinal arch appears to be more flattened than can be accounted for by the elevation of the first metatarsal bone. This is due to the fact that in eversion the arch rolls over, as it were, to the medial side, so that its concavity faces laterally and downwards instead of directly downwards.

When the posture is changed from the position of rest to one of activity, the foot becomes slightly inverted, the medial longitudinal arch is both apparently and actually raised and the transverse arch is accentuated by the action of the peroneus longus (p. 649). In this position the foot functions as an almost rigid but yet slightly resilient lever, as the full value of both arches can be utilised.

It should be observed that when the foot is on the ground it is not free to move round the talus in the movements of eversion and inversion, and these movements are brought about, in large part if not entirely, by a twisting of the talus on the rest of the foot. This twisting is the result of rotation of the lower limb, either at the knee or at the hip-joint, and is transmitted to the talus through the tibiofibular mortise.

Applied Anatomy.—In young children the foot appears to be completely flat in the resting upright posture, owing to the fact that it is everted at the subtalar joints and supinated at the first cuneometatarsal and cuneonavicular joints; during activity, however, the arched form of the foot becomes at once apparent. In most adults, on the other hand, the foot does not flatten completely in the resting upright posture, for, with increase of age, the arches become to some extent permanent structures. In some adults—particularly those with long and narrow feet—the foot appears to be abnormally flat in the resting posture, but the arches become apparent during activity. The functions of the foot are not impaired, but, despite this fact, these cases are often described as exhibiting a 'first degree flat foot.'

There are two varieties of flat foot associated with marked impairment of function. In the first the flat, everted position assumed during rest persists when the resting posture

is changed to one of activity, although the foot can still assume a normal arched form when not bearing weight. In this variety the deformity is purely postural and is due to loss of muscle tone and lack of muscular coordination. It is commonly associated with pain which is due to stretching of the plantar ligaments of the joints of the foot. The condition is often a local manifestation of a general postural deficiency, and its cure therefore depends upon correction of bad postural habits and re-education of the muscles.

In the second variety the flat, everted position of the foot becomes fixed as a result either of persistent muscle spasm or of joint stiffness following some inflammatory process. Such cases are described as 'rigid flat foot,' as the arched form of the foot cannot be produced even by passive movements.

MYOLOGY

MUSCULAR tissue is known to the layman as ' flesh ', and it is most familiar to him as the lean parts of a joint of meat. There are three varieties of muscular tissue : (1) *striped* or *voluntary*, (2) *unstriped* or *plain*, and (3) *cardiac*. The microscopical characters of these three varieties have been described in a previous section (pp. 32 to 36). This section deals only with voluntary muscle.

The individual fibres of voluntary muscle with their sheaths of *sarcolemma* (p. 32) are bound together into bundles or fasciculi by a connective tissue covering, termed the perimysium. Groups of fasciculi are in turn bound together by a similar but denser covering, termed the epimysium, and these groups form the individual *voluntary muscles* of the body. The voluntary muscles of the eyeball, ear, tongue, palate, larynx and pharynx are considered along with the anatomy of the organs concerned, but all the other voluntary muscles of the body will be included in this section.

All muscular tissue possesses the property of contractility, and movements of the body as a whole or of any of its parts are effected by the active contraction of a group or groups of voluntary muscles.

Attachments.—In order that a muscle may exercise its function of producing movements, it must be attached at both of its extremities. When a muscle contracts, one of its attachments remains relatively stationary, while the other is approximated to it. The term *origin* is used to designate the more fixed attachment and the term *insertion* to designate the movable point at which the force of the muscle is applied. As a general rule, so far as the limbs are concerned, the origin is the more proximal extremity of a muscle and the insertion the more distal. In accordance with these definitions the contraction of a muscle results in the approximation of its insertion to its origin, but the terms are arbitrary and used for convenience only, and it frequently happens that the contraction of a muscle may result in the approximation of its origin to its insertion. The Gluteus maximus provides an illustration of this fact. When it assists in extending the flexed thigh, its insertion into the gluteal tuberosity of the femur is then approximated to its origin from the dorsal surface of the sacrum. On the other hand, when the body is bent forwards at the hips, the Glutei maximi play the principal part in restoring it to the erect posture and, in this movement, the origin is approximated to the insertion.

The voluntary muscles are attached to the bones, cartilages, ligaments, skin or to other muscles, either directly or through the medium of fibrous structures called tendons and aponeuroses. Where a muscle is attached directly to bone or cartilage, the perimysium blends with the periosteum or perichondrium so that the fleshy fibres do not actually come into direct relation with the osseous or cartilaginous tissue, although they may appear to do so. Where muscle fibres are inserted into skin, e.g. the muscles of facial expression, they lie as a flattened layer on its deep surface and their perimysium blends with the subcutaneous areolar tissue. It may be noted that in such cases the insertion is incapable of becoming the fixed point, so that contraction always approximates the insertion to the bony origin.

Most muscles are provided with tendons at one or both extremities. *Tendons* are known to the layman as ' sinews ' or ' leaders ' ; they consist of white fibrous tissue (p. 10) and are usually cord- or band-like in appearance. In flat, sheet-like muscles which have a wide area of attachment a relatively thin but strong fibrous sheet takes the place of a cord-like tendon and is termed an *aponeurosis*. Where no tendon or aponeurosis can be seen with the naked eye, the attachment appears to be fleshy in character, but, as already stated, it is actually effected through the medium of the fusion of the perimysium with the periosteum or perichondrium.

Where one muscle is attached to another, the character of the connexion may be fleshy, tendinous or aponeurotic. (1) The fleshy fibres may interlace,

e.g. the mylohyoid muscles, and the perimysium of the one fuses with the perimysium of the other. (2) The two muscles may be connected by a common tendon. Such muscles are termed digastric and the two fleshy bellies are usually set at an angle which is maintained by a fascial loop thrown round the tendon from an adjoining bony point. (3) The two muscles may be connected by the interlacement of the fibres in their aponeuroses, e.g. the muscles of the abdominal wall.

Attachments of muscles exert a definite influence in the modelling of the bones of the skeleton and, when the attachment is tendinous in character, localised, elevated areas are usually present. On the other hand, when the muscle is attached by fleshy fibres the bony surface is smooth, and shows no corresponding elevations.

The muscles of the limbs with very few exceptions are inserted immediately distal to the joint on which they exert their principal action. This arrangement implies a loss of mechanical advantage, but what is lost in power is gained in the speed with which the hand or the foot, as the case may be, is moved over a wide range. For example, when the Brachialis muscle contracts, its insertion into the coronoid process of the ulna moves round an arc of a circle with a very short radius, but in the same period of time the hand moves round the corresponding arc of a circle whose radius is the length of the forearm and hand.

Muscular form.—The *form* of a muscle depends on the number and arrangement of its constituent fibres. When the fibres are arranged parallel or nearly parallel to what may be termed the 'line of pull' of the muscle, the full advantage of the muscular contractility is available and the maximum range is obtained. Such muscles may be *quadrilateral*, like the Thyrohyoid ; *fusiform*, like the Flexor carpi radialis ; or *straplike*, such as the Sartorius. If, on the other hand, the fibres are arranged obliquely in relation to the 'line of pull', the range is diminished, for the force of the muscular action can then be resolved into two components, one acting in the 'line of pull' and the other at right angles to it and therefore valueless so far as the range of the muscle is concerned. This oblique arrangement of the fibres is seen (*a*) in *unipennate* muscles such as the Flexor pollicis longus, in which the tendon of insertion extends upwards along one border of the muscle, (*b*) in *bipennate* muscles, such as the Rectus femoris, where the tendon extends upwards through the middle of the muscle, and (*c*) in *multipennate* muscles, such as the Deltoid, where a number of extensions pass upwards into the muscle from its tendon of insertion. The same arrangement is seen (*d*) in *triangular* muscles, such as the Temporalis, in which the muscular fibres converge on an apical tendon. As a rule the various forms of pennate and triangular muscles contain a larger number of fibres than fusiform, quadrilateral or straplike muscles, and they are found in situations where increased power is essential, because the power of a muscle is directly proportionate to the number of its constituent fibres.

Muscular contraction.—When a muscle is called on to participate actively in the production of a movement, all of its fibres are not necessarily thrown into contraction, for it adapts itself to the work which it is required to perform, and the more vigorous the effort demanded, the greater the number of fibres involved. During contraction a muscle fibre may shorten by thirty to forty per cent. of its uncontracted length.* As all the fibres in a given muscle are attached by one end to the tendon of origin, or its prolongation into the muscle, and by the other to the tendon of insertion, the maximum amount of shortening of the muscle is equal to the maximum amount of shortening of any one fibre, provided that all the fibres in the muscle are uniform in length, e.g. Sartorius. Owing to the rigidity of the bones, the amount of shortening possible is only a small percentage of the distance between the origin and the insertion, and the length of muscle fibres is adapted to their requirements. When, therefore, the muscle fibres are arranged parallel to the 'line of pull,' the muscular belly may be relatively short, and it is then provided with a long tendon—an arrangement which is both economical and efficient, for muscle tissue has a high metabolic rate and white fibrous tissue a low one.

* According to R. Wheeler Haines, *Journal of Anatomy*, vols. lxvi. and lxix., muscle fibres normally contract to 57 per cent. of their length when fully stretched.

Muscular actions.—Theoretically a muscle is capable of acting on every joint over which it passes, and the particular movements in which it takes part depend on the relationship of its 'line of pull' to the axes of the movements of the joint. For example, a muscle which passes in front of the transverse axis of the shoulder-joint will take part in the movement of flexion and, if it passes below the joint, it will also take part in adduction. It is movements, however, and not individual muscles which are represented in the cerebral cortex and it does not follow that a muscle will participate in a given movement because the mechanics of its attachments enable it to do so.

When a movement is carried out, a definite combination of muscles is called into play, and no muscle can be omitted nor can one be added, voluntarily. One muscle or more of the combination is the *prime mover*, and its active contraction necessarily involves the relaxation of its *antagonist*. The full effect, however, of the contraction of a prime mover can be obtained only when one of its attachments (usually the origin) is fixed; therefore, in the case of limb movements, every contraction of the prime movers is accompanied by the contraction of groups of *fixation muscles*. For example, the Deltoid is the prime mover in abduction of the arm and it can exert its full effect only when its clavicular and scapular origins are fixed. As a result abduction of the arm is always accompanied by contraction of muscles inserted into the scapula; and they are the fixation muscles for that movement. Some muscles pass over several joints, although they are prime movers of one joint only; and it may be necessary to counteract the effect of their action on the intermediate joints in the interests of efficiency. For this purpose a group of *synergic muscles* is brought into play. When the fist is clenched firmly, the prime movers are the flexors of the fingers, the flexors and adductor of the thumb and the Opponens pollicis muscle. The long flexors pass in front of the wrist-joint and are able to flex that joint, but only at the expense of the power with which they act on the digits. The extensors of the wrist, which are the synergic muscles for the movement, are therefore thrown into contraction in order to steady the wrist and obviate this loss of power. It should be observed, however, that there is no essential difference between fixation and synergic muscles, in so far as they both prevent waste of power and loss of efficiency on the part of the prime movers.

Under certain conditions the muscular groups which are called into play for some movements are profoundly altered by the action of gravity. When the body is in the erect posture flexion of the trunk is initiated by the ventral muscles, but thereafter the movement is carried out by the action of gravity, controlled and regulated by the Sacrospinales. The abducted arm is brought down to the side in a similar manner. In this instance the action of gravity is controlled by the Deltoid muscle, and the adductor muscles do not participate in the movement unless resistance is encountered.

It will now be apparent that the efficient performance of any movement depends on the proper co-ordination of prime movers, antagonists and fixation and synergic muscles, and this co-ordination is ensured by the manifold connexions which exist within the central nervous system.

Types of muscle fibres.—Many bivalves are provided with two distinct types of voluntary muscle. The one consists of pale fibres, which are capable of rapid contraction and have a high metabolic rate. They come into play to effect the closure of the shell. The other type consists of dark, red fibres, which contract more slowly and have a lower metabolic rate. They maintain the movement inaugurated by the pale fibres and their function is to keep the shell closed. In man and other vertebrates both pale and red fibres are present in all the voluntary muscles, but in varying proportions. It has been estimated that in some muscles, e.g. the Gastrocnemius, the pale fibres predominate, while in others, e.g. the Soleus, the red fibres are in the majority, and it has been suggested that some muscles are concerned with the initiation and performance of movements, while others are mainly postural, i.e. their function is to maintain the position so acquired.

Muscle tonus.—Living muscle never becomes fully relaxed, except under the influence of narcotic drugs, but is constantly in a condition of very slight contraction, the degree of which is subject to variation with the state of health

of the individual. This property of muscle tissue is termed 'muscle tonus,' and it has an important function to perform in connexion with posture. Thus the tonus of the deep muscles of the calf of the leg is responsible, to a very large extent, for the maintenance of the arches of the foot: the head is kept poised on the top of the vertebral column by the balance of the tonus of the flexor and extensor muscles: the abdominal viscera are maintained in place by the pressure exerted by the normal tonus of the abdominal muscles.

As a result of the possession of tonus, muscles have no slack to take in when they are required to contract, and movements can therefore be carried out without any initial lag.

THE TENDONS, APONEUROSES AND FASCIÆ

The **tendons** are tough, whitish cords, varying in length and thickness, and devoid of elasticity. They consist almost entirely of white fibrous tissue, the fibrils of which have an undulating course parallel with each other and are firmly united together. They are very sparingly supplied with blood-vessels, the smaller tendons having in their interior no trace of them. Nerves supplying tendons end in what are known as neurotendinous spindles or organs of Golgi; these are described with the organs of the senses.

The **aponeuroses** are flattened or expanded tendons, of a pearly-white colour, iridescent and often glistening; they are only sparingly supplied with blood-vessels.

The tendons and aponeuroses connect the muscles with the structures to be moved, such as the bones and cartilages. Where the end of a muscle is continued directly into a tendon, the line of junction between the two is usually well-defined, but where the muscle meets the tendon obliquely, bundles of tendon fibres generally run for a variable distance into the substance of the muscle, so that the line of junction is irregular. Microscopic examination shows that, in either case, the tendon is subdivided into small bundles, corresponding in size and number with the fibres of the muscle. Each muscular fibre ends in a more or less rounded extremity covered with sarcolemma, and the fibres of each tendon bundle are intimately united with the sarcolemma covering the end of the muscular fibre. The mode of union is well shown when the muscle fibre has shrunk inside its sarcolemma.

In situations where a muscle has to bend round a bony point to reach its insertion, the fleshy fibres cease before the change of direction begins so that the part subjected to pressure at the bend is tendinous in character. Friction is obviated by the provision of a synovial sheath or bursa (p. 428).

The **fasciæ** are fibro-areolar, membranous laminæ, of variable thickness and strength, found in all regions of the body, investing the softer and more delicate organs. During the process of development many of the cells of the mesoderm are differentiated into bones, muscles, vessels, etc.; the cells of the mesoderm which are not so utilised form an investment for these structures and are differentiated into the true skin and the fasciæ of the body. The fasciæ are subdivided into superficial and deep.

The *superficial fascia* is found immediately beneath the skin over the entire surface of the body. It connects the skin to the subjacent parts, and consists of fibro-areolar tissue, containing in its meshes pellicles of fat in varying quantity. It varies in thickness in different parts of the body; in the groin it is so thick that it may be subdivided into several laminæ. It facilitates the movement of the skin, serves as a soft bed for the passage of vessels and nerves to the skin, and retains the warmth of the body, since fat is a bad conductor of heat. Beneath the fatty layer there is generally another layer of superficial fascia, almost devoid of adipose tissue, in which the trunks of the subcutaneous vessels and nerves and the superficial lymph-glands are found. Certain cutaneous muscles are situated in the superficial fascia, e.g. the Platysma and the muscles of the face. The superficial fascia is most distinct at the lower part of the abdomen, in the perineum, and in the limbs; it is very thin on the dorsal aspects of the hands and feet, on the side of the neck, in the face, and around the anus. It is very dense in the scalp, palms of the hands, and soles

of the feet, forming a fibro-fatty layer which binds the skin firmly to the underlying structures.

The *deep fascia* is a dense, inelastic membrane, forming sheaths for the muscles, and in some cases affording them broad surfaces for attachment. It consists of bundles of white fibrous tissue, placed parallel with one another and connected together by other fibres disposed in a rectilinear manner. It forms a strong investment which not only binds down collectively the muscles in each region, but may give a separate sheath to each, and to the vessels and nerves as well. It assists the muscles in their actions by the degree of tension and pressure it makes upon their surfaces; in certain situations the degree of tension and pressure is regulated by muscles inserted into it, as, for instance, by the Tensor fasciæ latæ and Gluteus maximus in the thigh, and the Palmaris longus in the hand. In the limbs, the fascia not only invests the limb, but gives off septa which separate the various muscles, and are attached to the periosteum: these prolongations of fasciæ are usually spoken of as intermuscular septa.

In some situations the deep fascia shows a localised thickening, consisting largely of transversely running fibres. These are termed *retinacula* and they form retaining bands in the neighbourhood of the wrist and ankle joints to hold down the tendons. They are attached to the adjoining bony prominences and they help to form osteofibrous canals through which the tendons pass. When the muscles concerned contract vigorously, and bring about movements of the hand or foot, the tendons pull against the retinacula, which function as pulleys and serve to prevent loss of power. Synovial sheaths are provided for the tendons in these situations in order to obviate friction.

Similar fascial thickenings occur in the palm of the hand and the sole of the foot and on the flexor surfaces of the digits. In the first two situations, in addition to exercising a restraining effect on the tendons, they have a protective function.

The fasciæ and muscles may be grouped into those of the head and neck; of the trunk; of the upper limb; and of the lower limb.

THE FASCIÆ AND MUSCLES OF THE HEAD

I. The Muscles of Facial Expression

(*A*) *The Muscles of the Scalp*

Occipitofrontalis (Epicranius)

The **superficial fascia** in the scalp is a firm, fibro-fatty layer, intimately adherent to the skin, and to the underlying Occipitofrontalis muscle and its aponeurosis; behind, it is continuous with the superficial fascia at the back of the neck; laterally, it is prolonged into the temporal region, where it is looser in texture.

The **Occipitofrontalis** (Epicranius) is a broad, musculofibrous layer which covers the top of the skull, from the nuchal lines to the eyebrows. It consists of four bellies—two occipital and two frontal—connected by an intervening aponeurosis, termed the epicranial aponeurosis (galea aponeurotica).

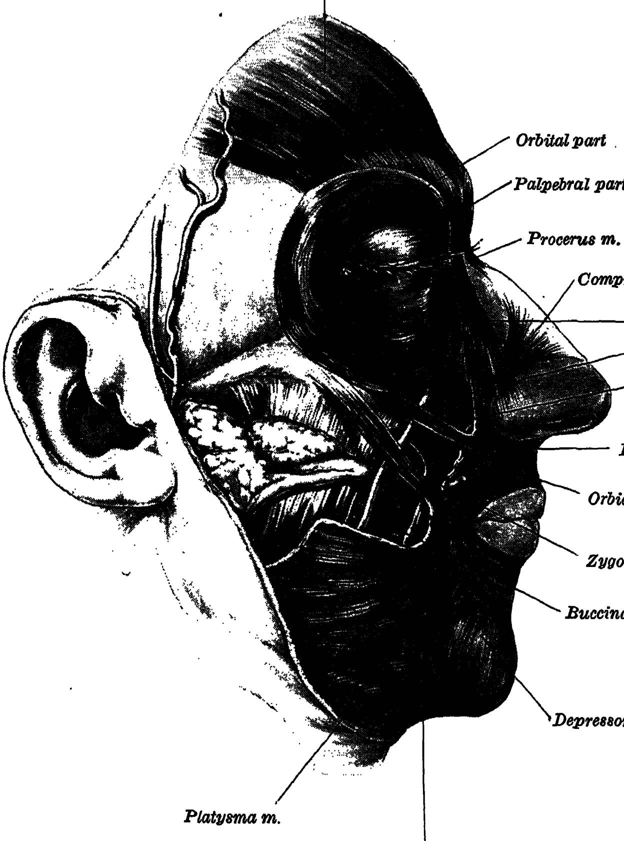
Each *Occipital belly*, thin and quadrilateral in form, arises by tendinous fibres from the lateral two-thirds of the highest nuchal line of the occipital bone, and from the mastoid part of the temporal bone. It ends in the epicranial aponeurosis.

Each *Frontal belly* (fig. 574) is thin, of a quadrilateral form, and intimately adherent to the superficial fascia. It is broader than the Occipital belly and its fibres are longer and paler in colour. It has no bony attachments. Its medial fibres are continuous with those of the Procerus; its intermediate fibres blend with the Corrugator and Orbicularis oculi; and its lateral fibres are also blended with the latter muscle over the zygomatic process of the frontal bone. From these attachments the fibres are directed upwards, and join the epicranial aponeurosis in front of the coronal suture. The medial margins of the Frontal bellies are joined together for some distance above the root of the nose; but

between the Occipital bellies there is a considerable, though variable, interval, occupied by an extension of the epicranial aponeurosis.

The **epicranial aponeurosis** (galea aponeurotica) (fig. 575) covers the upper part of the cranium; behind, it is attached, in the interval between the Occipital bellies, to the external occipital protuberance and highest nuchal line of the occipital bone; in front, it sends a short and narrow prolongation between the Frontal bellies. On each side it gives origin to the Auriculares anterior et superior; in this situation it becomes thinner, and is continued over the temporal

Fig. 574.—The muscles of the scalp and face. Right lateral aspect.



fascia to the zygomatic arch. It is closely united to the skin by the firm, fibro-fatty superficial fascia; it is connected to the pericranium by loose cellular tissue which allows of the movement of the epicranial aponeurosis, the latter carrying with it the skin of the scalp.

Nerve-supply.—The Occipital belly is supplied by the posterior auricular branch, and the Frontal belly by the temporal branches, of the facial nerve.

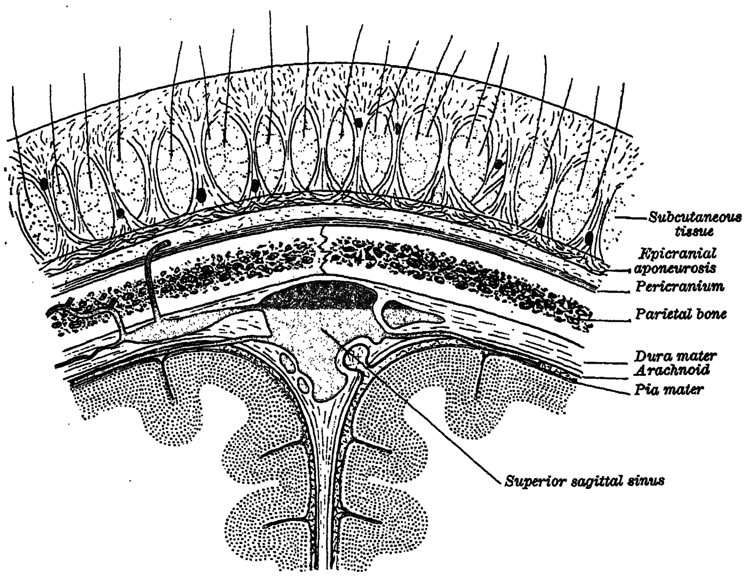
Actions.—The Occipital bellies draw the scalp backwards; the Frontal bellies acting from above raise the eyebrows and the skin over the root of the nose; acting from below they draw the scalp forwards, throwing the integument of the forehead into transverse wrinkles. The Occipital and Frontal bellies, acting alternately, move the entire scalp backwards and forwards. In the ordinary action of the Frontal bellies the eyebrows are elevated, thus giving to the face the expression of surprise: if the action be exaggerated, the eyebrows are

still further raised, and the skin of the forehead thrown into transverse wrinkles, as in the expression of fright or horror.

A thin muscular slip, termed the *Transversus nuchæ*, is present in about 25 per cent. of cases ; it arises from the external occipital protuberance or from the superior nuchal line, either superficial or deep to the Trapezius ; it is frequently inserted with the Auricularis posterior, but may join the posterior edge of the Sternomastoid.

Applied Anatomy.—The scalp consists of five layers, viz. the skin, subcutaneous tissue, Occipitofrontalis and its aponeurosis, subaponeurotic areolar tissue, and pericranium (fig. 575). But from a surgical standpoint it is better to regard the first three of these as a single layer, since they are all intimately united, and when torn off in an accident, or turned down as a flap in a surgical operation, remain firmly connected to each other. In consequence of the dense character of the subcutaneous tissue, the amount of swelling which

FIG. 575.—A coronal section through the scalp and skull. Diagrammatic.



occurs as the result of inflammation is slight ; and a wound which does not involve the Occipitofrontalis or its aponeurosis does not gape. The blood-vessels which lie in this tissue do not contract when wounded, and therefore the hæmorrhage from scalp wounds is often very considerable. It can, however, always be arrested by pressure—a matter of great importance, as, owing to the retraction of the cut ends, it is often very difficult or impossible to pick up with forceps a wounded vessel in the scalp.

The subaponeurotic areolar tissue is, from a surgical point of view, of considerable importance. It is loose and lax, and is easily torn through ; and hence, in wounds of the scalp, it is this tissue which is torn when the flap is separated from the parts beneath. The vessels are contained in the flap, and there is little risk of sloughing, unless the vitality of the part has been actually destroyed by the injury.

(*B*) *The Muscles of the Eyelids*

Levator palpebræ superioris. Orbicularis oculi. Corrugator.

The Levator palpebræ superioris is described with the anatomy of the eye.

The **Orbicularis oculi** (figs. 574, 576) is a broad, flat, elliptical muscle which occupies the eyelids, surrounds the circumference of the orbit, spreads over the temporal region, and downwards on the cheek. It consists of three main portions—orbital, palpebral and lacrimal.

The *orbital portion* of the Orbicularis oculi, of a reddish colour and thicker than the palpebral portion, arises from the nasal part of the frontal bone, from the frontal process of the maxilla (fig. 577), and from the medial palpebral

Fig. 576.—The left Orbicularis oculi. Posterior aspect.

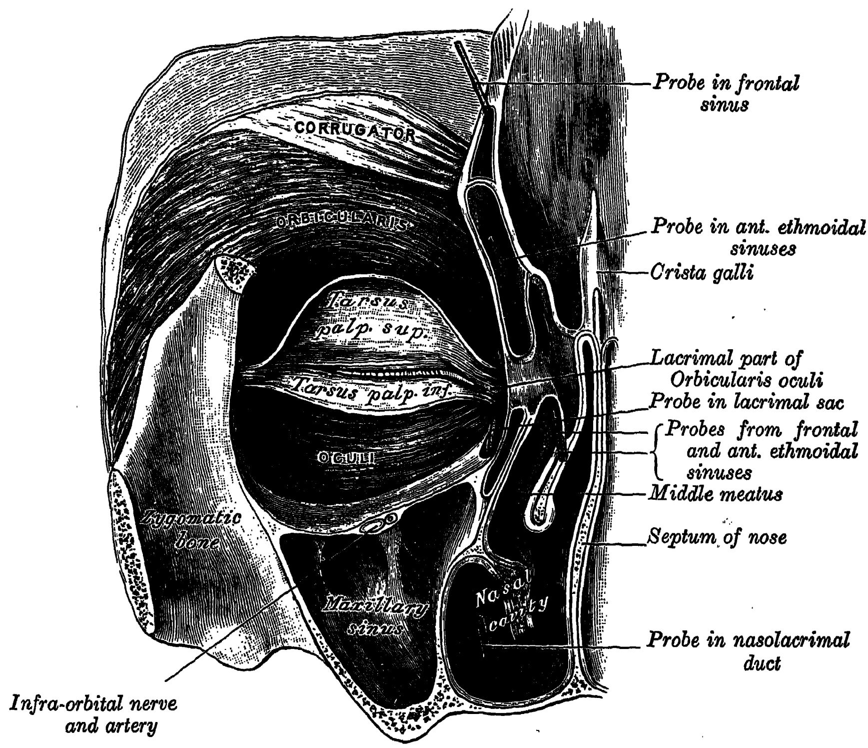


Fig. 577.—A sketch showing the attachments of the muscles around the right orbital opening.

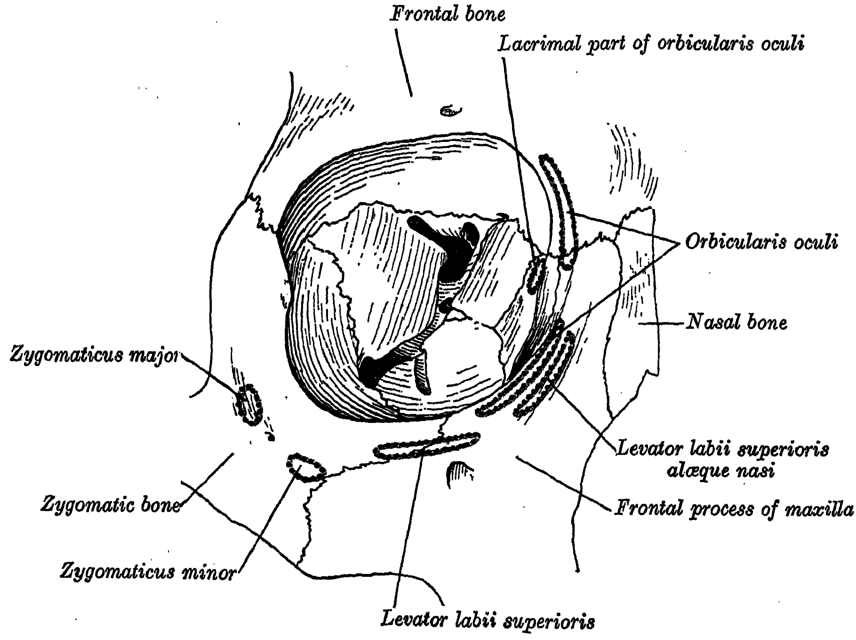


ligament, which interrupts the line of the bony origin. Its fibres form complete ellipses without interruption on the lateral side, the upper fibres blending with the Frontal belly of Occipitofrontalis and the Corrugator.

The *palpebral portion* of the Orbicularis oculi is thin and pale ; it arises from the medial palpebral ligament, chiefly from its superficial and partly from its deep surface, but not from its lower margin ; it arises also from the bone immediately above and below the ligament. The muscular fibres sweep across the eyelids in front of the orbital septum and at the lateral commissure interlace to form the lateral palpebral raphe. A small bundle of very fine fibres lies close to the margin of each eyelid, behind the eyelashes ; it is named the *ciliary bundle.*

The *lacrimal portion* of the Orbicularis oculi (Tensor tarsi) lies behind the lacrimal sac, but is separated from it by the lacrimal fascia. It arises from the fascia covering the lacrimal sac, from the upper part of the crest of the lacrimal bone, and from the adjacent part of the lateral surface of the lacrimal bone (fig. 576). Passing laterally behind the lacrimal sac the muscle divides into an upper and a lower slip ; some of the fibres of these slips are inserted into the tarsi of the eyelids and are closely related to the lacrimal canaliculi, but most of them are continued across the eyelids in front of the tarsi and interlace in the lateral palpebral raphe.

The *medial palpebral ligament,* about 4 mm. in length and 2 mm. in breadth, is attached to the frontal process of the maxilla in front of the nasolacrimal groove. Crossing the lacrimal sac, it divides into an upper and a lower part, which are attached to the medial end of the corresponding tarsus. It is separated from the lacrimal sac by the lacrimal fascia.

The *lateral palpebral raphe* is a much weaker structure than the medial palpebral ligament. It is formed by the interlacing of the lateral ends of the palpebral fibres of the Orbicularis oculi, strengthened on its deep surface by the orbital septum. A few lobules of the lacrimal gland lie between it and the more deeply placed lateral palpebral ligament (Whitnall).

Nerve-supply.—The Orbicularis oculi is supplied by the temporal and zygomatic branches of the facial nerve.

Actions.—The Orbicularis oculi is the sphincter muscle of the eyelids. The palpebral portion acts involuntarily, closing the lids gently, as in sleep or in blinking ; the orbital portion is subject to the will. When the entire muscle is brought into action, the skin of the forehead, temple, and cheek is drawn towards the medial angle of the orbit, and the eyelids are firmly closed. The skin thus drawn upon is thrown into folds, especially radiating from the lateral angle of the eyelids ; these folds become permanent in old age, and form the so-called ' crow's feet.' The Levator palpebræ superioris is the direct antagonist of this muscle since it raises the upper eyelid and exposes the front of the bulb of the eye. The lacrimal part of the Orbicularis oculi draws the eyelids and the papillæ lacrimales medially, and directs them into the lacus lacrimalis ; at the same time it exerts traction on the lacrimal fascia and so dilates the lacrimal sac.

The **Corrugator** is a small pyramidal muscle, placed at the medial end of the eyebrow, deep to the Frontal belly of Occipitofrontalis and to the Orbicularis oculi. It arises from the medial end of the superciliary arch ; and its fibres pass laterally and slightly upwards, and are inserted into the deep surface of the skin, above the middle of the orbital arch.

Nerve-supply.—The Corrugator is supplied by the temporal branches of the facial nerve.

Actions.—The Corrugator draws the eyebrow medially and downwards, producing the vertical wrinkles of the forehead. It is the ' frowning ' muscle, and may be regarded as the principal muscle in the expression of suffering.

(*C*) *The Muscles of the Nose* (fig. 574)

Procerus.	Depressor septi.
Compressor naris.	Dilator naris.

The **Procerus** is a small pyramidal slip continuous with the medial part of the Frontal belly of the Occipitofrontalis. It arises from the fascia covering the

lower part of the nasal bone and the upper part of the upper nasal cartilage; it is inserted into the skin over the lower part of the forehead between the two eyebrows.

Actions.—The Procerus draws down the medial angle of the eyebrow and produces the transverse wrinkles over the bridge of the nose.

The **Compressor naris** (Nasalis, pars transversa) arises from the maxilla, above and lateral to the incisor teeth; its fibres proceed upwards and medially and expand into a thin aponeurosis, which is continuous on the bridge of the nose with that of the muscle of the opposite side, and with the aponeurosis of the Procerus.

Actions.—The Compressor naris compresses the nasal aperture at the junction of the vestibule with the nasal cavity.

The **Dilator naris** * (Nasalis, pars alaris) arises from the maxilla below and medial to the origin of the Compressor naris, and is inserted into the ala nasi.

Actions.—The Dilator naris draws the ala downwards and laterally, and so assists in widening the anterior nasal aperture.

The **Depressor septi**, which is often regarded as a constituent portion of the Dilator naris, arises from the maxilla above the central incisor tooth; its fibres ascend to be inserted into the septum mobile nasi. It lies between the mucous membrane and muscular structure of the lip.

Actions.—The Depressor septi assists the Dilator naris to widen the nasal aperture.

Nerve-supply.—All the muscles of this group are supplied by the upper buccal branches of the facial nerve.

(*D*) *The Muscles of the Mouth* (fig. 574)

Levator labii superioris alæque nasi.†	Mentalis.
Levator labii superioris.†	Depressor labii inferioris.
Zygomaticus minor.†	Depressor anguli oris.
Levator anguli oris.	Buccinator.
Zygomaticus major.	Orbicularis oris.

Risorius.

The **Levator labii superioris alæque nasi** † arises from the upper part of the frontal process of the maxilla, and passing obliquely downwards and laterally divides into medial and lateral slips. The medial slip is inserted into the lower nasal cartilage (greater alar cartilage) and skin of the nose; the lateral slip is prolonged into the lateral part of the upper lip, and blends with the Levator labii superioris and with the Orbicularis oris.

Actions.—The lateral slip raises and everts the upper lip; the medial slip acts as a dilator of the nostril.

The **Levator labii superioris** † arises from the lower margin of the orbital opening immediately above the infra-orbital foramen, some of its fibres arising from the maxilla and others from the zygomatic bone. Its fibres converge to be inserted into the muscular substance of the upper lip between the lateral slip of the Levator labii superioris alæque nasi and the Levator anguli oris.

Actions.—The Levator labii superioris raises and everts the upper lip. It assists the Zygomaticus minor to form the nasolabial furrow, which passes from the side of the nose to the upper lip and gives to the face an expression of sadness.

The **Zygomaticus minor** † arises from the lateral surface of the zygomatic bone immediately behind the zygomaticomaxillary suture, and passes downwards and medially to be inserted into the muscular substance of the upper lip. It is separated from the Levator labii superioris by a narrow interval (fig. 574).

Actions.—The Zygomaticus minor assists in elevating the upper lip and in the production of the nasolabial furrow. When the Levator labii superioris

* The Dilatatores naris (B.N.A.) are represented by a few, poorly developed muscular slips which arise from the margin of the anterior bony aperture of the nose and the adjoining nasal cartilages and are inserted into the skin near the margin of the nostril.

† In the B.N.A. the Levator labii superioris alæque nasi, the Levator labii superioris and the Zygomaticus minor are grouped together and are termed the *angular*, *infra-orbital* and *zygomatic heads*, respectively, of the Quadratus labii superioris.

alæque nasi, the Levator labii superioris and the Zygomaticus minor are in action together they give to the countenance the expression of contempt and disdain.

The **Levator anguli oris** (Caninus) arises from the canine fossa, just below the infra-orbital foramen, and is inserted into the angle of the mouth, intermingling with the fibres of the Zygomaticus major, Depressor anguli oris (Triangularis), and Orbicularis oris. Between the Levator anguli oris and the Levator labii superioris are the infra-orbital vessels and plexus of nerves.

Actions.—The Levator anguli oris raises the angle of the mouth and assists in producing the nasolabial furrow.

The **Zygomaticus major** (Zygomaticus) arises from the zygomatic bone, in front of the zygomatico-temporal suture, and is inserted into the angle of the mouth, where it blends with the fibres of the Levator anguli oris (Caninus), Orbicularis oris, and Depressor anguli oris (Triangularis).

Actions.—The Zygomaticus major draws the angle of the mouth upwards and laterally as in laughing.

Nerve-supply.—All the five preceding muscles are supplied by the buccal branches of the facial nerve.

The **Mentalis** is a conical fasciculus, situated at the side of the frenulum of the lower lip. It arises from the incisive fossa of the mandible and descends to be inserted into the skin of the chin.

Actions.—The Mentalis raises and protrudes the lower lip, and at the same time wrinkles the skin of the chin, expressing doubt or disdain.

The **Depressor labii inferioris** (Quadratus labii inferioris) is a quadrilateral muscle. It arises from the oblique line of the mandible, between the symphysis menti and the mental foramen, and passes upwards and medially, to be inserted into the skin of the lower lip, its fibres blending with those of its fellow of the opposite side and with the Orbicularis oris. At its origin it is continuous with the fibres of the Platysma. Much yellow fat is intermingled with the superficial fibres of this muscle.*

Actions.—The Depressor labii inferioris draws the lower lip downwards and a little laterally, as in the expression of irony.

The **Depressor anguli oris** (Triangularis) arises from the oblique line of the mandible, below and lateral to the Depressor labii inferioris ; its fibres converge and are inserted by a narrow fasciculus into the angle of the mouth. At its origin it is continuous with the Platysma, and at its insertion with the Orbicularis oris and Risorius ; some of its fibres are directly continuous with those of the Levator anguli oris (Caninus), and others are occasionally found crossing from the muscle of one side to that of the other ; these latter fibres constitute the *Transversus menti.*

Actions.—The Depressor anguli oris draws the angle of the mouth downwards and laterally.

Nerve-supply.—The Mentalis, the Depressor labii inferioris and the Depressor anguli oris are all supplied by the mandibular branch of the facial nerve.

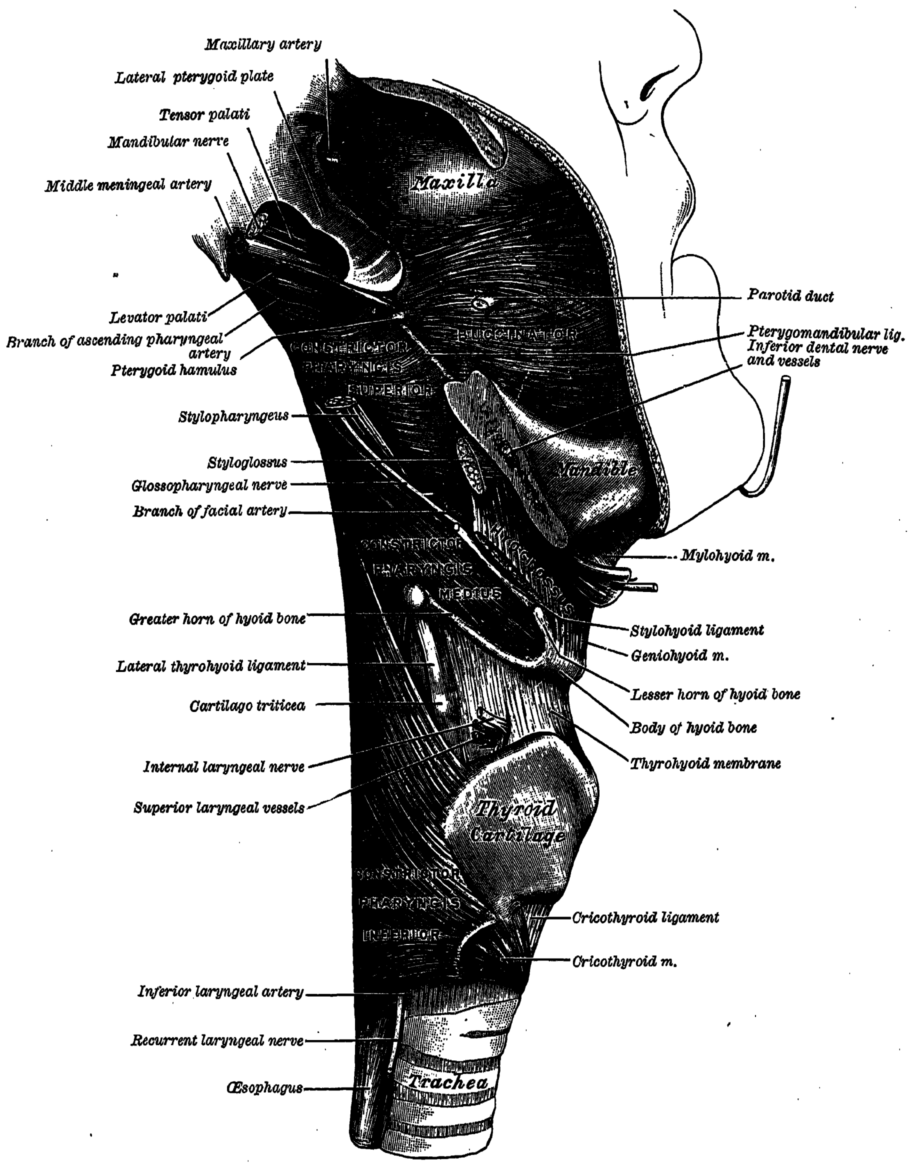
The **Buccinator** (fig. 578) is a thin quadrilateral muscle, occupying the interval between the maxilla and the mandible, at the side of the face. It arises from the outer surfaces of the alveolar processes of the maxilla and mandible, opposite to the three molar teeth ; and, behind, from the anterior border of the pterygomandibular ligament (pterygomandibular raphe), which separates the muscle from the Superior constrictor of the pharynx. Between the tuberosity of the maxilla and the upper end of the pterygomandibular ligament, a few fibres arise from a fine tendinous band which bridges the interval between the maxilla and the pterygoid hamulus. The tendon of the Tensor palati on its way to the soft palate pierces the pharyngeal wall in the small gap which lies behind this tendinous band. The fibres of the Buccinator converge towards the angle of the mouth, where the central fibres intersect each other, those from below being continuous with the upper segment of the Orbicularis oris, and

* The Zygomaticus major and minor and the Levator labii superioris are sometimes more or less concealed by a thin sheet of muscle, named the *Musculus malaris,* and continuous with the Orbicularis oculi. (Consult an article on the facial muscles, etc., by G. H. S. Lightoller, *Journal of Anatomy,* vol. lx. 1925.)

those from above with the lower segment; the highest and lowest fibres are continued forward into the corresponding lip without decussation.

Relations.—The Buccinator is on the same plane as the Superior Constrictor of the pharynx and is covered by the buccopharyngeal fascia. It is in relation by its *superficial surface*, behind, with a large mass of fat, which separates it from the ramus of the mandible,

FIG. 578.—The Buccinator and the muscles of the pharynx.



the Masseter and a small portion of the Temporalis; this fat has been named the *suctorial pad*, because it is supposed to assist in the act of sucking. In front the superficial surface of the Buccinator is in relation with the Zygomaticus major, Risorius, Levator and Depressor anguli oris, and the parotid duct, which pierces it opposite the second molar tooth of the maxilla; the facial (external maxillary) artery and anterior facial vein cross it from below upwards; it is also crossed by branches of the facial and buccal nerves. The *deep surface* is in relation with the buccal glands and mucous membrane of the mouth.

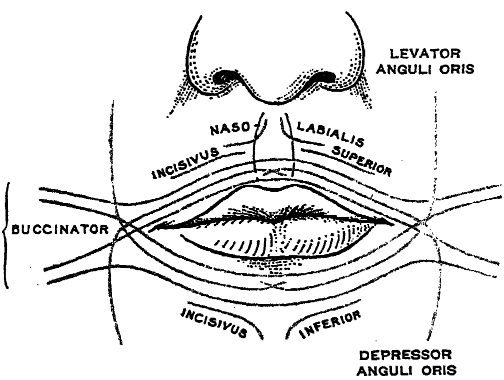
Nerve-supply.—The Buccinator is supplied by the lower buccal branches of the facial nerve.

Actions.—The Buccinator muscles compress the cheeks against the teeth, so that during the process of mastication the food is kept under the immediate pressure of the teeth. When the cheeks have been previously distended with air, the Buccinators expel it between the lips, as in blowing a trumpet; hence the name (*buccina*, a trumpet).

The *pterygomandibular ligament* (pterygomandibular raphe) is a tendinous band which is attached by one extremity to the hamulus of the medial pterygoid plate, and by the other to the posterior end of the mylohyoid line of the mandible. *Medially* it is covered by the mucous membrane of the mouth. *Laterally* it is separated from the ramus of the mandible by a quantity of adipose tissue. *Posteriorly* it gives attachment to the Superior constrictor of the pharynx, and *anteriorly* to a part of the Buccinator (fig. 578).

The **Orbicularis oris** (figs. 574, 579) is not a simple sphincter muscle like the Orbicularis oculi; it is made up of several strata of fibres which surround the orifice of the mouth but have different directions. It consists partly of fibres derived from the other facial muscles which are inserted into the lips, and partly of fibres proper to the lips. Of the former, a considerable number are derived from the Buccinator, and form the deeper stratum of the Orbicularis. Some of the Buccinator fibres—namely, those near the middle of the muscle—decussate at the angle of the mouth; the uppermost and lowermost fibres pass across the lips from side to side without decussation. Superficial to this is a second stratum, formed by the Levator and Depressor anguli oris (Caninus and Triangularis), which cross each other at the angle of the mouth; the fibres from the Levator pass to the lower lip, and those from the Depressor to the upper lip, along which they run, to be inserted into the skin near the anterior median line. Fibres are also derived from the Levator labii superioris, the Zygomaticus major and minor, and the Depressor labii inferioris (Quadratus labii inferioris); these intermingle with the transverse fibres described above, and have principally an oblique direction. The proper fibres of the lips are oblique, and pass from the deep surface of the skin to the mucous membrane, through the thickness of the lip. Finally there are fibres by which the muscle is connected with the maxillæ and the septum of the nose, above, and with the mandible, below. In the upper lip these consist of two bands, lateral and medial, on each side; the lateral band (*m. incisivus labii superioris*) arises from the alveolar border of the maxilla, opposite the lateral incisor tooth, and arching laterally is continuous with the other muscles at the angle of the mouth; the medial band (*m. nasolabialis*) connects the upper lip to the back of the septum of the nose. The interval between the two medial bands corresponds with the depression, called the *philtrum*, seen on the upper lip below the septum of the nose. The additional fibres for the lower lip constitute a slip (*m. incisivus labii inferioris*) on each side; this slip arises from the mandible, lateral to the Mentalis, and mingles with the other muscles at the angle of the mouth.

FIG. 579.—A scheme showing the arrangement of the fibres of the Orbicularis oris.



Nerve-supply.—The Orbicularis oris is supplied by the lower buccal and the mandibular branches of the facial nerve.

Actions.—The Orbicularis oris in its ordinary action effects the direct closure of the lips; by its deep, assisted by its oblique, fibres, it compresses the lips against the teeth. The superficial part, consisting principally of the decussating fibres, brings the lips together and protrudes them.

The **Risorius** arises from the parotid fascia and is inserted into the skin at

the angle of the mouth (fig. 574). It is a narrow bundle of fibres, broadest at its origin, but varying much in its size and form.

Nerve-supply.—The Risorius is supplied by the buccal branches of the facial nerve.

Actions.—The Risorius retracts the angle of the mouth, and produces an unpleasant grinning expression.*

II. The Muscles of Mastication

Masseter.	Pterygoideus lateralis.
Temporalis.	Pterygoideus medialis.

A strong layer of fascia, derived from the deep cervical fascia and named the **parotid fascia**, covers the Masseter and is firmly connected with it. It is attached to the lower border of the zygomatic arch, and invests the parotid gland (p. 536).

The **Masseter** (fig. 586) is a quadrilateral muscle, consisting of two portions, superficial and deep. The *superficial portion*, the larger, arises by a thick aponeurosis from the zygomatic process of the maxilla, and from the anterior two-thirds of the lower border of the zygomatic arch ; its fibres pass downwards and backwards, to be inserted into the angle and lower one-half of the lateral surface of the ramus of the mandible. The *deep portion* is much smaller and is partly concealed by the superficial portion ; it arises from the posterior one-third of the lower border and from the whole of the medial surface of the zygomatic arch ; its fibres pass almost vertically downwards to be inserted into the lateral surfaces of the coronoid process and the upper one-half of the ramus of the mandible.

Relations.—*Superficial* to the muscle are the integument, the Platysma, the Risorius, the Zygomaticus major, and the parotid gland ; the parotid duct, branches of the facial nerve, and the transverse facial vessels cross the muscle. The *deep surface* is in relation with the insertion of the Temporal muscle and the ramus of the mandible ; a mass of fat separates it in front from the Buccinator muscle and the buccal nerve. The masseteric nerve and artery reach the deep surface of the muscle by passing through the posterior part of the mandibular notch. The *posterior margin* is overlapped by the parotid gland ; the *anterior margin* projects over the Buccinator and is crossed below by the anterior facial vein.

Nerve-supply.—The Masseter is supplied by a branch of the anterior trunk of the mandibular nerve.

Actions.—The Masseter pulls the mandible towards and against the maxillæ ; from its relation to the axis of movement it can act with very great force.

The **temporal fascia** covers the Temporal muscle. It is a strong, fibrous investment, covered, laterally, by the Auriculares anterior et superior, the epicranial aponeurosis, and part of the Orbicularis oculi. The superficial temporal vessels and the auriculotemporal nerve cross it from below upwards. Above, it is a single layer, attached to the entire extent of the superior temporal line ; below, it consists of two layers, one of which is attached to the lateral, and the other to the medial border of the zygomatic arch. A small quantity of fat, the zygomatic branch of the superficial temporal artery, and the zygomatico-temporal branch of the maxillary nerve, are contained between these two layers. The deep surface of the fascia affords attachment to the superficial fibres of the Temporalis.

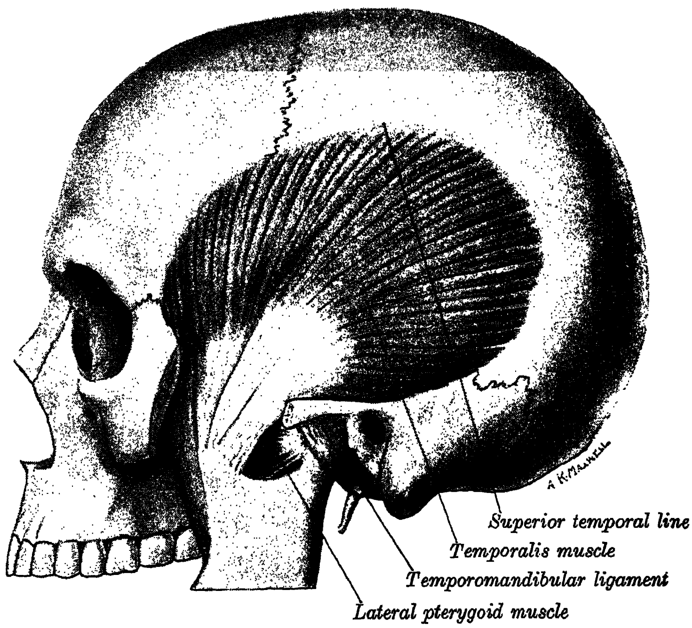
The **Temporalis** (fig. 580) is a fan-shaped muscle, situated at the side of the head. It arises from the whole of the temporal fossa (except the portion formed by the zygomatic bone) and from the deep surface of the temporal fascia. Its fibres converge as they descend, and end in a tendon which passes through the gap between the zygomatic arch and the side of the skull, and is inserted into the medial surface, apex, and anterior border of the coronoid process, and the

* Lightoller (*loc. cit.*) gives a detailed description of a *knot* or localised thickening where the fibres of the muscles surrounding or running to the oral fissure meet and intermingle. This knot is placed about 1 cm. lateral to the angle of the mouth, and has the form of a flattened cone with its base on the mucous membrane of the mouth ; the base, which is crescentic, has a vertical measurement of about 4 cm., and curves forward for a short distance into the lips.

anterior border of the ramus of the mandible nearly as far forwards as the last molar tooth.

Relations.—*Superficial* to the muscle are the skin, the Auriculares anterior et superior, the temporal fascia, the superficial temporal vessels, the auriculotemporal nerve, the temporal branches of the facial nerve, the zygomaticotemporal nerve, the epicranial aponeurosis, the zygomatic arch, and the Masseter. The *deep surface* is in relation with the temporal fossa, the Lateral pterygoid and part of the Buccinator, the maxillary artery and its deep temporal branches, the deep temporal nerves, and the buccal vessels and nerve. *Behind* the tendon of the muscle the vessels and nerve to the Masseter traverse the mandibular notch. The *anterior border* is separated from the zygomatic bone by a mass of fat.

FIG. 580.—The left Temporalis muscle. The zygomatic arch and the Masseter muscle have been removed.



Nerve-supply.—The Temporalis is supplied by the deep temporal branches of the anterior trunk of the mandibular nerve.

Actions.—The Temporal muscle elevates the mandible and so closes the mouth. This movement requires both the upward pull of the anterior fibres and the backward pull of the posterior fibres, because the head of the mandible rests on the articular eminence when the mouth is open. The posterior fibres draw the mandible backwards after it has been protruded.

The **Pterygoideus lateralis** (Pterygoideus externus) (fig. 581) is a short, thick muscle, somewhat conical in form. It arises by two heads : an *upper* from the infratemporal surface and infratemporal crest of the greater wing of the sphenoid bone ; and a *lower* from the lateral surface of the lateral pterygoid plate. Its fibres pass backwards and laterally, to be inserted into a depression on the front of the neck of the mandible, and into the articular capsule and disc of the mandibular articulation.

Relations.—Its *superficial surface* is in relation with the ramus of the mandible, the maxillary artery, which crosses it,* the tendon of the Temporal muscle and the Masseter. Its *deep surface* rests against the upper part of the Pterygoideus medialis, the sphenomandibular ligament, the middle meningeal artery, and the mandibular nerve ; its *upper border* is in relation with the temporal and masseteric branches of the mandibular nerve ; its *lower border* with the lingual and inferior dental (alveolar) nerves. The buccal (buccinator) nerve and the maxillary artery pass between the heads of the muscle.

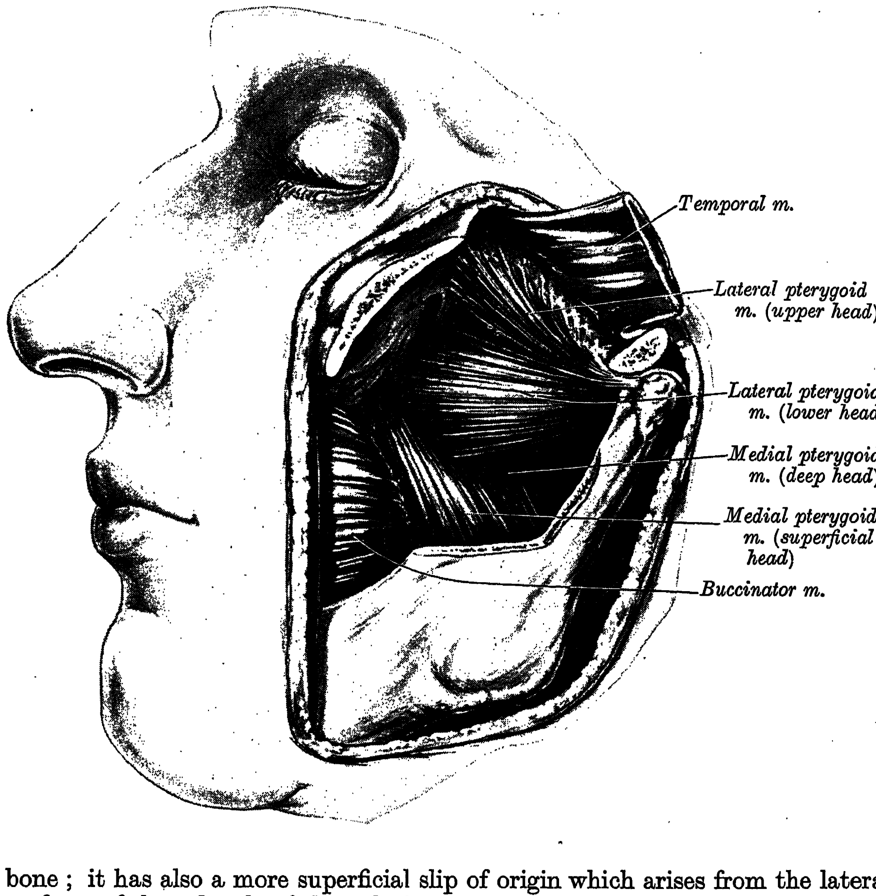
Nerve-supply.—The Lateral pterygoid muscle is supplied by a branch from the anterior trunk of the mandibular nerve.

* The artery often lies deep to the muscle, as shown in Fig. 582.

Actions.—The Lateral pterygoid muscle assists in opening the mouth, by pulling forward the condyloid process of the mandible and the articular disc, while the body of the mandible is being depressed by the suprahyoid muscles. Acting with the Medial pterygoid muscle it protrudes the mandible so that the lower incisors are projected in front of the upper.

The **Pterygoideus medialis** (Pterygoideus internus) (fig. 581), a thick, quadrilateral muscle, arises from the medial surface of the lateral pterygoid plate, and from the grooved surface of the tubercle (pyramidal process) of the palatine

Fig. 581.—The left Pterygoid muscles. The zygomatic arch and a portion of the ramus of the mandible have been removed.



bone; it has also a more superficial slip of origin which arises from the lateral surfaces of the tubercle of the palatine bone and tuberosity of the maxilla, and lies at first on the surface of the lower part of the lower head of the Lateral pterygoid muscle. Its fibres pass downwards, laterally, and backwards, and are inserted, by a strong tendinous lamina, into the lower and back part of the medial surfaces of the ramus and angle of the mandible, as high as the mandibular foramen.

Relations.—The *lateral surface* of the muscle is in relation with the ramus of the mandible, from which it is separated, at its upper part, by the Lateral pterygoid, the sphenomandibular ligament, the maxillary artery, the inferior dental vessels and nerve, the lingual nerve, and a process of the parotid gland. The *medial surface* is in relation with the Tensor palati, and is separated from the Superior constrictor of the pharynx by the Styloglossus, the Stylopharyngeus and some areolar tissue.

Nerve-supply.—The Medial pterygoid muscle is supplied by a branch from the mandibular nerve.

Actions.—The Medial pterygoid muscle assists in approximating the mandible to the maxillæ. Acting with the Lateral pterygoid it protrudes the

mandible. When the two Pterygoid muscles of one side are in action, the corresponding side of the mandible is drawn forwards, while the head of the mandible on the opposite side remains comparatively fixed ; by an alternating action of the muscles of the two sides, the side-to-side movements, such as take place during trituration of the food, are effected.

Fig. 582.—The structures in relation with the left Pterygoid muscles.

The **Pterygospinous ligament**, which is occasionally replaced by muscle fibres, stretches between the spine of the sphenoid bone and the posterior border of the lateral pterygoid plate near its upper end. It is sometimes ossified and then helps to bound a foramen which transmits the branches of the mandibular nerve destined for the Temporal, Masseter and Lateral pterygoid muscles.

THE FASCIÆ AND MUSCLES OF THE ANTEROLATERAL REGION OF THE NECK

The anterolateral muscles of the neck may be arranged into the following groups :

I. Superficial and lateral cervical.	III. Anterior vertebral.
II. Supra- and infra-hyoid.	IV. Lateral vertebral.

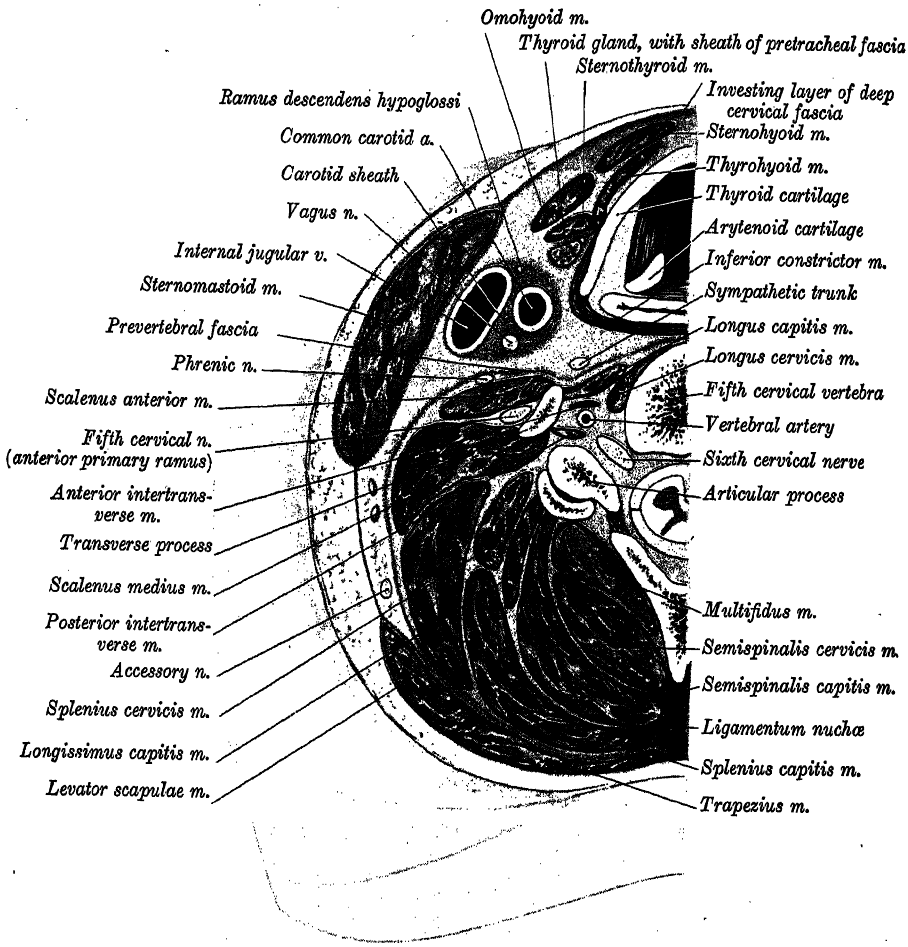
The **superficial fascia** of the neck is a thin lamina investing the Platysma and is hardly demonstrable as a separate membrane.

The **deep cervical fascia** (fig. 583) lies under cover of the Platysma, and invests the muscles of the neck. It consists of fibro-areolar tissue which occupies all the intervals that would otherwise exist between the muscles, viscera, vessels, etc., of the neck. In certain situations the white fibres predominate, and the fascia assumes the form of a thin fibrous sheet or layer, but elsewhere the tissue is loosely arranged and is easily broken down. It becomes condensed

around the blood-vessels, providing them with fibrous sheaths which here, as elsewhere in the body, bind the arteries and their accompanying veins closely together.

The investing portion of the fascia is attached behind to the ligamentum nuchæ and to the spine of the seventh cervical vertebra. It forms a thin investment for the Trapezius, and from the anterior border of this muscle is continued forwards, as a rather loose areolar layer covering the posterior triangle of the neck, to the posterior border of the Sternomastoid, where it

FIG. 583.—A transverse section through the left half of the neck to show the arrangement of the deep cervical fascia. Semidiagrammatic.



begins to assume the appearance of a fascial membrane. Along the hinder edge of the Sternomastoid it divides to enclose the muscle, and at the anterior margin again forms a single lamella, which covers the anterior triangle of the neck and reaches forwards to the median plane, where it is continuous with the corresponding lamella from the opposite side of the neck. In the median plane of the neck it is fixed to the symphysis menti and the body of the hyoid bone.

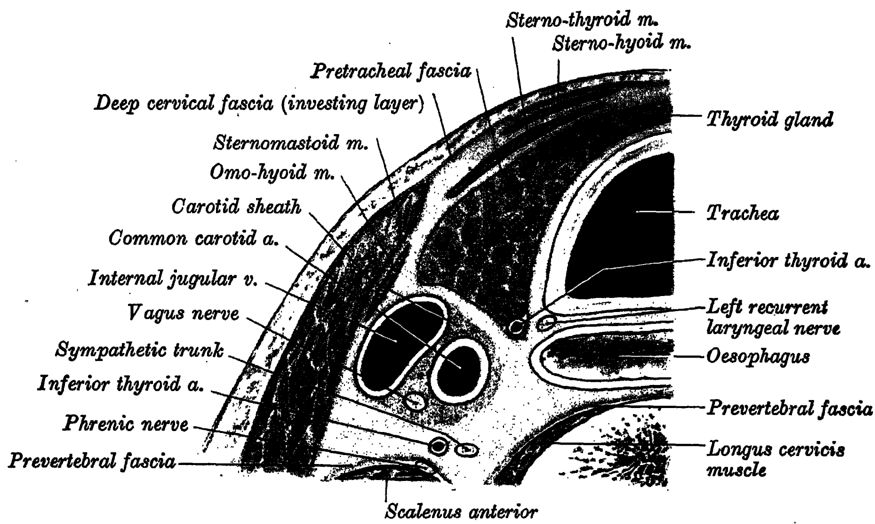
Above, the fascia is attached to the superior nuchal line of the occipital bone, to the mastoid process of the temporal bone, and to the whole length of the base of the mandible. Opposite the angle of the mandible it is very strong, and binds the anterior edge of the Sternomastoid firmly to that bone. Between the mandible and the mastoid process it ensheathes the parotid gland—the layer which covers the gland extends upwards under the name of the *parotid fascia*

and is fixed to the zygomatic arch. From the part which passes deep to the parotid gland a strong band ascends to the styloid process, forming the *stylo-mandibular ligament* (p. 433).

Below, the fascia is attached to the acromion, the clavicle and the manubrium sterni. Some little distance above the last, it splits into a superficial and a deep layer. The former is attached to the anterior border of the manubrium, the latter to its posterior border and to the interclavicular ligament. Between these two layers there is a slit-like interval, termed the *suprasternal space* ; it contains a small quantity of areolar tissue, the lower portions of the anterior jugular veins and the jugular arch, the sternal heads of the Sternomastoid muscles, and sometimes a lymph-gland.

The *carotid sheath* is a condensation of the cervical fascia in which the common and internal carotid arteries, the internal jugular vein, the vagus nerve and the constituents of the ansa hypoglossi are imbedded. It is thicker on the arteries than it is on the vein, and peripherally it is connected to the neighbouring layers by loose areolar tissue (fig. 584).

FIG. 584.—Part of a transverse section through the lower part of the neck to show the carotid sheath. Semidiagrammatic.



The *prevertebral layer* of the cervical fascia covers the prevertebral muscles and extends laterally on the Scalenus anterior, the Scalenus medius and the Levator scapulæ muscles, i.e. it forms a fascial floor for the posterior triangle of the neck. As the subclavian artery and the brachial nerves emerge from behind the Scalenus anterior they carry the prevertebral fascia downwards and laterally behind the clavicle to form the *axillary sheath.* Traced laterally round the neck, the prevertebral fascia rapidly becomes thinner and more areolar in character and it is lost as a definite fibrous layer under cover of the Trapezius. Superiorly it is attached to the base of the skull, and inferiorly it is carried downwards in front of the longus cervicis (longus colli) muscles into the superior mediastinum, where it blends with the anterior longitudinal ligament. Anteriorly the prevertebral layer is separated from the pharynx and its covering buccopharyngeal fascia by a loose cellular interval which is termed the *retro-pharyngeal space.* Further from the median plane, the same loose areolar tissue connects the prevertebral layer to the pretracheal fascia, the carotid sheath and the fascia on the deep surface of the Sternomastoid muscle. It should be observed that all the anterior primary rami of the cervical nerves lie at first on the deep surface of the prevertebral layer, and certain of their important branches retain this position throughout their course in the neck, viz. the phrenic, the nerve to the Rhomboids (dorsalis scapulæ nerve) and the nerve to Serratus anterior (long thoracic).

The *pretracheal layer* of the cervical fascia is very thin and owes such importance as it possesses to its intimate relationship with the thyroid gland, for which it provides a fine fascial sheath. Above, it is attached to the arch of the cricoid cartilage, and, below, it is continued into the superior mediastinum as an investment for the inferior thyroid veins.

Applied Anatomy.—The deep cervical fascia is of considerable importance from a surgical point of view. The investing layer opposes the extension of abscesses towards the surface, and pus forming beneath it has a tendency to extend laterally. If the pus be contained in the anterior triangle, it may find its way into the mediastinum, in front of the pretracheal layer of fascia; but owing to the thinness of the fascia in this situation it more frequently finds its way to the surface and points above the sternum. Pus forming behind the prevertebral layer, in cases, for instance, of caries of the bodies of the cervical vertebræ, may extend towards the lateral part of the neck and point in the posterior triangle, or may perforate this layer of fascia and the buccopharyngeal fascia and point into the pharynx (retropharyngeal abscess).

In cases of cut throat, when the wound involves only the investing layer the injury is usually trivial, the special danger being injury to the external jugular vein. But where the second of the two layers is opened up, important structures may be injured, and serious results follow.

I. The Superficial and Lateral Cervical Muscles

Platysma. Trapezius. Sternocleidomastoideus.

The **Platysma** (fig. 574) is a broad sheet arising from the fascia covering the upper parts of the Pectoralis major and Deltoid; its fibres cross the clavicle, and proceed obliquely upwards and medially in the side of the neck. The anterior fibres interlace, below and behind the symphysis menti, with the fibres of the muscle of the opposite side; the posterior fibres cross the mandible, some being inserted into the bone below the oblique line, others into the skin and subcutaneous tissue of the lower part of the face, many of these fibres blending with the muscles about the angle and lower part of the mouth. Sometimes fibres can be traced to the Zygomaticus major or to the margin of the Orbicularis oculi. Under cover of the Platysma, the external jugular vein descends from the angle of the mandible to the middle of the clavicle.

Nerve-supply.—The Platysma is supplied by the cervical branch of the facial nerve.

Actions.—When the entire Platysma is in action it produces a wrinkling of the surface of the skin of the neck in an oblique direction, and tends to diminish the concavity between the jaw and the side of the neck. Its anterior portion, which is the thickest part of the muscle, may assist in depressing the mandible; it also serves to draw down the lower lip and angle of the mouth in the expression of horror or surprise.

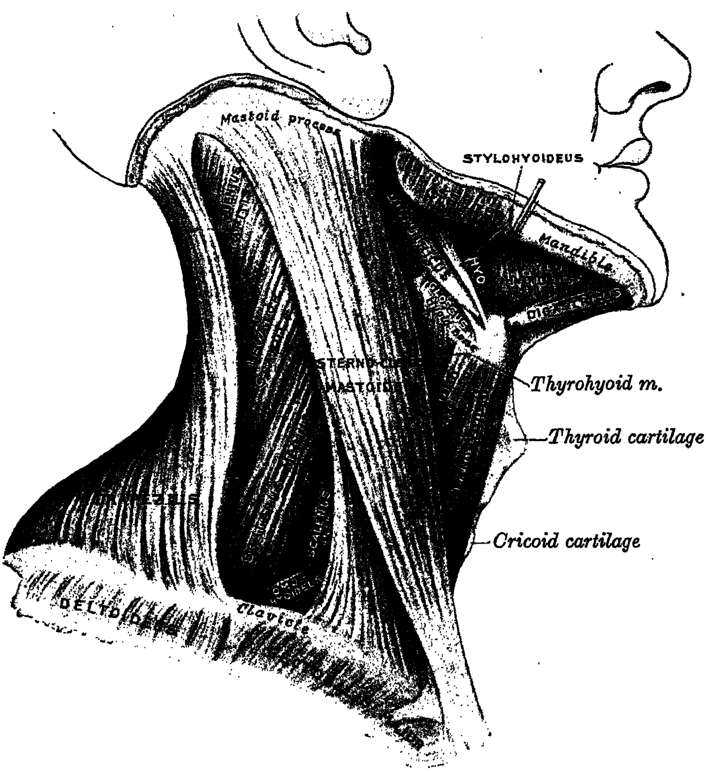
The **Trapezius** is described on p. 582.

The **Sternomastoid** (fig. 585) passes obliquely across the side of the neck. It is thick and narrow at its central part, but broader and thinner at each end. It arises by two heads. The *medial* or *sternal head* is a rounded tendinous fasciculus, which arises from the upper part of the anterior surface of the manubrium sterni, and is directed upwards, laterally, and backwards. The *lateral* or *clavicular head,* composed of fleshy and aponeurotic fibres, arises from the superior border and anterior surface of the medial one-third of the clavicle, and is directed almost vertically upwards. The two heads are separated from each other at their origins by a triangular interval, but, as they ascend, the clavicular head passes under cover of the sternal head and blends with its deep surface below the middle of the neck, forming a thick, rounded belly. The muscle is inserted by a strong tendon into the lateral surface of the mastoid process, from its apex to its superior border, and by a thin aponeurosis into the lateral half of the superior nuchal line of the occipital bone.

The clavicular head of the Sternomastoid may be as narrow as the sternal head, or may have a width of 7·5 cm.; when it is broad it is occasionally subdivided into several slips. More rarely, the adjoining margins of the Sternomastoid and Trapezius are in contact.

This muscle divides the quadrilateral area of the side of the neck into two triangles, an anterior and a posterior. The boundaries of the *anterior triangle* are, in front, the median line of the neck ; above, the base of the mandible, and a line continuing this from the angle of the mandible to the Sternomastoid ; behind, the anterior border of the Sternomastoid. The apex of the triangle is at the upper border of the sternum. The boundaries of the *posterior triangle* are, in front, the posterior border of the Sternomastoid ; below, the middle one-third of the clavicle ; behind, the anterior margin of the Trapezius. The apex corresponds with the meeting of the Sternomastoid and Trapezius on the occipital bone. The subdivisions and contents of these triangles are given on pp. 716 to 720.

FIG. 585.—The muscles of the neck. Right lateral aspect.



Relations.—*Superficial* to the muscle are the skin and Platysma ; it is separated from the Platysma by the external jugular vein, the great auricular and anterior cutaneous cervical nerves, and the investing layer of the deep cervical fascia. Near its insertion the muscle is overlapped by a small portion of the parotid gland. The *deep surface* of the muscle is related at its origin to the sternoclavicular joint ; it lies upon the Sternohyoid, Sternothyroid and the Omohyoid muscles, while the anterior jugular vein crosses deep to it but superficial to the infrahyoid muscles immediately above the clavicle. The carotid sheath and the subclavian artery are deep to these muscles. Between the Omohyoid and the posterior belly of the Digastric the anterior part of the Sternomastoid overlaps the common, internal and external carotid arteries, the internal jugular, common facial and lingual veins, the deep cervical lymph glands, and the vagus, descendens hypoglossi and descending cervical nerves. The sternomastoid branch of the superior thyroid artery crosses deep to the muscle at the upper border of the Omohyoid. The posterior part of the muscle is related deeply to the Splenius, Levator scapulæ and Scaleni, the cervical plexus, the upper part of the brachial plexus, the phrenic nerve, and the transverse cervical and suprascapular arteries. The occipital artery crosses deep to the muscle at, or under cover of, the lower border of the Digastric, where the accessory nerve, which pierces the muscle, runs downwards and laterally deep to it. At its insertion the muscle lies superficial to the mastoid process, and to the Splenius, Longissimus capitis, and the posterior belly of the Digastric.

Nerve-supply.—The Sternomastoid is supplied by the accessory nerve, which traverses it, and by branches from the anterior primary rami of the second and third cervical nerves.

Actions.—When one Sternomastoid acts, it draws the head towards the shoulder of the same side; it also rotates the head so as to carry the face towards the opposite side. Acting together from their sternoclavicular attachments the two muscles flex the head and the cervical part of the vertebral column; if the head be fixed, they assist in elevating the thorax in forced inspiration.

Applied Anatomy.—The deformity known as *wry-neck* is due to a contracted condition of the Sternomastoid. It may be temporary, as the result of direct irritation of the muscle or of the nerves supplying it. It may, however, be permanent, and is then most often due to injury to the muscle during birth, rupture of the fibres and subsequent cicatricial contraction taking place. In these cases, division of the muscle is often necessary to effect a cure.

There is also a condition coming on in adult life (spasmodic torticollis) which begins with tonic or clonic spasm of one Sternomastoid, soon followed by a spasm of the Trapezius, particularly its clavicular portion.

II. The Supra- and Infra-hyoid Muscles

The suprahyoid muscles are:

Digastricus.	Mylohyoideus.
Stylohyoideus.	Geniohyoideus.

The **Digastric** (fig. 585) consists of two fleshy bellies united by an intermediate rounded tendon. It lies below the body of the mandible, and extends, in a curved form, from the mastoid process to the chin. The *posterior belly*, longer than the anterior, arises from the mastoid notch of the temporal bone and passes downwards and forwards. The *anterior belly* arises from the digastric fossa on the base of the mandible close to the median plane, and passes downwards and backwards. The two bellies end in an intermediate tendon, which perforates the Stylohyoid muscle. It is held in connexion with the side of the body and the greater cornu of the hyoid bone by a fibrous loop, which is sometimes lined by a synovial sheath. An aponeurotic layer, sometimes named the *suprahyoid aponeurosis*, is given off from the tendon of the Digastric muscle, and is attached to the body and greater cornu of the hyoid bone.

Relations.—Its superficial surface is in relation with the Platysma, Sternomastoid, part of the Splenius, Longissimus capitis, mastoid process, Stylohyoid and the parotid gland. The *deep surface* of the anterior belly lies on the Mylohyoid; that of the posterior belly on the Superior oblique, Rectus capitis lateralis, the transverse process of the atlas vertebra, the accessory nerve, internal jugular vein, occipital artery, hypoglossal nerve, the internal and external carotid, the facial and lingual arteries and the Hyoglossus muscle (fig. 586).

Nerve-supply.—The anterior belly of the Digastric is supplied by the mylohyoid branch of the inferior dental (inferior alveolar) nerve; the posterior belly by the facial nerve.

Actions.—When the anterior belly of the Digastric takes its fixed point below, it depresses the front of the mandible. When both bellies are in action from above they elevate the hyoid bone.

The Digastric divides the upper part of the anterior triangle of the neck into three triangles: (1) the *digastric triangle*, bounded above by the base of the mandible and a line continuing this from the angle of the mandible to the Sternomastoid, below by the posterior belly of the Digastric and the Stylohyoid, in front by the anterior belly of the Digastric; (2) the *carotid triangle*, bounded above by the posterior belly of the Digastric and Stylohyoid, behind by the Sternomastoid, below by the Omohyoid; (3) the *submental triangle*, bounded on each side by the anterior belly of the Digastric, and inferiorly by the body of the hyoid bone.

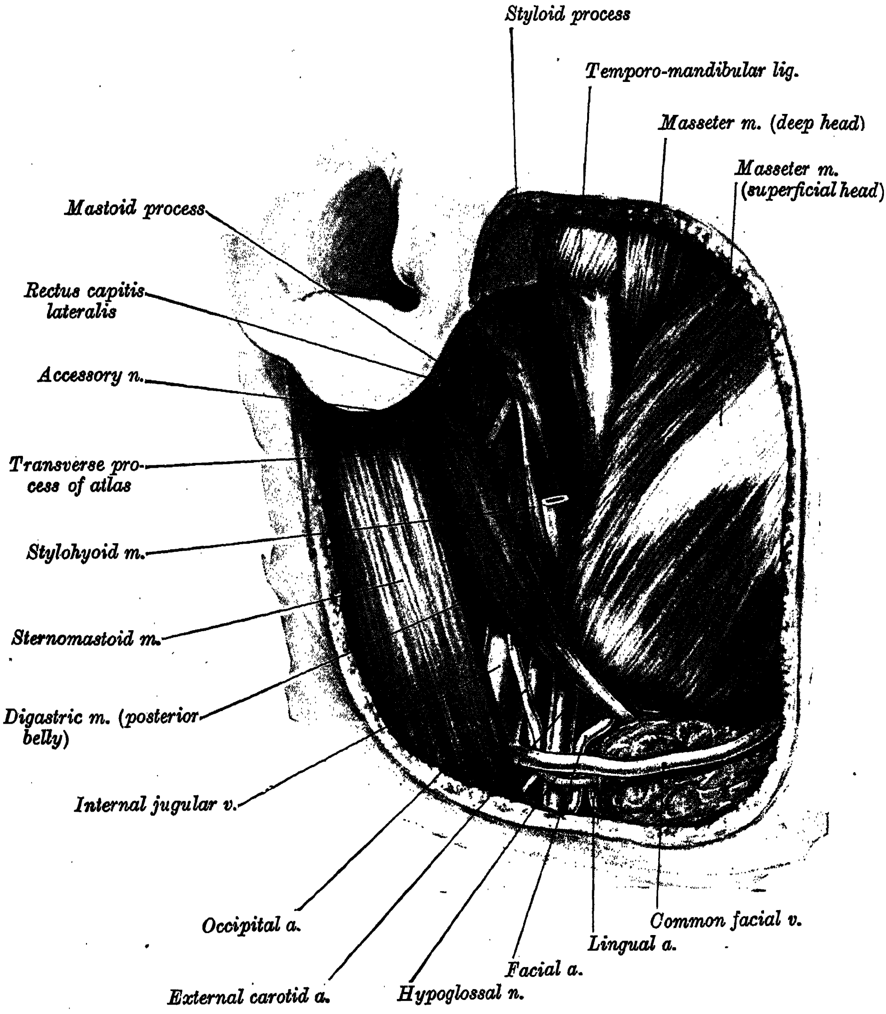
The **Stylohyoid** (figs. 586, 587) arises by a delicate little tendon from the posterior and lateral surfaces of the styloid process, near its base; and, passing

downwards and forwards, is inserted into the body of the hyoid bone, at its junction with the greater cornu, and just above the Omohyoid. It is perforated, near its insertion, by the tendon of the Digastric.

Nerve-supply.—The Stylohyoid is supplied by the facial nerve.

Action.—The Stylohyoid draws the hyoid bone upwards and backwards during the act of deglutition.

Fig. 586.—The relations of the posterior belly of the Digastric muscle of the right side.



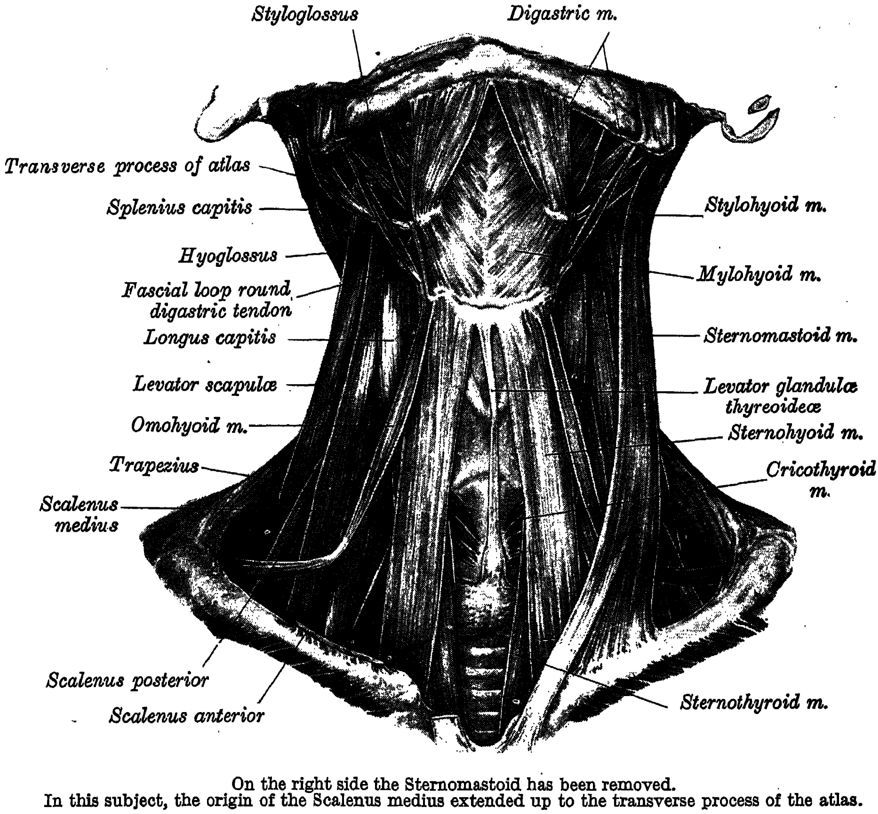
The parotid gland has been removed; the external carotid artery has been divided below its point of entry into the gland; and the facial nerve has been cut just below the stylomastoid foramen.

The *stylohyoid ligament.*—In connexion with the Stylohyoid muscle a ligamentous band, named the *stylohyoid ligament,* may be described. It is a fibrous cord, which is attached to the tip of the styloid process of the temporal bone and to the lesser cornu of the hyoid bone. It gives origin to the highest fibres of the Constrictor pharyngis medius and is intimately related to the lateral wall of the oral pharynx (fig. 1150). Below, it is covered by the Hyoglossus muscle. It frequently contains a little piece of cartilage in its centre, is often partially ossified, and in many animals forms a distinct bone, termed the *epihyal.* The stylohyoid ligament represents a portion of the skeletal element of the second visceral arch.

The **Mylohyoid** (figs. 585, 587) is situated immediately above the anterior belly of the Digastric, and forms, with its fellow of the opposite side, a muscular floor for the cavity of the mouth. It is a flat, triangular sheet which arises from the whole length of the mylohyoid line of the mandible. The posterior fibres pass medially and slightly downwards, to be inserted into the front of the body of the hyoid bone near its lower border. The middle and anterior fibres are inserted into a median fibrous raphe which stretches from the symphysis menti to the hyoid bone. This median raphe is sometimes wanting ; if so, the two muscles are continuous.

Relations.—Its *superficial* or *inferior surface* is in relation with the Platysma, the anterior belly of the Digastric, the suprahyoid aponeurosis, the superficial part of the submandibular (submaxillary) gland, the facial and submental vessels, and the mylohyoid vessels and nerve.

FIG. 587.—The muscles of the front of the neck.



On the right side the Sternomastoid has been removed.
In this subject, the origin of the Scalenus medius extended up to the transverse process of the atlas.

Its *deep* or *superior surface* is in relation with the Geniohyoid, part of the Hyoglossus, and the Styloglossus muscles, the hypoglossal and lingual nerves, the submandibular ganglion, the sublingual gland, the deep portion of the submandibular gland and the submandibular duct, the lingual and sublingual vessels, and the buccal mucous membrane.

Nerve-supply.—The Mylohyoid muscle is supplied by the mylohyoid branch of the inferior dental (inferior alveolar) nerve.

Actions.—Acting from below the Mylohyoid depresses the front of the mandible ; acting from above it raises the hyoid bone and the floor of the mouth.

The **Geniohyoid** (fig. 1146) is a narrow muscle, situated above the medial part of the Mylohyoid. It arises from the inferior genial tubercles on the back of the symphysis menti, and runs backwards and slightly downwards, to be inserted into the anterior surface of the body of the hyoid bone ; it is in contact with its fellow of the opposite side.

Nerve-supply.—The Geniohyoid muscle is supplied by the first cervical nerve through the hypoglossal nerve.

Actions.—When the Geniohyoid acts from the hyoid bone, it depresses the front of the mandible; when it acts from the mandible it raises and pulls forwards the hyoid bone.

The infrahyoid muscles are:

Sternohyoideus.	Thyreohyoideus.
Sternothyreoideus.	Omohyoideus.

The **Sternohyoid** (figs. 585, 587), a thin, narrow muscle, arises from the posterior surface of the medial end of the clavicle, the posterior sternoclavicular ligament, and the upper and posterior part of the manubrium sterni. Passing upwards and medially, it is inserted into the lower border of the body of the hyoid bone. It sometimes presents, near its origin, a transverse tendinous intersection. Below, the Sternohyoid is separated from its fellow by a considerable interval; but the two muscles come into contact with each other in the middle of their course, and are contiguous above.

Nerve-supply.—The Sternohyoid muscle is supplied by branches from the loop (ansa hypoglossi) between the ramus descendens hypoglossi and the nervus descendens cervicalis.

Action.—The Sternohyoid depresses the hyoid bone.

The **Sternothyroid** (figs. 585, 587) is shorter and wider than the Sternohyoid, and lies under cover of it. It arises from the posterior surface of the manubrium sterni below the origin of the Sternohyoid, and from the edge of the cartilage of the first rib, and sometimes that of the second; it is inserted into the oblique line on the lamina of the thyroid cartilage. At the lower part of the neck this muscle is in contact with its fellow, but it diverges as it ascends; it is occasionally traversed by a transverse or oblique tendinous intersection. It is closely applied to the anterolateral surface of the lobe of the thyroid gland.

Nerve-supply.—The Sternothyroid muscle is supplied by branches from the ansa hypoglossi.

Action.—The Sternothyroid draws the larynx downwards.

The **Thyrohyoid**, a small, quadrilateral muscle, may be looked upon as an upward continuation of the Sternothyroid. It arises from the oblique line on the lamina of the thyroid cartilage, and is inserted into the lower border of the greater cornu of the hyoid bone.

Nerve-supply.—The Thyrohyoid muscle is supplied by a branch from the hypoglossal nerve. Like the nerve to the Geniohyoid, this nerve is ultimately derived from the first cervical nerve.

Actions.—The Thyrohyoid depresses the hyoid bone, or raises the larynx.

The **Omohyoid** (figs. 585, 587) consists of two fleshy bellies united at an angle by an intermediate tendon. It arises from the upper border of the scapula near the suprascapular notch, and occasionally from the suprascapular (superior transverse) ligament, its extent of attachment to the scapula varying from a few millimetres to 2·5 cm. From this origin, the *inferior belly* forms a flat, narrow fasciculus, which inclines forwards and slightly upwards across the lower part of the neck, being bound to the clavicle by a fibrous expansion; it then passes behind the Sternomastoid and there ends in the intermediate tendon. The *superior belly* passes almost vertically upwards from this tendon, close to the lateral border of the Sternohyoid muscle, and is inserted into the lower border of the body of the hyoid bone, lateral to the insertion of the Sternohyoid. The intermediate tendon, which varies in length and form, usually lies on the internal jugular vein, opposite the arch of the cricoid cartilage. It is held in position by a process of the deep cervical fascia which ensheathes it and is attached below to the clavicle and the first rib; it is by this fascial process that the angular form of the muscle is maintained.

Nerve-supply.—The superior belly of the Omohyoid is supplied by the ramus descendens hypoglossi; the inferior belly by a branch from the ansa hypoglossi.

Actions.—The Omohyoid muscle depresses the hyoid bone and carries it backwards and laterally. The Omohyoids are concerned also in prolonged inspiratory efforts; by rendering tense the lower part of the deep cervical fascia they lessen the inward suction of the soft parts, which would otherwise compress the great vessels and the apices of the lungs.

The inferior belly of the Omohyoid divides the posterior triangle of the neck

into an upper or *occipital* and a lower or *subclavian* triangle, while its superior belly divides the anterior triangle into an upper or *carotid* and a lower or *muscular* triangle.

III. The Anterior Vertebral Muscles (fig. 588)

Longus cervicis.	Rectus capitis anterior.
Longus capitis.	Rectus capitis lateralis.

The **Longus cervicis** (Longus colli) is situated on the anterior surface of the vertebral column, between the atlas and the third thoracic vertebra. It is divisible into three portions, an inferior oblique, a superior oblique, and a vertical; its origin and insertion consist of tendinous slips. The *inferior oblique portion*, which is the smallest part of the muscle, arises from the front of the bodies of the first two or three thoracic vertebræ; it runs upwards and laterally, and is inserted into the anterior tubercles of the transverse processes of the fifth and sixth cervical vertebræ. The *superior oblique portion* arises from the anterior tubercles of the transverse processes of the third, fourth and fifth cervical vertebræ; it is directed upwards and medially, and is inserted by a narrow tendon into the anterolateral surface of the tubercle on the anterior arch of the atlas. The *vertical portion* arises from the front of the bodies of the upper three thoracic and lower three cervical vertebræ, and is inserted into the front of the bodies of the second, third and fourth cervical vertebræ.

Nerve-supply.—The Longus cervicis is supplied by branches from the anterior primary rami of the second, third and fourth cervical nerves.

Actions.—The Longus cervicis bends the cervical portion of the vertebral column forwards; in addition, the oblique portions flex the column laterally and the inferior oblique portion rotates it to the opposite side.

The **Longus capitis**, broad and thick above, narrow below, arises by tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, fifth and sixth cervical vertebræ, and is inserted into the inferior surface of the basilar part of the occipital bone.

Nerve-supply.—The Longus capitis is supplied by branches from the anterior primary rami of the first, second and third cervical nerves.

Action.—The Longus capitis flexes the head.

The **Rectus capitis anterior** is a short, flat muscle situated behind the upper part of the Longus capitis. It arises from the anterior surface of the lateral mass of the atlas, and from the root of its transverse process, and is inserted into the inferior surface of the basilar part of the occipital bone in front of the occipital condyle.

Nerve-supply.—The Rectus capitis anterior is supplied by branches from the loop between the anterior primary rami of the first and second cervical nerves.

Action.—The Rectus capitis anterior flexes the head.

The **Rectus capitis lateralis** is a short, flat muscle which arises from the upper surface of the transverse process of the atlas and is inserted into the under surface of the jugular process of the occipital bone. In view of its attachments and its relations to the anterior and posterior primary rami of the first cervical nerve, the rectus capitis lateralis is regarded as homologous with the posterior intertransverse muscles.

Nerve-supply.—The Rectus capitis lateralis is supplied by branches from the loop between the anterior primary rami of the first and second cervical nerves.

Action.—The Rectus capitis lateralis bends the head to the same side.

IV. The Lateral Vertebral Muscles (fig. 588)

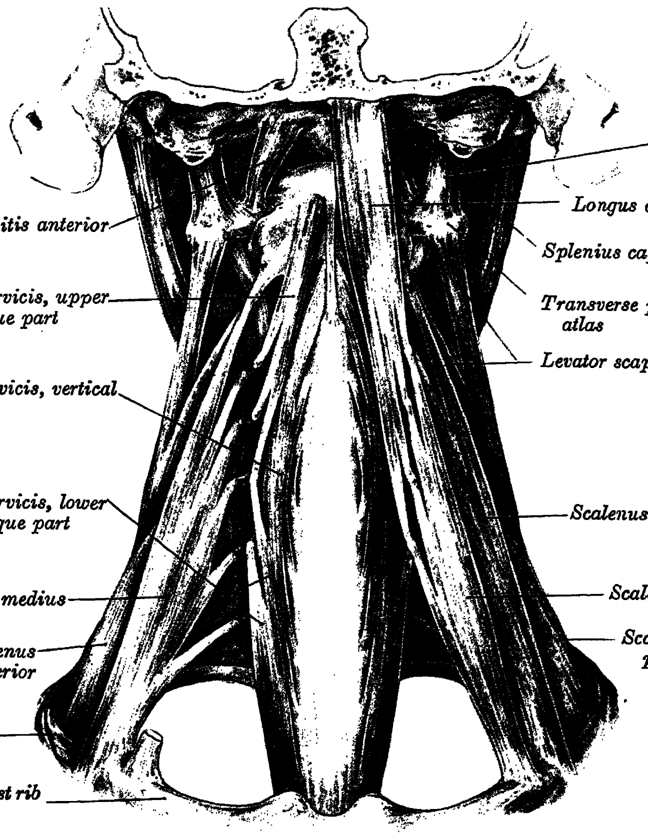
Scalenus anterior. Scalenus medius.
Scalenus posterior.

The **Scalenus anterior** lies deeply at the side of the neck, behind the Sternomastoid muscle. It arises from the anterior tubercles of the transverse processes of the third, fourth, fifth, and sixth cervical vertebræ, and descending,

almost vertically, is inserted by a narrow, flat tendon into the scalene tubercle on the inner border of the first rib, and into the ridge on the upper surface of the rib in front of the groove for the subclavian artery.

Relations.—*In front* of it are the clavicle, the Subclavius, Sternomastoid, and Omohyoid muscles, the lateral portion of the carotid sheath, the transverse cervical, suprascapular and ascending cervical arteries, the subclavian vein, the prevertebral fascia and the phrenic nerve. Its *posterior surface* is in relation with the pleura, and with the nerves forming the brachial plexus and the subclavian artery, which separate it from the Scalenus medius. Below, it is separated from the Longus cervicis by an angular interval (fig. 593), in which the vertebral artery, with its companion vein on its lateral side, ascends to reach the foramen

FIG. 588.—The anterior and lateral vertebral muscles.



On the right side the Scalenus anterior and the Longus capitis have been removed.

transversarium of the sixth cervical vertebra. The inferior thyroid artery crosses the interval from the lateral to the medial side near its apex. The sympathetic trunk and its inferior cervical ganglion are closely related to the medial side of this part of the vertebral artery. On the left side the thoracic duct crosses this interval at the level of the seventh cervical vertebra and usually comes into contact with the medial edge of the muscle. Above, it is separated from the Longus capitis by the ascending cervical branch of the inferior thyroid artery.

Nerve-supply.—The Scalenus anterior is supplied by branches from the anterior primary rami of the fourth, fifth, and sixth cervical nerves.

Actions.—Acting from below the Scalenus anterior bends the cervical portion of the vertebral column forwards and laterally and rotates it towards the opposite side. When the muscle acts from above it assists in elevating the first rib.

The **Scalenus medius**, the largest and longest of the Scaleni, arises from the front of the posterior tubercles of the transverse processes of the lower six

cervical vertebræ, and frequently extends upwards to the transverse process of the atlas (fig. 587); it is inserted into the upper surface of the first rib, between the tubercle of the rib and the groove for the subclavian artery.

Relations.—Its *anterolateral surface* is in relation with the Sternomastoid; it is crossed by the clavicle and the Omohyoid: *anteriorly*, it is separated from the Scalenus anterior by the subclavian artery and the cervical nerves. The Levator scapulæ and the Scalenus posterior are posterolateral to it. The upper two roots of the nerve to Serratus anterior (long thoracic nerve), and the nerve to the Rhomboids (dorsal scapular nerve) pierce the substance of the muscle and appear on its lateral surface.

Nerve-supply.—The Scalenus medius is supplied by branches from the anterior primary rami of the cervical nerves.

Actions.—The Scalenus medius, acting from below, bends the cervical part of the vertebral column to the same side; acting from above it helps to raise the thorax.

The **Scalenus posterior**, the smallest and deepest of the Scaleni, arises from the posterior tubercles of the transverse processes of the fourth, fifth, and sixth cervical vertebræ, and is inserted by a thin tendon into the outer surface of the second rib, behind the tubercle for the Serratus anterior. It is occasionally blended with the Scalenus medius.

Nerve-supply.—The Scalenus posterior is supplied by branches from the anterior primary rami of the lower three cervical nerves.

Actions.—The Scalenus posterior bends the lower end of the cervical part of the vertebral column to the same side, when the second rib is fixed; if its upper attachment be fixed it helps to elevate the thorax.

THE FASCIÆ AND MUSCLES OF THE TRUNK

The muscles of the trunk may be arranged in six groups:

I. Deep muscles of the back.	IV. Muscles of the abdomen.
II. Suboccipital muscles.	V. Muscles of the pelvis.
III. Muscles of the thorax.	VI. Muscles of the perineum.

I. The Deep Muscles of the Back (fig. 590)

The deep or intrinsic muscles of the back consist of a complex group of muscles extending from the pelvis to the skull. They are:

Splenius capitis.	Multifidus.
Splenius cervicis.	Rotatores.
Sacrospinalis.	Interspinales.
Semispinalis.	Intertransversarii.

The **lumbar fascia** (lumbodorsal fascia) covers the deep muscles of the back of the trunk. Above, it passes in front of the Serratus posterior superior and is continuous with the investing fascial layer on the back of the neck.

In the thoracic region the lumbar fascia is a thin fibrous lamina covering the extensor muscles of the vertebral column and separating them from the muscles connecting the vertebral column to the upper extremity. It contains both longitudinal and transverse fibres, and is attached, *medially*, to the spines of the thoracic vertebræ; *laterally*, to the angles of the ribs.

In the lumbar region the lumbar fascia is in three layers, anterior, middle and posterior (fig. 589). The posterior layer is attached to the spines of the lumbar and sacral vertebræ and to the supraspinous ligament; the middle layer is attached, *medially*, to the tips of the transverse processes of the lumbar vertebræ, and to the intertransverse ligaments, *below*, to the iliac crest, and *above*, to the lower border of the twelfth rib and to the lumbocostal ligament (p. 447). The anterior layer covers the Quadratus lumborum and is attached *medially* to the anterior surfaces of the transverse processes of the lumbar vertebræ under cover of the lateral part of the Psoas major muscle. *Below*, it is attached to the iliolumbar ligament and the adjoining part of the iliac crest; *above*, it forms the lateral arcuate ligament (p. 555). The posterior and middle layers unite at the lateral margin of the Sacrospinalis, and at the lateral border of the Quadratus lumborum they are joined by the anterior layer to form the tendon of origin of the Transversus abdominis.

The **Splenius capitis** (fig. 613) arises from the lower half of the ligamentum nuchæ, from the spine of the seventh cervical vertebra, and from the spines of the upper three or four thoracic vertebræ. The fibres of the muscle are directed upwards and laterally and are inserted, under cover of the Sternomastoid muscle, into the mastoid process of the temporal bone, and into the rough surface on the occipital bone just below the lateral third of the superior nuchal line. It forms a part of the floor of the posterior triangle of the neck, above and behind the Levator scapulæ.

Nerve-supply.—The Splenius capitis is supplied by the lateral branches of the posterior primary rami of the middle cervical nerves.

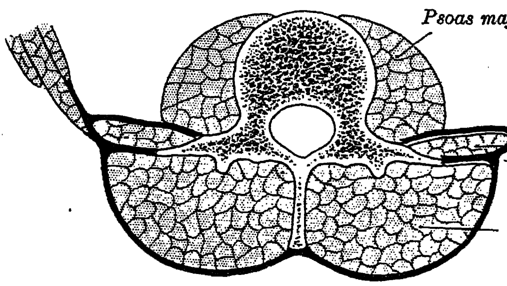
The **Splenius cervicis** (fig. 613) arises from the spines of the third to the sixth thoracic vertebræ ; it is inserted into the posterior tubercles of the transverse processes of the upper two or three cervical vertebræ immediately under cover of the origin of the Levator scapulæ.

Nerve-supply.—The Splenius cervicis is supplied by lateral branches of the posterior primary rami of the lower cervical nerves.

Actions.—The Splenii of the two sides, acting together, draw the head directly backwards ; acting separately, they draw the head to one side, and slightly rotate it, turning the face to the same side.

The **Sacrospinalis** (fig. 590), and its prolongations in the thoracic and cervical regions, lie in the groove on the side of the vertebral column, covered in the

FIG. 589.—A transverse section through the posterior abdominal wall, to show the disposition of the lumbar fascia. Diagrammatic.



lumbar and thoracic regions by the lumbar fascia. They form a large muscular and tendinous mass, which varies in size and structure at different parts of the vertebral column. In the sacral region it is narrow and pointed, and at its origin chiefly tendinous in structure. In the lumbar region it forms a thick fleshy mass which, on being followed upwards, divides into three columns ; these gradually diminish in size as they ascend to be inserted into the vertebræ and ribs.

The Sacrospinalis arises from the anterior surface of a broad and thick tendon, which is attached to the spinous tubercles of the sacrum (middle sacral crest), to the spines of the lumbar and the eleventh and twelfth thoracic vertebræ, to the supraspinous ligament, to the medial aspect of the dorsal segment (p. 368) of the iliac crest and to the transverse tubercles (lateral crest) of the sacrum, where it blends with the sacrotuberous and posterior sacro-iliac ligaments ; some of its fibres are continuous with the fibres of origin of the Gluteus maximus. The muscular fibres form a large fleshy mass, which splits in the upper lumbar region into three columns, viz. a lateral, the *Iliocostocervicalis*, an intermediate, the *Longissimus*, and a medial, the *Spinalis*. Each of these consists, from below upwards, of three parts, as follows :

Lateral Column.	*Intermediate Column.*	*Medial Column.*
Iliocostocervicalis	Longissimus.	Spinalis.
(*a*) Iliocostalis.	(*a*) L. thoracis.	(*a*) S. thoracis.
(*b*) Costalis.	(*b*) L. cervicis.	(*b*) S. cervicis.
(*c*) Costocervicalis.	(*c*) L. capitis.	(*c*) S. capitis.

The **Iliocostalis** (Iliocostalis lumborum) is inserted, by flattened tendons, into the inferior borders of the angles of the lower six or seven ribs.

The **Costalis** (Iliocostalis dorsi) arises from the upper borders of the angles of the lower

six ribs *medial* to the tendons of insertion of the Iliocostalis ; it is inserted into the upper borders of the angles of the upper six ribs and into the back of the transverse process of the seventh cervical vertebra.

The **Costocervicalis** (Iliocostalis cervicis) arises from the angles of the third, fourth, fifth and sixth ribs *medial* to the tendons of insertion of the costalis, and is inserted into the posterior tubercles of the transverse processes of the fourth, fifth and sixth cervical vertebræ.

Nerve-supply.—These three muscles are supplied by the posterior primary rami of the lower cervical, the thoracic and the upper lumbar nerves.

Actions.—These muscles are extensors of the vertebral column ; they also bend it to one side. The slips attached to the ribs act as depressors of the thorax.

The **Longissimus thoracis** is the intermediate and largest of the continuations of the Sacrospinalis. In the lumbar region, where it is as yet blended with the Iliocostalis, some of its fibres are attached to the whole length of the posterior surfaces of the transverse processes and the accessory processes of the lumbar vertebræ, and to the middle layer of the lumbar fascia. In the thoracic region it is inserted, by rounded tendons, into the tips of the transverse processes of all the thoracic vertebræ, and by fleshy processes into the lower nine or ten ribs between their tubercles and angles.

The **Longissimus cervicis**, situated medial to the Longissimus thoracis, arises by long thin tendons from the summits of the transverse processes of the upper four or five thoracic vertebræ, and is inserted by similar tendons into the posterior tubercles of the transverse processes of the cervical vertebræ from the second to the sixth inclusive.

The **Longissimus capitis** lies between the Longissimus cervicis and the Semispinalis capitis. It arises by tendons from the transverse processes of the upper four or five thoracic vertebræ, and the articular processes of the lower three or four cervical vertebræ, and is inserted into the posterior margin of the mastoid process, deep to the Splenius capitis and Sternomastoid. It is usually crossed by a tendinous intersection near its insertion.

Nerve-supply.—The Longissimi are supplied by the posterior primary rami of the lower cervical, the thoracic and the lumbar nerves.

Actions.—The Longissimi thoracis et cervicis bend the vertebral column backwards and laterally ; the Longissimus capitis extends the head, and turns the face towards the same side.

The **Spinalis thoracis**, the medial continuation of the Sacrospinalis, is scarcely separable as a distinct muscle. It is situated at the medial side of the Longissimus thoracis, and is intimately blended with it ; it arises by three or four tendons from the spines of the eleventh and twelfth thoracic, and first and second lumbar vertebræ ; these, uniting, form a small muscle which is inserted by separate tendons into the spines of the upper thoracic vertebræ, the number varying from four to eight. It is intimately united with the Semispinalis thoracis, which lies deep to it.

The **Spinalis cervicis** is an inconstant muscle, which arises from the lower part of the ligamentum nuchæ, the spine of the seventh cervical, and sometimes from the spines of the first and second thoracic vertebræ, and is inserted into the spine of the axis, and occasionally into the spines of the two vertebræ below it.

The **Spinalis capitis** is usually more or less blended with the Semispinalis capitis.

Nerve-supply.—The Spinales are supplied by the posterior primary rami of the lower cervical and thoracic nerves.

Actions.—The Spinales extend the vertebral column.

The **Semispinalis thoracis** consists of thin, fleshy fasciculi, interposed between tendons of considerable length. It arises by a series of tendons from the transverse processes of the thoracic vertebræ from the sixth to the tenth inclusive, and is inserted, by tendons, into the spines of the upper four thoracic and lower two cervical vertebræ.

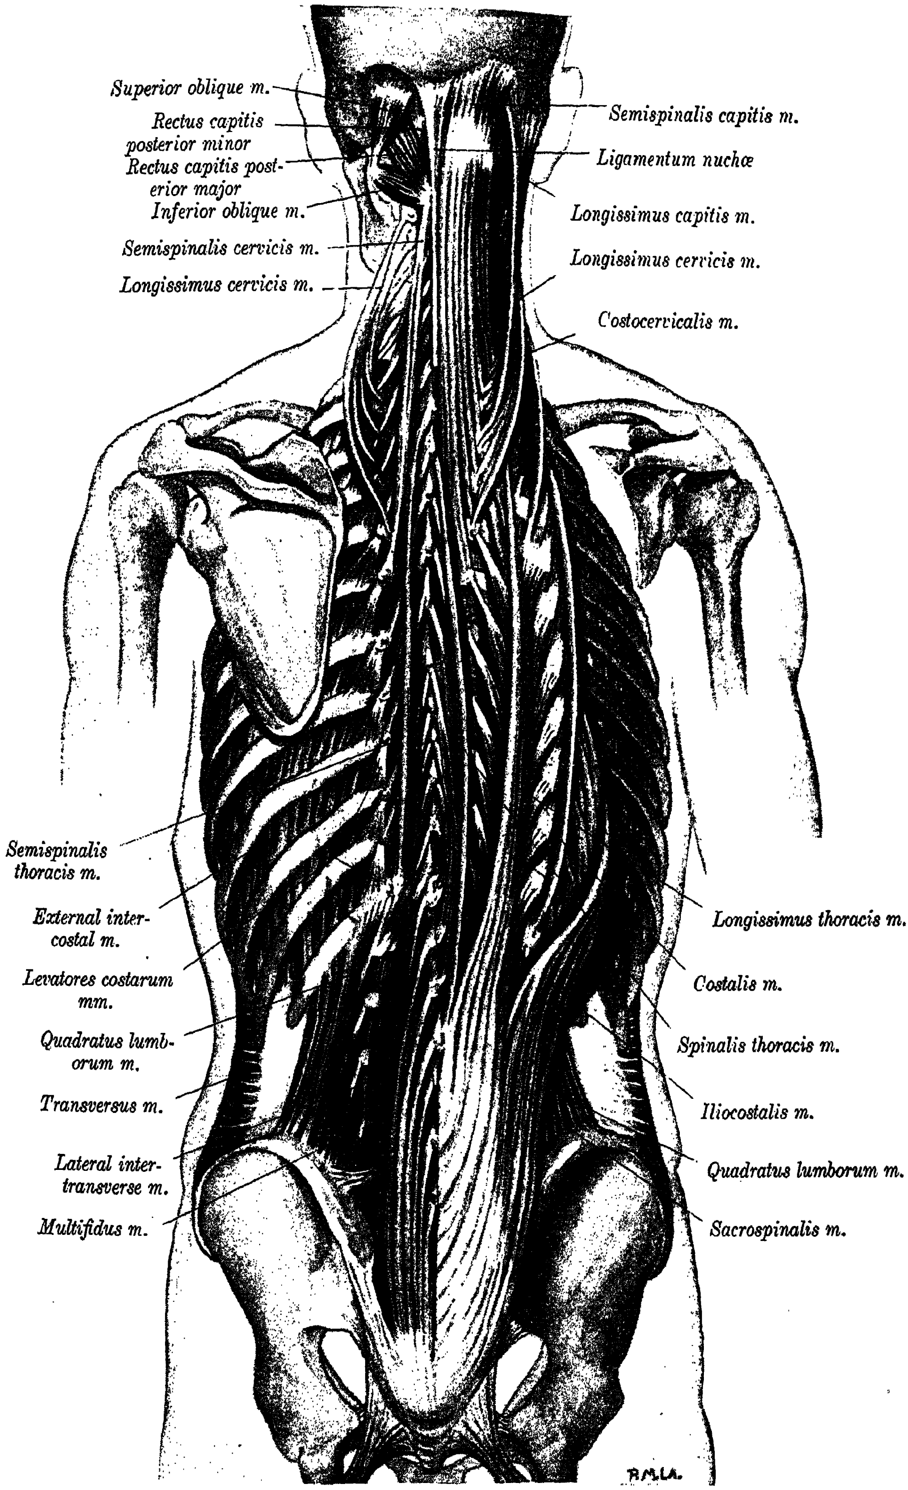
The **Semispinalis cervicis**, thicker than the preceding, arises by a series of tendinous and fleshy fibres from the transverse processes of the upper five or six thoracic vertebræ, and is inserted into the cervical spines, from the axis to the fifth inclusive. The fasciculus connected with the axis is the largest, and is chiefly muscular in structure.

The **Semispinalis capitis** is situated at the back part of the neck, under cover of the Splenius, and medial to the Longissimi cervicis et capitis. It arises by a series of tendons from the tips of the transverse processes of the upper six or seven thoracic and the seventh cervical vertebræ, and from the articular processes of the fourth, fifth, and sixth cervical vertebræ and, occasionally, from the spine of the seventh cervical or first thoracic vertebra. The tendons are succeeded by a broad muscle, which passes upwards and is inserted into the medial part of the area between the superior and inferior nuchal lines of the occipital bone. The medial part, usually more or less distinct from the rest of the muscle, is named the *Spinalis capitis* ; it is sometimes called the *Biventer cervicis*, since it is traversed by an imperfect tendinous intersection.

Nerve-supply.—The Semispinales are supplied by the posterior primary rami of the cervical and thoracic nerves.

Actions.—The Semispinales thoracis et cervicis extend the thoracic and cervical portions of the vertebral column, and rotate them towards the opposite side ; the Semispinalis capitis extends the head, and turns the face slightly towards the opposite side.

FIG. 590.—The deep muscles of the back.



N.B.—On the left side the Sacrospinalis muscle and its upward continuations (with the exception of the Longissimus cervicis m., which has been turned laterally) and the Semispinalis capitis muscle have been removed.

The **Multifidus** consists of a number of fleshy and tendinous fasciculi, which fill the groove at the side of the spines of the vertebræ, from the sacrum to the axis. In the sacral region, the fasciculi arise from the back of the sacrum as low as the fourth sacral foramen, from the aponeurosis of origin of the Sacrospinalis, from the medial surface of the posterior superior iliac spine and from the posterior sacro-iliac ligaments; in the lumbar region, from all the mamillary processes; in the thoracic region, from all the transverse processes; and in the cervical region, from the articular processes of the lower four vertebræ. Each fasciculus passes obliquely upwards and medially, and is inserted into the whole length of the spine of one of the vertebræ above. The fasciculi vary in length; the most superficial pass from one vertebra to the third or fourth above; those next in depth run from one vertebra to the second or third above; while the deepest connect contiguous vertebræ.

Nerve-supply.—The Multifidus is supplied by the posterior primary rami of the spinal nerves.

Actions.—The fasciculi of the Multifidus bend the segments of the vertebral column backwards and laterally, and rotate them towards the opposite side.

The **Rotatores** lie deep to the Multifidus and are found only in the thoracic region; they are eleven in number on each side, and are small and somewhat quadrilateral in form. Each arises from the upper and posterior part of the transverse process of one vertebra, and is inserted into the lower border and lateral surface of the lamina of the vertebra next above, the fibres extending as far as the root of the spine. The first is found between the first and second thoracic vertebræ; the last, between the eleventh and twelfth. Sometimes the number of these muscles is diminished by the absence of one or more from the upper or lower end of the series.

Nerve-supply.—The Rotatores are supplied by the posterior primary rami of the spinal nerves.

Actions.—The Rotatores mainly rotate the individual vertebræ towards the opposite side.

The **Interspinales** are short muscular fasciculi, placed in pairs between the spines of contiguous vertebræ, one on each side of the interspinous ligament. In the *cervical region* they are most distinct, and consist of six pairs; the first is situated between the axis and third vertebra, and the last between the seventh cervical and the first thoracic vertebræ. They are small narrow bundles, attached, above and below, to the apices of the spines. In the *thoracic region* they are found between the first and second vertebræ, and sometimes between the second and third, and the eleventh and twelfth vertebræ. In the *lumbar region* there are four pairs in the intervals between the five lumbar vertebræ. A pair is occasionally found between the last thoracic and first lumbar vertebræ, and another between the fifth lumbar vertebra and the sacrum.

Nerve-supply.—The Interspinales are supplied by the posterior primary rami of the spinal nerves.

Actions.—The Interspinales extend those segments of the vertebral column to which they are attached.

The **Extensor coccygis** is a slender muscular fasciculus, which is not always present; it extends over the lower part of the posterior surface of the sacrum and coccyx. It arises by tendinous fibres from the last segment of the sacrum, or first piece of the coccyx, and passes downwards to be inserted into the lower part of the coccyx. It is a rudiment of the Levator caudæ muscle of the lower animals.

The **Intertransversarii** are small muscles placed between the transverse processes of the vertebræ. They are best developed in the *cervical region* where they consist of anterior and posterior slips, which are separated by the anterior primary rami of the spinal nerves. The *posterior intertransverse muscles* are subdivisible into medial and lateral slips, which are separate morphological entities. The *anterior intertransverse muscles* and the lateral parts of the posterior muscles connect the costal processes of contiguous vertebræ, and the medial parts of the posterior muscles connect the true transverse processes. There are seven pairs of these muscles, the highest between the atlas and axis, and the lowest between the seventh cervical vertebra and the first thoracic, but the anterior muscle between the atlas and axis is often absent. In the *thoracic region* they consist of single muscles, which are present between the transverse processes of the three lower thoracic vertebræ only and between the transverse processes of the last thoracic vertebra and the first lumbar. In the *lumbar region* they again consist of two sets of muscles, one named the *Intertransversarii mediales*, connecting the accessory process of one vertebra with the mamillary process of the next, and the other named the *Intertransversarii laterales*, which are really divisible into ventral and dorsal parts.* The ventral parts connect the transverse processes (costal elements) of the lumbar vertebræ, and each dorsal part connects the accessory process to the transverse process of the succeeding vertebra.

* J. D. Lickley, *Journal of Anatomy and Physiology*, vol. xxxix., 1905, and A. J. E. Cave, *Journal of Anatomy*, vol. lxxi., 1937. According to the latter, the Intertransversarii mediales are homologous with the thoracic intertransverse muscles and with the medial slips of the posterior muscles in the cervical region: the ventral parts of the Intertransversarii laterales are homologous with both the lateral parts of the posterior muscles and the anterior muscles in the cervical region: and the dorsal parts of the Intertransversarii laterales are homologous with the levatores costarum.

Nerve-supply.—The Intertransversarii mediales, the thoracic Intertransversarii and the medial parts of the posterior intertransverse muscles in the cervical region are supplied by the posterior primary rami of the spinal nerves; the others are supplied by the anterior primary rami.

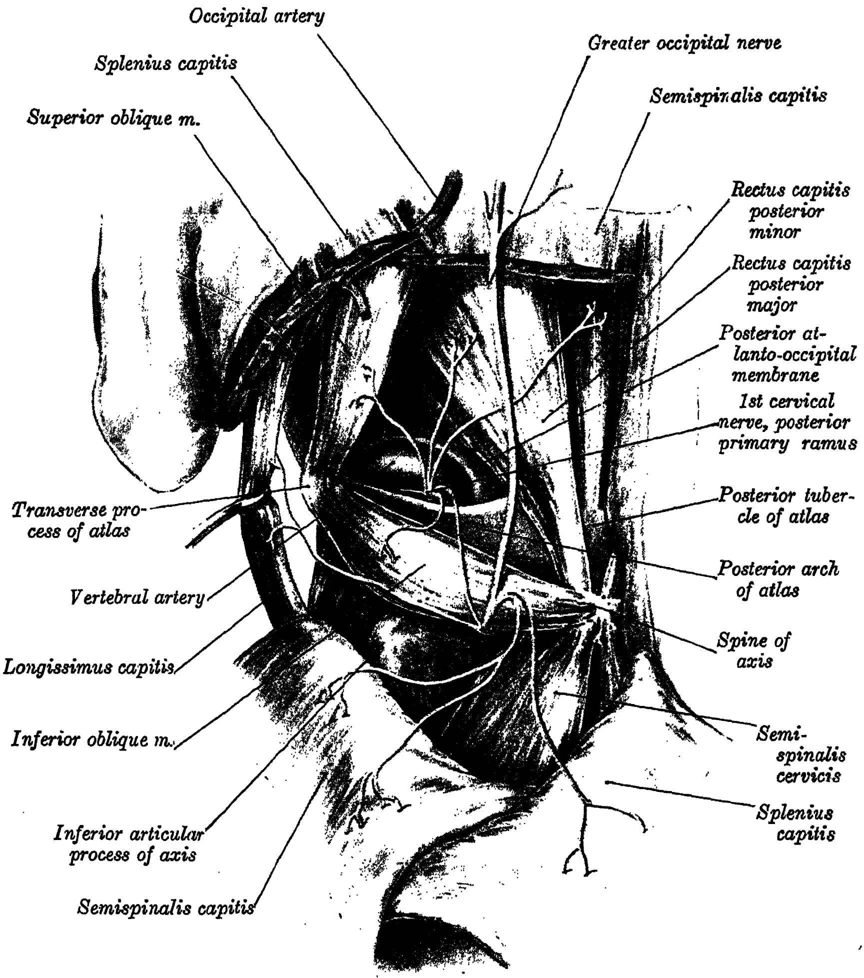
Actions.—The intertransverse muscles act as lateral flexors of those segments of the vertebral column to which they are attached.

II. The Suboccipital Muscles (fig. 591)

Rectus capitis posterior major.	Obliquus capitis inferior.
Rectus capitis posterior minor.	Obliquus capitis superior.

The **Rectus capitis posterior major** arises by a pointed tendon from the spine of the axis, and, becoming broader as it ascends, is inserted into the lateral

Fig. 591.—The left suboccipital triangle and muscles.



part of the inferior nuchal line of the occipital bone, and into the bone immediately below the line. As the muscles of the two sides pass upwards and laterally, they leave between them a triangular space, in which parts of the Recti capitis posteriores minores are seen.

Actions.—The Rectus capitis posterior major extends the head, and turns the face towards the same side.

The **Rectus capitis posterior minor** arises by a narrow pointed tendon from the tubercle on the posterior arch of the atlas, and, widening as it ascends, is

inserted into the medial part of the inferior nuchal line of the occipital bone and also into the bone between that line and the foramen magnum.

Action.—The Rectus capitis posterior minor extends the head.

The **Obliquus capitis inferior**, the larger of the two Oblique muscles, arises from the lateral surface of the spine of the axis, and passes laterally and slightly upwards, to be inserted into the lower and back part of the transverse process of the atlas.

Action.—The Obliquus capitis inferior turns the face towards the same side. *Owing to the length of the transverse process of the atlas the muscle is enabled to act to good mechanical advantage.*

The **Obliquus capitis superior**, narrow below, wide and expanded above, arises by tendinous fibres from the upper surface of the transverse process of the atlas. It passes upwards and backwards, and is inserted into the occipital bone, between the superior and inferior nuchal lines, lateral to the Semispinalis capitis and overlapping the insertion of the Rectus capitis posterior major.

Actions.—The Obliquus capitis superior bends the head backwards and to the same side.

Nerve-supply.—All the suboccipital muscles are supplied by the posterior primary ramus of C. 1.

The suboccipital triangle.—This triangle is bounded, above and medially, by the Rectus capitis posterior major; above and laterally, by the Obliquus capitis superior; below and laterally, by the Obliquus capitis inferior. Medially, the roof is formed by a layer of dense fibrofatty tissue, situated deep to the Semispinalis capitis, and, laterally, by the Longissimus capitis and sometimes by the Splenius capitis, which covers the Obliquus capitis superior. The floor of the triangle is formed by the posterior atlanto-occipital membrane and the posterior arch of the atlas; the vertebral artery and the posterior primary ramus of the first cervical nerve (fig. 591) lie in the groove on the upper surface of the posterior arch of the atlas.

III. The Muscles of the Thorax.

Intercostales externi.
Intercostales interni.
Transversus thoracis.
  Sternocostalis.
  Intercostales intimi.
  Subcostales.
Levatores costarum.
Serratus posterior superior.
Serratus posterior inferior.
Diaphragm.

The **Intercostales** externi et interni (fig. 615) are two thin layers of muscular and tendinous fibres occupying each of the intercostal spaces. They are named *external* and *internal* from their surface relations—the external being superficial to the internal.

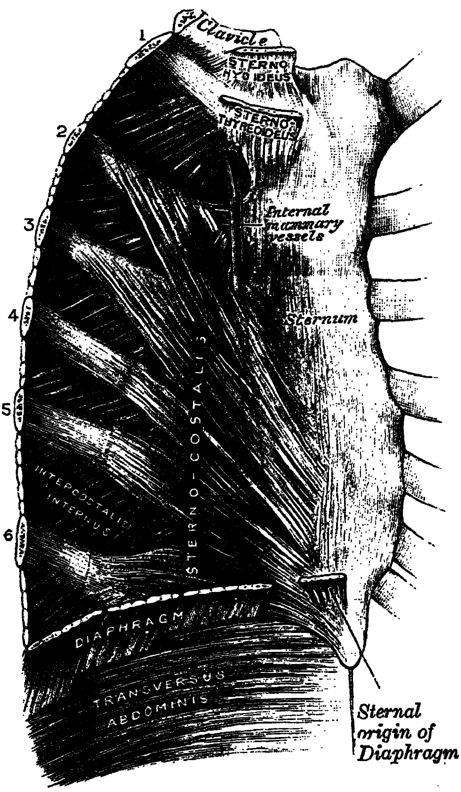
The **Intercostales externi** are eleven in number on each side. Their attachments extend from the tubercles of the ribs behind, where they are intimately related to the posterior fibres of the superior costotransverse ligaments, to near the cartilages of the ribs in front, where each is replaced by an aponeurotic layer named the *anterior intercostal membrane*, which is continued forwards to the sternum. Each muscle arises from the lower border of one rib, and is inserted into the upper border of the rib below. In the lower two spaces they extend to the ends of the rib-cartilages, and in the upper two or three spaces they do not quite reach the ends of the ribs. They are thicker than the Internal intercostals, and their fibres are directed obliquely downwards and laterally on the back of the thorax, and downwards, forwards, and medially on the front.

The **Intercostales interni** are also eleven in number on each side. Their attachments commence anteriorly at the sternum, in the interspaces between the cartilages of the true ribs, and at the anterior extremities of the cartilages of the false ribs, and extend backwards as far as the angles of the ribs, where each is replaced by an aponeurotic layer named the *posterior intercostal membrane*, which is continuous with the anterior fibres of the superior costotransverse ligament. Each muscle arises from the floor of the costal groove and the corresponding costal cartilage, and is inserted into the upper border of the rib below. Their fibres are also directed obliquely, but at right angles to those of the External intercostal muscles.

Actions.—The actions of the External and Internal intercostal muscles are very difficult to determine. It is generally believed that both groups act as elevators of the ribs, although some investigators have attributed the opposite action to the Internal intercostals. In addition, they form strong elastic supports, which prevent the intercostal spaces being drawn in or bulged out during respiration. The anterior portions of the Internal intercostals probably have an additional function in keeping the sternocostal and interchondral joint-surfaces in apposition, the posterior portions of the External intercostals performing a similar function for the costovertebral joints.

The **Transversus thoracis** is a thin plane of muscular and tendinous fibres situated upon the inner surface of the chest wall. It forms an incomplete investment and is divisible into three parts, viz.: the Subcostales, the Intercostales intimi and the Sternocostalis.

Fig. 592.—The left Sternocostalis. Posterior surface.



The **Subcostales** consist of muscular and aponeurotic fasciculi, and are usually well developed only in the lower part of the thorax; each arises from the inner surface of one rib near its angle, and is inserted into the inner surface of the second or third rib below. Their fibres run in the same direction as those of the Internal intercostals. They intervene between the intercostal vessels and nerves and the pleura.

Actions.—The Subcostals depress the ribs.

The **Intercostales intimi** * are placed on the deep surfaces of the Internal intercostals and their fibres pass in the same direction. Each is attached to the inner surfaces of two adjoining ribs. Poorly developed, sometimes absent, in the upper intercostal spaces, the Intercostales intimi become gradually more extensive from above downwards. Below each covers the middle two-fourths of the intercostal space, and its posterior border is edge to edge with the lateral border of the corresponding Subcostalis muscle. Like the Subcostales the Intercostales intimi separate the intercostal vessels and nerves from the pleura (fig. 593).

Actions.—The Intercostales intimi act in the same way as the Internal intercostals.

The **Sternocostalis** (Transversus thoracis) is situated upon the inner surface of the front wall of the chest (fig. 592). It arises from the lower third of the posterior surface of the body of the sternum, from the posterior surface of the xiphoid process, and from the posterior surfaces of the costal cartilages of the lower three or four true ribs near their sternal ends. Its fibres diverge as they pass upwards and laterally, to be inserted by slips into the lower borders and inner surfaces of the costal cartilages of the second, third, fourth, fifth, and sixth ribs. The lowest fibres of this muscle are horizontal, and are edge to edge with the highest fibres of the Transversus abdominis; the intermediate fibres are oblique, while the highest are almost vertical. This muscle varies in its attach-

* These muscles were originally called Intracostales, and they are regarded by some anatomists merely as parts of the Internal intercostals. For a full description consult the following: T. Walmsley, *Journal of Anatomy*, vol. l., and F. Davies, R. J. Gladstone and E. P. Stibbe, *Journal of Anatomy*, vol. lxvi.

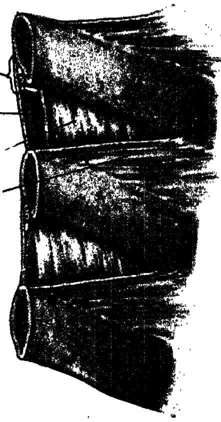
ments not only in different subjects but on opposite sides of the same subject. Like the other parts of the Transversus thoracis the Sternocostalis separates the intercostal nerves from the pleura.

Actions.—The Sternocostalis draws down the costal cartilages to which it is attached.

Nerve-supply.—All these muscles are supplied by the corresponding intercostal nerves.

The Levatores costarum (fig. 590), twelve in number on each side, are strong bundles which arise from the ends of the transverse processes of the seventh cervical and upper eleven thoracic vertebræ; they pass obliquely downwards and laterally, parallel with the posterior borders of the External intercostals, and each is inserted into the upper edge and outer surface of the rib immediately below the vertebra from which it takes origin, between the tubercle and the angle (Levatores costarum breves). Each of the four lower muscles divides into two fasciculi, one of which is inserted as above described; the other passes down to the second rib below its origin (Levatores costarum longi).

Fig. 593.—A dissection of a part of the thoracic wall, showing the position of the intercostal vessels and nerves relative to the intercostal muscles.



In both the spaces shown a part of the Intercostalis externus has been removed; in addition, in the upper space, a small strip of the Intercostalis internus has been reflected in order to expose the intercostal nerve lying on the surface of the Intercostalis intimus.

Nerve-supply.—The Levatores costarum are supplied by the intercostal nerves.

Actions.—The Levatores costarum being inserted near the fulcra of the ribs can have little or no elevating action on the ribs, but they may rotate the necks of the ribs in a forward direction; they are said to act as rotators and lateral flexors of the vertebral column.

The Serratus posterior superior is a thin, quadrilateral muscle, situated at the upper and posterior part of the thorax. It arises by a thin aponeurosis from the lower part of the ligamentum nuchæ, from the spines of the seventh cervical and upper two or three thoracic vertebræ and from the supraspinous ligament. Inclining downwards and laterally it is inserted, by four fleshy digitations, into the upper borders and outer surfaces of the second, third, fourth, and fifth ribs, a little beyond their angles. It lies superficial to the upward continuation of the lumbar fascia and is hidden by the Rhomboid muscles.

Nerve-supply.—The Serratus posterior superior is supplied by the second, third, fourth and fifth intercostal nerves.

Actions.—The Serratus posterior superior elevates the ribs to which it is attached.

The Serratus posterior inferior (fig. 613) is situated at the junction of the thoracic and lumbar regions: it is of an irregularly quadrilateral form, broader than the preceding muscle, and separated from it by a wide interval. It arises by a thin aponeurosis from the spines of the lower two thoracic and upper two or three lumbar vertebræ and from the supraspinous ligament; this aponeurosis is intimately blended with the lumbar fascia. Passing obliquely upwards and laterally, it becomes fleshy, and is inserted by four digitations into the inferior borders and outer surfaces of the lower four ribs, a little beyond their angles.

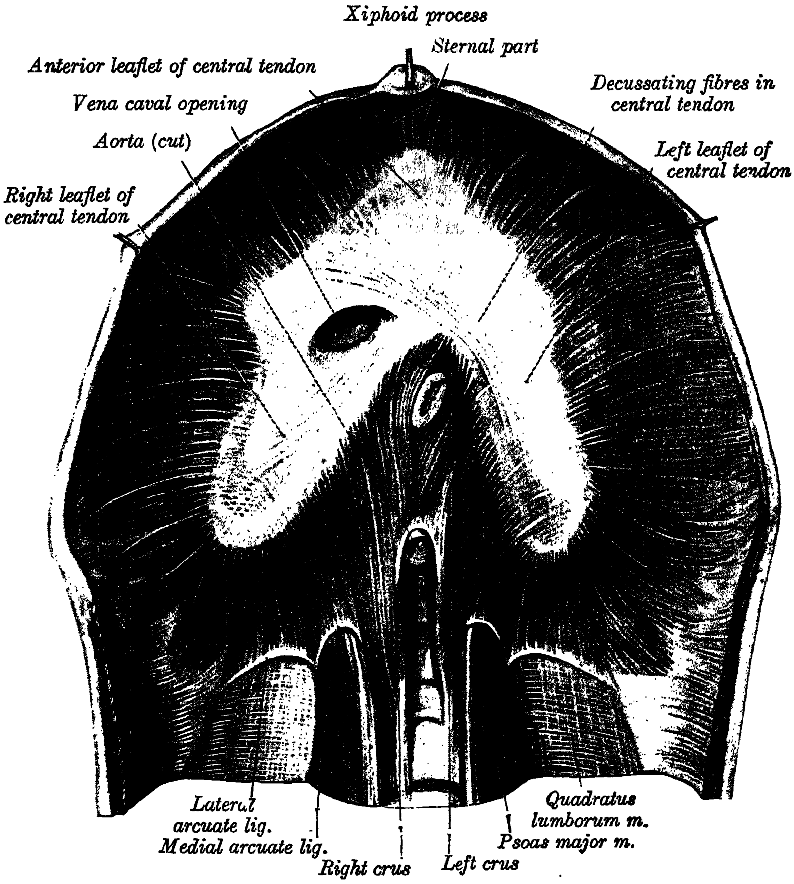
Nerve-supply.—The Serratus posterior inferior is supplied by the anterior primary rami of the ninth, tenth, eleventh and twelfth thoracic nerves.

Actions.—The Serratus posterior inferior draws the lower ribs downwards and backwards and thus elongates the thorax; it also fixes the lower ribs, thus assisting the inspiratory action of the Diaphragm and resisting the tendency of the latter to draw the lower ribs upwards and forwards.

The **Diaphragm** (fig. 594) is a dome-shaped, musculofibrous septum which separates the thoracic from the abdominal cavity, its convex upper surface forming the floor of the former, and its concave under surface the roof of the latter. Its peripheral part consists of muscular fibres which take origin from the circumference of the thoracic outlet and converge to be inserted into a central tendon.

The muscular fibres may be grouped according to their origins into three parts—sternal, costal, and vertebral. The *sternal part* arises by two fleshy slips from the back of the ziphoid process; the *costal part* from the inner surfaces of the cartilages and adjacent portions of the lower six ribs on each side, interdigitating with the Transversus abdominis (fig. 592); and the *vertebral part*

FIG. 594.—The Diaphragm. Abdominal surface.



from aponeurotic arches, named the arcuate ligaments (lumbocostal arches), and from the lumbar vertebræ by two pillars or *crura*. There are two arcuate ligaments, a lateral and a medial, on each side, and, in addition, a *median arcuate ligament* connects the two crura across the median plane.

The *lateral arcuate ligament* (lateral lumbocostal arch), which is a thickened band in the fascia covering the Quadratus lumborum, arches across the upper part of that muscle, and is attached, medially, to the front of the transverse process of the first lumbar vertebra, and, laterally, to the lower margin of the twelfth rib.

The *medial arcuate ligament* (medial lumbocostal arch) is a tendinous arch in the fascia covering the upper part of the Psoas major; medially, it is continuous with the lateral tendinous margin of the corresponding crus, and is attached to the side of the body of the first or second lumbar vertebra; laterally, it is fixed to the front of the transverse process of the first lumbar vertebra.

The crura.—At their origins the crura are tendinous in structure, and blend with the anterior longitudinal ligament of the vertebral column. The *right crus*, larger and longer than the left, arises from the anterior surfaces of the bodies and

intervertebral discs of the upper three lumbar vertebræ, while the *left crus* arises from the corresponding parts of the upper two only. The medial tendinous margins of the crura meet in the median plane to form an arch across the front of the aorta, which is termed the *median arcuate ligament*; it is often poorly defined.

From this series of origins the fibres of the Diaphragm converge to be inserted into the central tendon. The fibres arising from the xiphoid process are very short, and occasionally aponeurotic; those from the medial and lateral arcuate ligaments, and more especially those from the ribs and their cartilages, are longer, and describe marked curves as they ascend and converge to their insertion. The fibres arising from the crura diverge as they ascend, the most lateral being directed upwards and laterally to the central tendon. The medial fibres of the right crus ascend on the left side of the œsophageal opening, and occasionally a fleshy fasciculus from the medial side of the left crus crosses the aorta and runs obliquely through the fibres of the right crus towards the venacaval opening, but this fasciculus "is never continued upwards to help to bound the œsophageal passage on the right side" (Low *).

The *central tendon* of the Diaphragm is a thin but strong aponeurosis of closely interwoven fibres situated near the centre of the vault formed by the muscle, but somewhat closer to the front than to the back of the thorax, so that the posterior muscular fibres are the longer. It is placed immediately below the pericardium, with which it is partially blended. It is shaped somewhat like a trefoil leaf, and consists of three divisions or leaflets separated from one another by slight indentations. The middle leaflet has the form of an equilateral triangle, the apex of which is directed towards the xiphoid process of the sternum. The right and left leaflets are rather tongue-shaped and curve laterally and backwards, the left being a little narrower than the right. The central area of the tendon is occupied by four well-marked diagonal bands radiating from a thick central point like the bars of a St. Andrew's cross, and then expanding in a fan-shaped manner; the central point of decussation appears as a thick node of compressed tendinous strands situated in front of the œsophageal aperture, and to the left of the venacaval opening.†

Openings in the Diaphragm (fig. 594).—The Diaphragm is pierced by apertures for the passage of structures between the thorax and abdomen. Three large openings—the aortic, the œsophageal, and the venacaval—and a number of small ones are present.

The *aortic opening* is the lowest and most posterior of the large apertures; it lies at the level of the lower border of the twelfth thoracic vertebra, slightly to the left of the median plane. Strictly speaking, it is an osseo-aponeurotic opening between the vertebral column and the Diaphragm, and therefore behind the latter; occasionally some tendinous fibres from the medial parts of the crura pass behind the aorta, and convert the opening into a fibrous ring. The aortic opening transmits the aorta and the thoracic duct.‡

The *œsophageal opening* is situated in the muscular part of the Diaphragm at the level of the tenth thoracic vertebra; it is elliptical in shape, and is "formed by the splitting of the medial fibres of the right crus" (Low). It is placed above, in front, and a little to the left of the aortic opening, and transmits the œsophagus, the vagus nerves, and the œsophageal branches of the left gastric artery.

The *venacaval opening*, the highest of the three large openings, is situated about the level of the disc between the eighth and ninth thoracic vertebræ. It is quadrilateral in form, and is placed at the junction of the right leaflet with the central area, so that its margins are tendinous. It transmits the inferior vena cava, the wall of which is adherent to the margin of the opening, and some branches of the right phrenic nerve.

There are two *lesser apertures* in each crus; of these one transmits the greater and the other the lesser splanchnic nerve. The ganglionated trunks of the sympathetic usually enter the abdominal cavity behind the Diaphragm, deep to the medial arcuate ligaments. Openings for minute veins are frequently seen in the central tendon.

* Alex. Low, *Journal of Anatomy and Physiology*, vol. xlii.

† D. M. Blair, *Journal of Anatomy*, vol. lvii. p. 203.

‡ It is stated frequently that the azygos vein passes through the aortic opening, but this description is not always strictly accurate (see p. 827).

Blair (*loc. cit.*) describes one of varying size, but of constant position, and present in ten out of twelve specimens he examined. It occurs in the angle between the left pair of bands as they diverge from the central point of decussation, and he suggests that the vein it transmits may represent the suprahepatic part of the left vitelline vein.

On each side there are two small areas where the muscular fibres of the Diaphragm are deficient and are replaced by areolar tissue. One between the sternal and costal parts transmits the superior epigastric branch of the internal mammary artery and some lymph vessels from the abdominal wall and convex surface of the liver. The other, between the fibres springing from the medial and lateral arcuate ligaments, is less constant; when this interval exists, the upper and back part of the kidney is separated from the pleura by areolar tissue only.

Relations.—The upper surface of the Diaphragm is in relation with three serous membranes, viz. on each side with the pleura, which separates it from the base of the corresponding lung, and on the middle leaflet of the central tendon with the pericardium, which intervenes between it and the heart. The central portion lies on a slightly lower level than the summits of the lateral portions. The greater part of the under surface is covered by the peritoneum. The right side is accurately moulded over the convex surface of the right lobe of the liver, the right kidney, and right suprarenal gland; the left over the left lobe of the liver, the fundus of the stomach, the spleen, the left kidney, and the left suprarenal gland.

Nerve-supply.—The Diaphragm is supplied by the phrenic nerve and the lower six or seven intercostal nerves, the latter being distributed to the peripheral part of the muscle.

Actions.—The Diaphragm is the principal muscle of inspiration, and presents the form of a dome concave towards the abdomen. The central part of the dome is tendinous, and the pericardium is attached to its upper surface; the circumferential part is muscular. During inspiration the lowest ribs are fixed, and from these and the crura the muscular fibres contract and draw downwards and forwards the central tendon with the attached pericardium. In this movement the curvature of the Diaphragm is scarcely altered, the dome moving downwards nearly parallel to its original position and pushing before it the abdominal viscera. The descent of the abdominal viscera is permitted by the extensibility of the abdominal wall, but the limit of this is soon reached. The central tendon, applied to the abdominal viscera, then becomes a fixed point for the action of the Diaphragm, the effect of which is to elevate the lower ribs and through them to push forwards the body of the sternum and the upper ribs. The right cupola of the Diaphragm, lying on the liver, has a greater resistance to overcome than the left, which lies over the stomach, but to compensate for this the right crus and the fibres of the right side generally are stronger than those of the left.

In all expulsive acts the Diaphragm is called into action to give additional power to each effort. Thus, before sneezing, coughing, laughing, crying, or vomiting, and previous to the expulsion of urine, or fæces, or of the fœtus from the uterus, a deep inspiration takes place.

According to Whillis the fibres of the right crus exert a sphincteric action on the lower end of the œsophagus in man. The act of expiration, which immediately succeeds the act of swallowing, relaxes these fibres and allows the contents of the œsophagus to pass into the stomach.*

The height of the Diaphragm is constantly varying during respiration; it also varies with the degree of distension of the stomach and intestines and with the size of the liver. After a forced expiration the right cupola is on a level in front with the fourth costal cartilage, at the side with the fifth, sixth, and seventh ribs, and behind with the eighth rib; the left cupola is a little lower than the right. Halls Dally † states that the absolute range of movement between deep inspiration and deep expiration averages in the male and female 30 mm. on the right side and 28 mm. on the left; in quiet respiration the average movement is 12·5 mm. on the right side and 12 mm. on the left.

Skiagraphy shows that the height of the Diaphragm in the thorax varies considerably with the position of the body. It stands highest when the body is horizontal and the patient on his back, and in this position it performs the largest respiratory excursions

* J. Whillis, *Journal of Anatomy*, vol. lxi. 1931.

† *Journal of Anatomy and Physiology*, vol. xliii.

with normal breathing. When the body is erect the dome of the Diaphragm falls, and its respiratory movements become smaller. The dome falls still lower when the sitting posture is assumed, and in this position its respiratory excursions are smallest. When the body is horizontal and the patient on his side, the two halves of the Diaphragm do not behave alike. The uppermost half sinks to a level lower even than when the patient sits, and moves little with respiration; the lower half rises higher in the thorax than it does when the patient is supine, and its respiratory excursions are much increased.

It appears that the position of the Diaphragm in the thorax depends upon three main factors, viz.: (1) the elastic retraction of the lung-tissue, tending to pull it upwards; (2) the pressure exerted on its under surface by the viscera: this naturally tends to be a negative pressure, or downward suction, when the patient sits or stands, and a positive, or upward pressure, when he lies; (3) the intra-abdominal tension due to the abdominal muscles. These muscles are in a state of contraction in the standing position and not in the sitting; hence the Diaphragm is pushed up higher in the former position.

Applied Anatomy.—The oblique rise of the Diaphragm from the costal margin to the level of the fifth costal cartilage on the right side, and the sixth on the left, has to be borne in mind in opening an empyema. If the drainage tube be put in too low down. when the abscess cavity contracts the Diaphragm is drawn up against and blocks the tube before the abscess is cured.

The Mechanism of Respiration

The respiratory movements must be examined during (*a*) quiet respiration, and (*b*) deep respiration.

Quiet respiration.—The first and second pairs of ribs are fixed by the resistance of the cervical structures; the last pair, and through them the eleventh, by the Quadratus lumborum. The other ribs are elevated, so that the first two intercostal spaces are diminished while the others are increased in width. It has already been shown (p. 450) that elevation of the third, fourth, fifth and sixth ribs leads to an increase in the anteroposterior and transverse diameters of the thorax: the vertical diameter is increased by the descent of the diaphragmatic dome so that the lungs are expanded in all directions except backwards and upwards. Elevation of the eighth, ninth and tenth ribs is accompanied by a lateral and backward movement, leading to an increase in the transverse diameter of the upper part of the abdomen; the elasticity of the anterior abdominal wall allows a slight increase in the anteroposterior diameter of this part, and in this way the decrease in the vertical diameter of the abdomen is compensated and space provided for its displaced viscera. Expiration is effected by the elastic recoil of the thoracic walls, and by the action of the abdominal muscles, which push back the displaced abdominal viscera.

Deep respiration.—All the movements of quiet respiration are here carried out, but to a greater extent. In deep respiration the shoulders and the vertebral borders of the scapulæ are fixed and the Trapezius, Serratus anterior, Pectoral, and Latissimus dorsi muscles are called into play. The Scaleni are in strong action, and the Sternomastoids also assist when the head is fixed, by drawing up the sternum, and by fixing the clavicles. The first ribs are therefore no longer stationary, but are raised with the sternum; with them all the other ribs except the last are raised to a higher level. In conjunction with the increased descent of the Diaphragm this provides for a considerable augmentation of all the thoracic diameters. The anterior abdominal muscles come into action so that the umbilicus is drawn upwards and backwards, but this allows the Diaphragm to exert a more powerful influence on the lower ribs; the transverse diameter of the upper part of the abdomen is greatly increased and the infrasternal angle opened out. The deeper muscles of the back, e.g. the Serrati posteriores superiores and the Sacrospinales and their continuations, are also brought into action; the thoracic curve of the vertebral column is partially straightened, and the whole column, above the lower lumbar vertebræ, drawn backwards. This increases the anteroposterior diameters of the thorax and upper part of the abdomen and widens the intercostal spaces. Deep expiration is effected by the recoil of the thoracic walls and by the contraction of the anterolateral muscles of the abdominal wall.

Halls Dally (*loc. cit.*) gives the following figures as representing the average changes which occur during deepest possible respiration. The manubrium sterni moves 30 mm. in an upward and 14 mm. in a forward direction; the width of the infrasternal angle, at a

level of 30 mm. below the articulation between the body of the sternum and the xiphoid process, is increased by 26 mm.; the umbilicus is retracted and drawn upwards for a distance of 18 mm.

Applied Anatomy.—The changes in the height of the Diaphragm during alterations in posture explain why patients suffering from severe dyspnœa are most comfortable and least short of breath when they sit up. In unilateral disease of the pleura or lungs interference with the position or movement of the Diaphragm can generally be observed skiagraphically. Middleton,* by estimating the vital capacity in cases where the action of the Diaphragm was impaired by thoracic wounds or empyema, concludes that the normal diaphragmatic contraction is responsible for 60 per cent. of the respiratory exchange in deep breathing.

IV. The Muscles of the Abdomen

The muscles of the abdomen may be divided into anterolateral and posterior groups.

1. The Anterolateral Muscles

Obliquus externus. Transversus.
Obliquus internus. Rectus.
Pyramidalis.

The **superficial fascia** of the abdomen consists, over the greater part of the abdominal wall, of a single layer containing a variable amount of fat; but near the groin the fascia is easily divisible into two layers, between which are found the superficial vessels, nerves, and inguinal lymph-glands.

The superficial layer of the fascia is thick, areolar in texture, and contains in its meshes a varying quantity of fat. Below, it passes over the inguinal ligament, and is continuous with the superficial fascia of the thigh. In the male this layer is continued over the penis and outer surface of the spermatic cord to the scrotum. As it passes to the scrotum it changes its characteristics, becoming thin, destitute of adipose tissue, and of a pale reddish colour; in the scrotum it acquires some involuntary muscular fibres and forms the *dartos* muscle. From the scrotum it may be traced backwards into continuity with the superficial fascia of the perineum. In the female it is continued from the abdomen into the labia majora.

The deep layer of the fascia, thinner and more membranous than the superficial layer, contains a considerable quantity of elastic fibres. It is loosely connected by areolar tissue to the aponeurosis of the External oblique muscle, but in the median plane it is more intimately adherent to the linea alba and to the symphysis pubis, and is prolonged on to the dorsum of the penis, forming the *fundiform ligament*; above, it is continuous with the superficial fascia over the rest of the trunk; below and laterally, it blends with the fascia lata of the thigh a little below and parallel with the inguinal ligament (fig. 596); below and medially, it is continued over the penis and spermatic cord to the scrotum, where it helps to form the dartos muscle. From the scrotum it may be traced backwards into continuity with the membranous layer of the superficial fascia of the perineum (p. 577). In the female it is continued into the labia majora and thence to the fascia of the perineum.

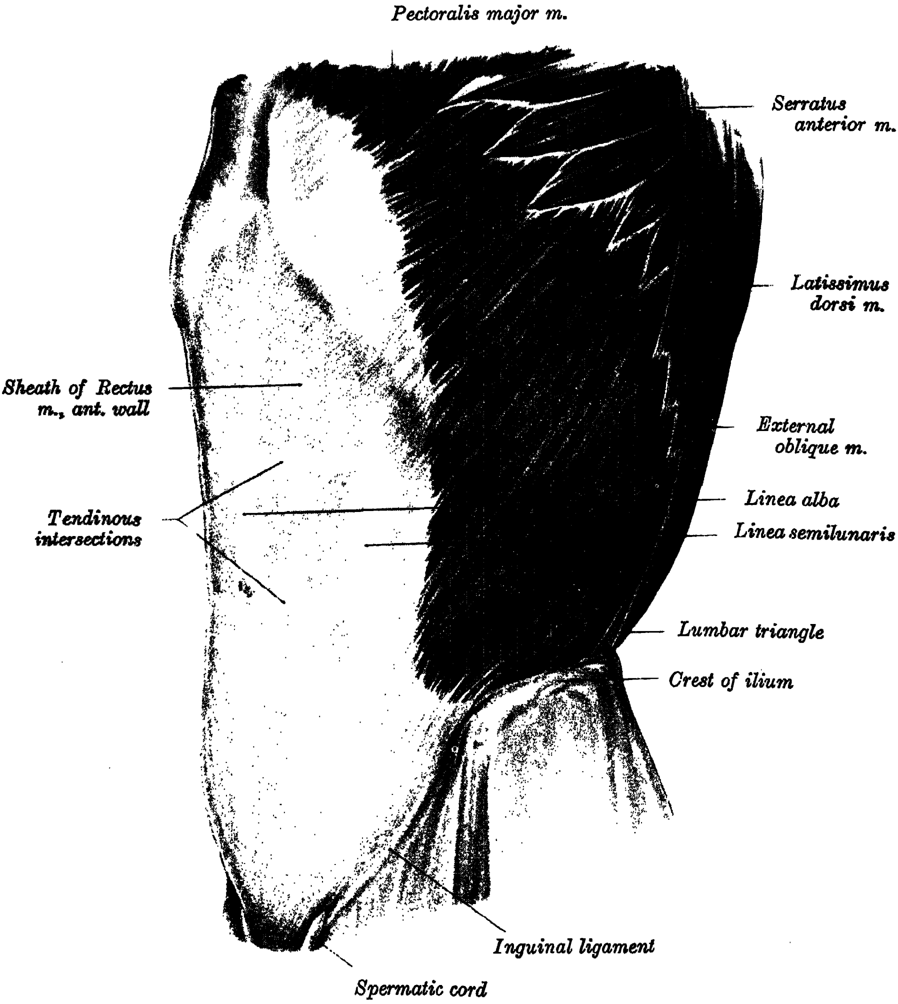
The **Obliquus externus abdominis** (fig. 595), situated on the lateral and anterior parts of the abdomen, is the largest and the most superficial of the three flat muscles in this region. It arises, by eight fleshy slips, from the external surfaces and inferior borders of the lower eight ribs; these slips interdigitate with the slips of origin of the Serratus anterior and Latissimus dorsi, and are arranged in an oblique line which runs downwards and backwards, the upper ones being attached close to the cartilages of the corresponding ribs, the lowest to the apex of the cartilage of the last rib, the middle ones to the ribs at some distance from their cartilages. From these attachments the fleshy fibres proceed in various directions. Those from the lower two ribs pass nearly vertically downwards, and are inserted into the anterior half or more of the outer lip of the ventral segment of the iliac crest (p. 368); the middle and upper fibres, directed downwards and forwards, end in an aponeurosis, opposite a line drawn vertically from the ninth costal cartilage to a little below the level of

* *American Journal of Medical Science*, 1923, p. 222.

the umbilicus, and then inclining laterally to the anterior superior iliac spine. None of the fleshy fibres of the muscle extend downwards beyond a line drawn from the anterior superior iliac spine to the umbilicus. The posterior border of the muscle is free.

The *aponeurosis* of the External oblique muscle is a thin but strong membranous structure, the fibres of which are directed downwards and medially. In the median plane its fibres end in the *linea alba* (fig. 595), a tendinous raphe which stretches from the xiphoid process to the symphysis pubis. There it is

FIG. 595.—The left Obliquus externus abdominis.



continuous with the aponeurosis of the corresponding muscle of the opposite side and the two together cover the front of the abdomen. Above and laterally, it is covered by, and gives origin to, the lower fibres of the Pectoralis major; below, its fibres are closely aggregated together, and extend obliquely across from the anterior superior iliac spine to the pubic tubercle and the pectineal line.

The margin of that portion of the aponeurosis which extends between the anterior superior iliac spine and the pubic tubercle is a thick band, folded backwards upon itself to present a grooved upper surface, and continuous below with the fascia lata of the thigh; it is called the *inguinal ligament*. A small portion is reflected from the medial part of the inguinal ligament, and is attached to the pectineal line of the pubis; it is called the *pectineal part of the inguinal ligament* (lacunar ligament). From the attachment of the latter a few fibres pass upwards and medially, behind the superior crus of the superficial inguinal ring

(subcutaneous inguinal ring), to the linea alba; they diverge as they ascend, and form a thin triangular fibrous band, which is called the *reflected part of the inguinal ligament* (fig. 602).

The complete insertion of the muscle can now be summarised. The highest fibres are inserted into the xiphoid process; the succeeding fibres into the linea alba, the upper border of the pubic symphysis and the adjoining part of the pubic crest, the pubic tubercle and the adjoining part of the pectineal line; and the lowest fibres into the anterior superior iliac spine and the anterior two-thirds of the outer lip of the ventral segment of the iliac crest.

FIG. 596.—A superficial dissection of the groin and the lower part of the anterior abdominal wall. Right side.

Nerve-supply.—The External oblique muscle is supplied by the anterior primary rami of the lower thoracic nerves.

Actions.—When the thorax and pelvis are fixed the External oblique muscles compress the abdominal viscera and thus assist in expelling the fæces from the rectum, the urine from the bladder, the fœtus from the uterus, and the contents of the stomach in vomiting. If the pelvis and vertebral column be fixed the muscles depress and compress the lower part of the thorax, assisting in expiration. If the pelvis alone be fixed, the trunk is bent forwards when both muscles act; if the muscle of one side act, the trunk is bent towards that side and the front of the abdomen turned towards the opposite side. If the thorax be fixed, the muscles, acting together, draw the front of the pelvis upwards and help to flex the lumbar part of the vertebral column.

Certain parts of the aponeurosis of the External oblique muscle require more detailed consideration.

The **superficial inguinal ring** (subcutaneous inguinal ring) (figs. 596, 597) is an interval in the aponeurosis, just above and lateral to the crest of the pubis. The aperture is somewhat triangular in form, and its direction is oblique, corresponding with the course of the fibres of the aponeurosis. It measures from base to apex about 2·5 cm., and across the base about 1·25 cm. Its base is formed by the crest of the pubis, and its sides by the margins of the opening in the aponeurosis, which are called the *crura of the ring*; above, the crura are

Fig. 597.—A superficial dissection of the groin and the lower part of the anterior abdominal wall. Left side.

connected by a series of curved *intercrural fibres*. The inferior crus of the ring is the stronger, and is formed by that portion of the inguinal ligament which is inserted into the pubic tubercle; it is curved so as to form a kind of groove, upon which, in the male, the spermatic cord rests. The superior crus is a thin, flat band, the fibres of which are attached to the front of the symphysis pubis, and interlace with the fibres of the opposite superior crus.

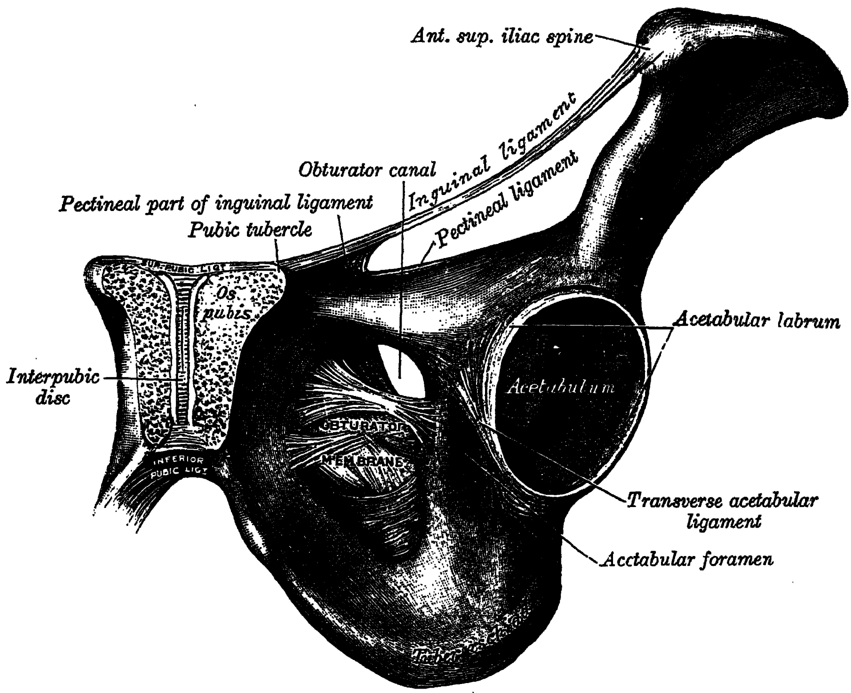
The superficial inguinal ring gives passage to the spermatic cord and ilio-inguinal nerve in the male, and to the round ligament of the uterus and the ilio-inguinal nerve in the female; it is much larger in men than in women, on account of the size of the spermatic cord.

The **intercrural fibres** are curved, tendinous fibres which arch across the lower part of the aponeurosis of the External oblique muscle, describing curves with the convexities downwards. They have received their name from the fact that they stretch across between the two crura of the superficial inguinal ring. They are much thicker and stronger at the inferior crus, where they are connected to the inguinal ligament, than superiorly, where they are inserted into the linea alba. The intercrural fibres increase the strength of the lower part of

the aponeurosis, and tend to prevent the divergence of the crura from each other; they are more strongly developed in the male than in the female. As they pass across the superficial inguinal ring they are connected together by delicate fibrous tissue, forming what is called the **external spermatic fascia** (intercrural fascia). This fascia is continued down as a tubular prolongation around the spermatic cord and testis, and forms the outermost of the coverings which enclose them. The superficial inguinal ring is seen as a distinct aperture only after the continuity between this fascia and the aponeurosis of the External oblique muscle has been severed.

The **inguinal ligament** (figs. 597, 598) is the lower border of the aponeurosis of the External oblique muscle, and stretches from the anterior superior iliac spine to the pubic tubercle. Its general direction is convex downwards towards

Fig. 598.—The left inguinal ligament.



the thigh, and it is continuous with the fascia lata. Its lateral one-half is rounded, and oblique in direction; its medial one-half gradually widens at its attachment to the pubis, is more horizontal in direction, and supports the spermatic cord.

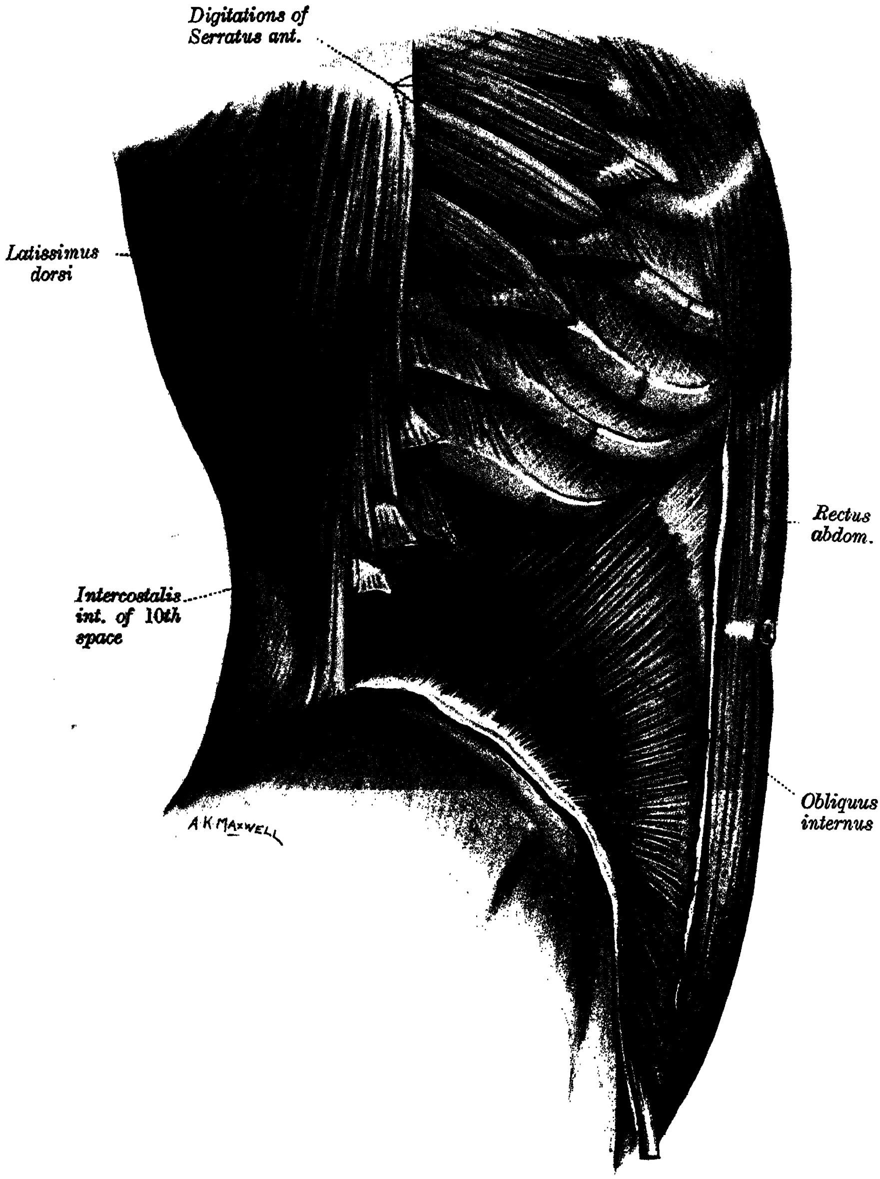
The **pectineal part of the inguinal ligament** (lacunar ligament) (fig. 598) is that portion of the aponeurosis of the External oblique muscle which passes backwards and laterally from the medial part of the inguinal ligament, and is attached to the medial end of the pectineal line. It is of a triangular form, and is almost horizontal in direction when the body is in the erect posture; it is a little larger in the male than in the female, and measures about 2 cm. from base to apex. Its base, directed laterally, is concave and thin, and forms the medial boundary of the femoral ring; its apex corresponds to the pubic tubercle. Its posterior margin is attached to the pectineal line, and is continuous with the pectineal fascia; its anterior margin is continuous with the inguinal ligament. Its surfaces are directed upwards and downwards.

The **reflected part of the inguinal ligament** (figs. 597, 602) is a triangular-shaped layer of tendinous fibres; it is formed by an expansion from the pectineal part of the inguinal ligament and the inferior crus of the superficial inguinal ring. It passes medially behind the spermatic cord, expands into a

triangular band behind the superior crus of the superficial inguinal ring and in front of the conjoint tendon (falx inguinalis aponeurotica); its fibres interlace with those of the opposite ligament at the linea alba.

The pectineal ligament (*ligament of Cooper*).—This is a strong fibrous band, which was first described by Sir Astley Cooper. It extends laterally from the

FIG. 599.—Dissection of the muscles of the side of the trunk. The External oblique muscle has been removed to show the Internal oblique, but its digitations from the ribs have been preserved. The sheath of the Rectus has been opened and its anterior wall removed. (From Quain's *Anatomy*, XI. Edition.)

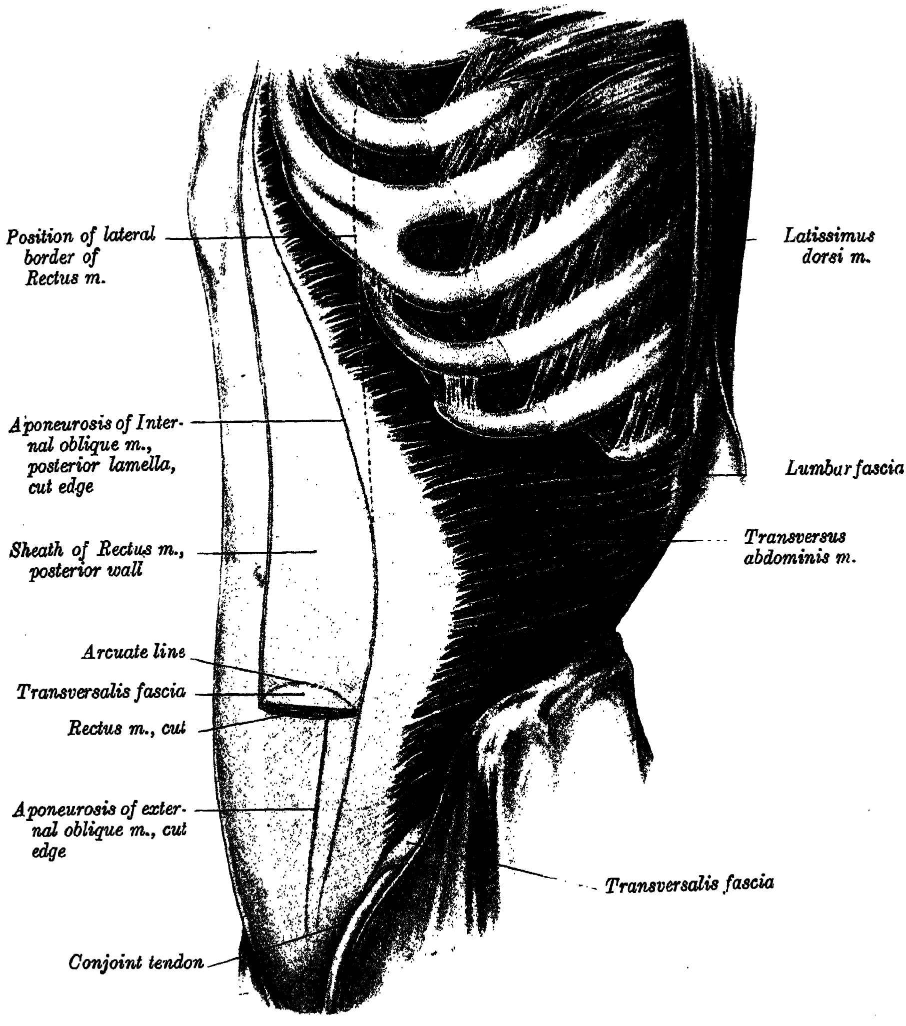


base of the pectineal part of the inguinal ligament (fig. 598) along the pectineal line, to which it is attached. It is strengthened by the pectineal fascia, and by a lateral expansion from the lower attachment of the linea alba (adminiculum lineæ albæ) (p. 570).

The **Obliquus internus abdominis** (fig. 599), which lies under cover of the External oblique, is a thinner and less bulky muscle. It arises, by fleshy fibres, from the lateral one-half of the grooved upper surface of the inguinal ligament,

from the anterior two-thirds of the intermediate area of the ventral segment of the iliac crest, and from the lumbar fascia (fig. 589). The posterior fibres ascend almost vertically, and are inserted into the inferior borders of the lower three ribs, and are there continuous with the Internal Intercostals. The fibres arising from the inguinal ligament, paler in colour than the others, arch downwards and medially across the spermatic cord in the male and the round ligament of the uterus in the female. Becoming tendinous they are inserted, conjointly

FIG. 600.—The left Transversus abdominis.



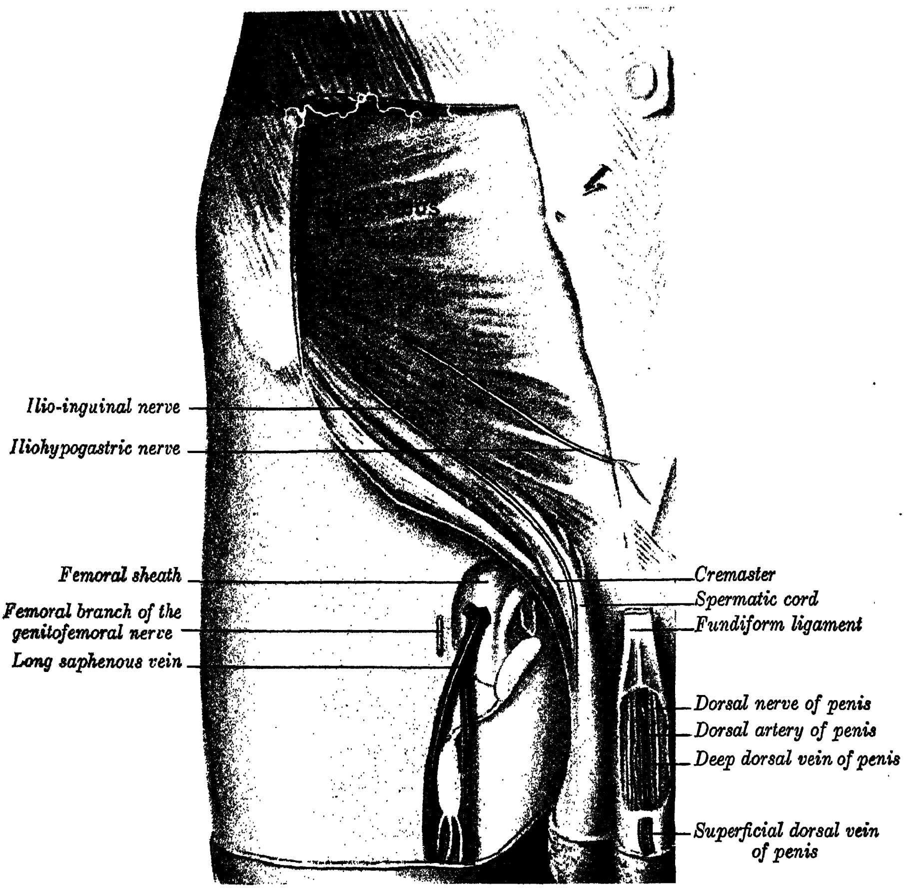
with the corresponding part of the aponeurosis of the Transversus abdominis, into the crest of the pubis and the medial part of the pectineal line, forming what is known as the *conjoint tendon* (inguinal aponeurotic falx). The rest of the fibres of the Internal oblique muscle diverge and end in an aponeurosis which gradually broadens from below upwards. The greater part of this aponeurosis splits at the lateral border of the Rectus abdominis into two lamellæ which ensheathe this muscle, and reunite at the linea alba. The anterior layer of this sheath blends with the aponeurosis of the External oblique muscle: the posterior layer fuses with the aponeurosis of the Transversus abdominis, and its upper part is attached to the cartilages of the seventh, eighth and ninth ribs.

Nerve-supply.—The Internal oblique muscle is supplied by the anterior primary rami of the lower six thoracic and the first lumbar nerves.

Actions.—The actions of the Internal oblique muscles are similar to those of the External oblique in compressing the abdomen (p. 561). Acting from below the Internal oblique muscle bends the thorax and turns the front of the abdomen towards the same side; acting from above it bends the lumbar part of the vertebral column to its own side and turns the front of the abdomen to the opposite side.

The **Cremaster** (fig. 601) is a thin muscular layer composed of a number of fasciculi which arise from the middle of the inguinal ligament, where its fibres

Fig. 601.—A dissection of the regions shown in fig. 596, but with a part of the Obliquus externus removed.



are continuous with those of the Internal oblique and also occasionally with the Transversus. It passes along the lateral side of the spermatic cord, and descends with it through the superficial inguinal ring upon the anterior and lateral surfaces of the cord, where it forms a series of loops which differ in thickness and length. At the upper part of the cord the loops are short, but they become successively longer, the longest reaching as far as the tunica vaginalis, into which a few are inserted. These loops are united together by areolar tissue, and form a thin covering over the cord and testis, named the *cremasteric fascia*. The fibres ascend along the medial and posterior surfaces of the cord, and are inserted by a small pointed tendon into the tubercle and crest of the pubis and into the front of the sheath of the Rectus abdominis.

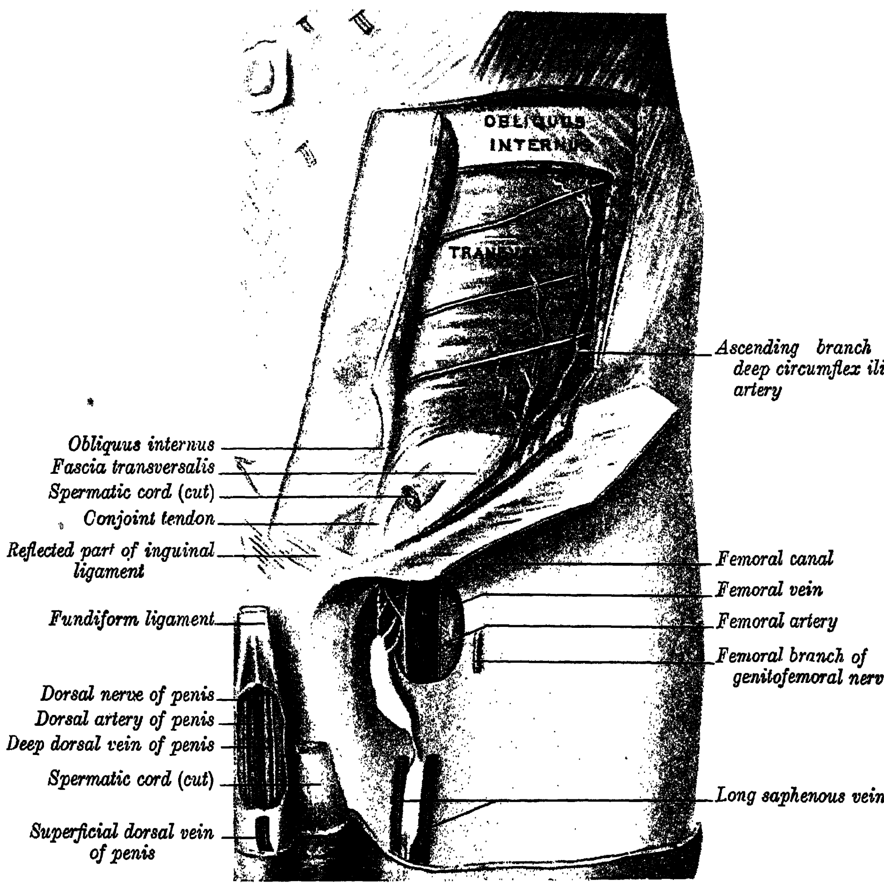
Nerve-supply.—The Cremaster is supplied by the genital (external spermatic) branch of the gemitofemoral nerve (L. 1 and 2).

Action.—The Cremaster is an involuntary muscle which pulls up the testis.

The **Transversus abdominis** (fig. 600), so called from the direction of its fibres, is the most internal of the flat muscles of the abdomen, being situated deep to

the Internal oblique. It arises by fleshy fibres from the lateral one-third of the inguinal ligament, from the anterior two-thirds of the inner lip of the ventral segment of the iliac crest, from the lumbar fascia as it extends between the iliac crest and the twelfth rib, and from the inner surfaces of the cartilages of the lower six ribs, interdigitating with the Diaphragm (fig. 592). The muscle ends in an aponeurosis, the lower fibres of which curve downwards and medially, and are inserted, together with those of the aponeurosis of the Internal oblique muscle, into the crest and pectineal line of the pubis, forming the conjoint

Fig. 602.—A dissection of the regions shown in fig. 597, but with portions of the Obliqui externus et internus removed.



tendon. The rest of the aponeurosis passes horizontally to the median plane, and is inserted into the linea alba; its upper three-fourths lie behind the Rectus abdominis and blend with the posterior lamella of the aponeurosis of the Internal oblique muscle; its lower one-fourth is in front of the Rectus. The upper muscular fibres of the Transversus abdominis are continued medially behind the Rectus abdominis (fig. 600) and the posterior lamella of the aponeurosis of the Internal oblique. Near the xiphoid process they reach to within 2 or 3 cm. of the linea alba. The muscular fibres of the Transversus abdominis run into the aponeurosis along a line which is concave medially (fig. 600), the aponeurosis being widest opposite the origin of the muscle from the lumbar fascia.

The *conjoint tendon* (falx inguinalis aponeurotica) of the Internal oblique and Transversus (fig. 602) is mainly formed by the lower part of the tendon of the Transversus, and is inserted into the crest and pectineal line of the pubis; it descends behind the superficial inguinal ring, thus serving to protect from behind what would otherwise be a weak point in the abdominal wall. The

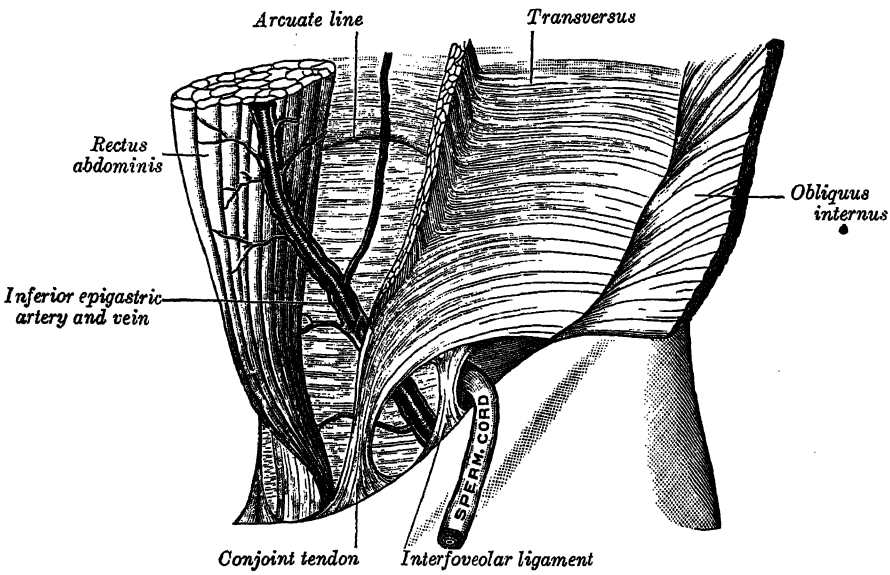
attachment to the pectineal line is frequently absent. Lateral to the conjoint tendon, an inconstant ligamentous band, named the *interfoveolar ligament* (fig. 603), may connect the lower margin of the Transversus to the superior ramus of the pubis ; it sometimes contains a few muscular fibres.

Nerve-supply.—The Transversus abdominis is supplied by the anterior primary rami of the lower six thoracic and the first lumbar nerves.

Actions.—The Transversi abdominis almost completely encircle the abdominal cavity ; in action they compress the abdominal contents.

The **Rectus abdominis** (fig. 604) is a long flat muscle, broader above than below, which extends along the whole length of the front of the abdomen, and is separated from its fellow of the opposite side by the linea alba. It arises by two tendons ; the lateral and larger is attached to the crest of the pubis : the medial interlaces with its fellow of the opposite side and is connected with the ligamentous fibres covering the front of the symphysis pubis. The muscle

Fig. 603.—The interfoveolar ligament. Anterior aspect. Modified from Braune.



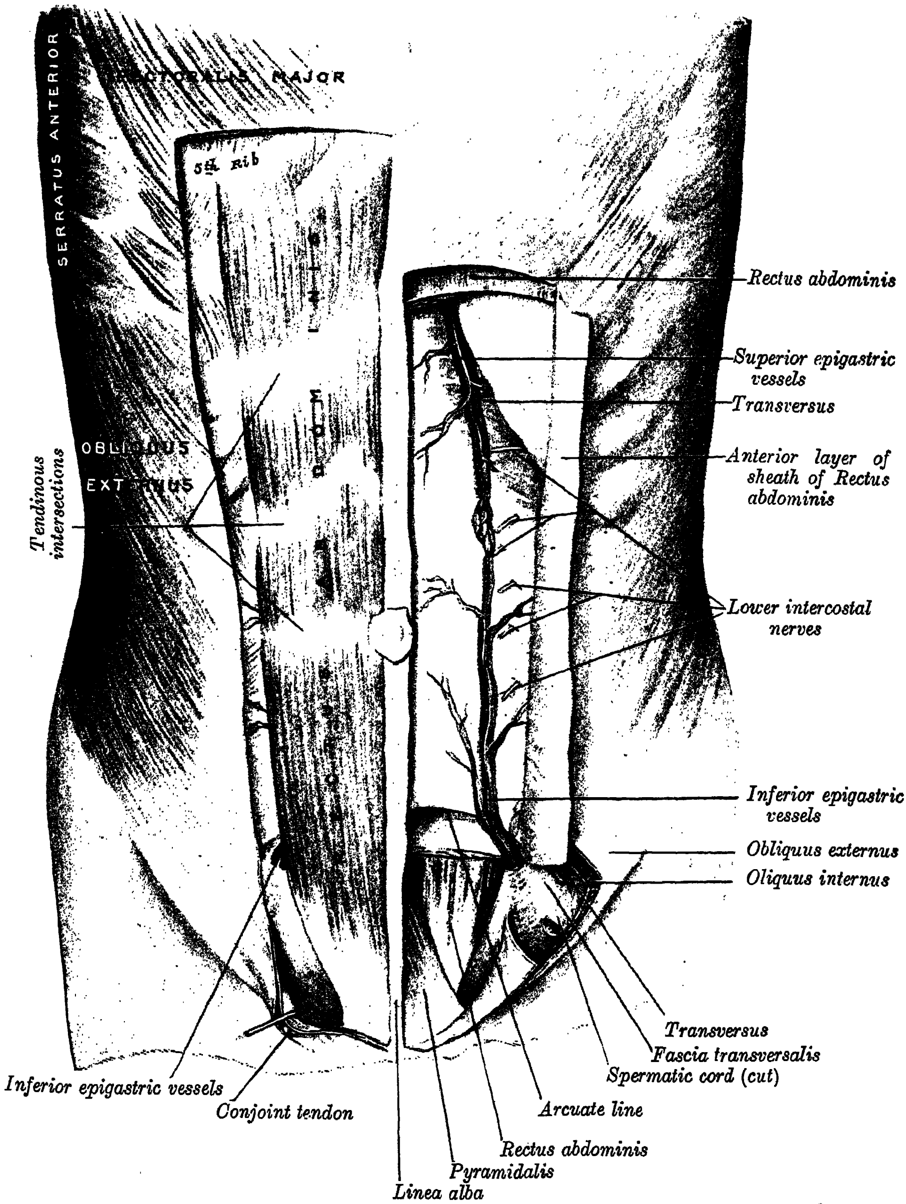
is inserted by three slips of unequal size into the cartilages of the fifth, sixth, and seventh ribs ; the most lateral fibres are usually inserted into the anterior extremity of the fifth rib ; the most medial are occasionally connected with the costoxiphoid ligaments and the side of the xiphoid process.

The rectus is intersected by three fibrous bands, named *tendinous intersections* ; one is usually situated opposite the umbilicus, another opposite the free end of the xiphoid process, and a third about midway between the xiphoid process and the umbilicus. These intersections pass transversely or obliquely across the muscle in a zigzag course ; they rarely extend completely through its substance and may pass only halfway across it ; *they are intimately adherent to the anterior lamina of the sheath of the muscle.* Sometimes one or two incomplete intersections are present below the umbilicus.

The Rectus abdominis is enclosed in a *sheath* (figs. 599, 600, 605) formed by the aponeuroses of the Obliqui and Transversus, which are arranged as follows : At the lateral margin of the Rectus, the aponeurosis of the Internal oblique divides into two lamellæ, one of which passes in front of the Rectus, blending with the aponeurosis of the External oblique, the other, behind it, blending with the aponeurosis of the Transversus, and these, joining again at the medial border of the Rectus, reach the linea alba. This arrangement of the aponeuroses exists from the costal margin to midway between the umbilicus and symphysis pubis, where the posterior wall of the sheath ends in a curved margin, named

the *arcuate line* (*linea semicircularis*) (fig. 604), the concavity of which is directed downwards. As already stated (p. 567) the muscular fibres of the upper part of the Transversus abdominis are continued behind the corresponding part of the Rectus abdominis to within 2 or 3 cm. of the linea alba (figs. 600, 604).

Fig. 604.—The right Rectus abdominis and the left Pyramidalis. The greater part of the left Rectus abdominis has been removed to show the superior and inferior epigastric vessels.



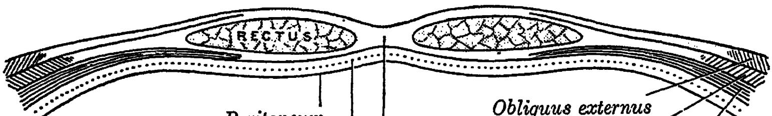
Below the level of the arcuate line the aponeuroses of all three muscles pass in front of the Rectus; those of the Transversus and Internal oblique are intimately fused together, but the aponeurosis of the External oblique is bound to them merely by loose connective tissue except in and near the median plane; behind, the Rectus is separated from the peritoneum by the transversalis fascia (fig. 606). Since the aponeuroses of the Internal oblique and Transversus only reach as high as the costal margin it follows that above this level the sheath of

the Rectus is deficient posteriorly, the muscle resting directly on the cartilages of the ribs; the front of this part of the Rectus is covered merely by the aponeurosis of the External oblique muscle.

The medial border of the muscle is closely related to the linea alba: its lateral border is marked on the surface of the anterior abdominal wall by a curved groove, termed the *linea semilunaris,* which extends from the tip of the ninth costal cartilage to the pubic tubercle. It is readily seen in a muscular subject even when the muscle is not actively contracting.

Nerve-supply.—The Rectus abdominis is supplied by the anterior primary rami of the lower six or seven thoracic nerves.

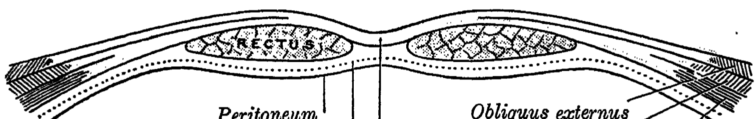
Fig. 605.—A transverse section through the anterior abdominal wall, above the umbilicus. Diagrammatic.



Actions.—The Rectus abdominis acting from above elevates the front of the pelvis; acting from below it depresses the thorax, and in continued action flexes the vertebral column. The two muscles are also powerful compressors of the abdominal viscera.

The **Pyramidalis** (fig. 604) is a triangular muscle, placed at the lower part of the abdomen, in front of the Rectus abdominis and within the sheath of that muscle. It arises by tendinous fibres from the front of the pubis and from the ligamentous fibres in front of the symphysis; the fleshy portion of the muscle passes upwards, diminishing in size as it ascends, and ends in a pointed extremity which is inserted into the linea alba midway between the umbilicus and pubis, but may extend to a higher level. This muscle may be larger on one side than on the other, or may be wanting on one or both sides.

Fig. 606.—A transverse section through the anterior abdominal wall, below the arcuate line. Diagrammatic.



Besides the Rectus and Pyramidalis, the sheath of the Rectus contains the superior and inferior epigastric arteries, and the terminal portions of the lower intercostal nerves.

Nerve-supply.—The Pyramidalis is supplied by the subcostal nerve (T. 12).

Action.—The Pyramidalis is a tensor of the linea alba.

The **linea alba** (figs. 595, 605) is a tendinous raphe stretching between the xiphoid process and the symphysis pubis. It is placed between the medial borders of the Recti, and is formed by the interlacement of the fibres of the aponeuroses of the Obliqui and Transversi. It is narrow below, corresponding to the linear interval existing between the Recti; but broader above, where these muscles diverge from each other. Its lower end has a double attachment—its superficial fibres passing in front of the medial heads of the Recti to the front of the symphysis pubis, while its deeper fibres form a triangular lamella, attached behind the Recti to the posterior surface of the crest of the pubis, and named the *adminiculum lineæ albæ.* The linea alba presents apertures for the passage of vessels and nerves; in the fœtus the umbilicus transmits the umbilical vessels, but it is closed a few days after birth.

The **transversalis fascia** is a thin membrane which lies between the inner surface of the Transversus muscle and the extraperitoneal fat. It forms part of the general layer of fascia lining the abdominal parietes, and is continuous with the iliac and pelvic fasciæ. In the inguinal region it is thick and dense in structure, and is joined by fibres from the aponeurosis of the Transversus, but it becomes thin as it ascends to the Diaphragm, and blends with the fascia covering the under surface of this muscle. Behind, it is lost on the surface of the lumbar (lumbodorsal) fascia, with which it blends. Below, it has the following attachments : posteriorly, to the whole length of the iliac crest, between the origins of the Transversus and Iliacus ; between the anterior superior iliac spine and the femoral vessels it is connected to the posterior margin of the inguinal ligament, and is there continuous with the iliac fascia. Medial to the femoral vessels it is thin and is fixed to the pectineal line of the pubis, behind the conjoint tendon, with which it is united ; it descends in front of the femoral vessels to form the anterior wall of the femoral sheath. The spermatic cord in the male, and the round ligament of the uterus in the female, pass through the transversalis fascia at a spot called the *deep inguinal ring* (abdominal inguinal ring). This opening is not visible externally since the transversalis fascia is prolonged on these structures as the *internal spermatic fascia*.

The **deep inguinal ring** (abdominal inguinal ring) is situated in the transversalis fascia, midway between the anterior superior iliac spine and the symphysis pubis, and 1·25 cm. above the inguinal ligament. It is of an oval form, the long axis of the oval being vertical ; it varies in size in different subjects, and is much larger in the male than in the female. It is related above to the arched lower margin of the Transversus abdominis, and medially to the inferior epigastric vessels and the interfoveolar ligament, when that structure is present. It transmits the spermatic cord in the male and the round ligament of the uterus in the female. From its circumference a thin funnel-shaped membrane, named the *internal spermatic fascia*, is continued as a covering on the spermatic cord and testis.

The **inguinal canal** contains the spermatic cord and the ilio-inguinal nerve in the male, and the round ligament of the uterus and the ilio-inguinal nerve in the female. It is an oblique canal about 4 cm. long, slanting downwards and medially, and placed parallel with, and a little above, the inguinal ligament ; it extends from the deep (abdominal) inguinal ring to the superficial (subcutaneous) inguinal ring. It is bounded *in front* throughout its whole length by the skin, superficial fascia, and aponeurosis of the External oblique, and in its lateral one-third by the fleshy fibres of origin of the Internal oblique muscle ; *behind*, by the reflected part of the inguinal ligament, the conjoint tendon, and the transversalis fascia, which separate it from the extraperitoneal connective tissue and the peritoneum ; *above*, by the arched fibres of the Internal oblique and Transversus abdominis ; *below*, by the union of the transversalis fascia with the inguinal ligament, and at its medial end by the pectineal part of the inguinal ligament (lacunar ligament).

The presence of the canal weakens the lower part of the anterior abdominal wall, but the weakness thus produced is compensated for partly by the obliquity of the canal and partly by the arrangement of the constituent parts of its walls. Owing to the oblique direction of the canal the two inguinal rings do not lie opposite to one another, and increases in the intra-abdominal pressure exercise their effect not only at the deep inguinal ring but also on the posterior wall of the canal so as to approximate it to the anterior wall. The posterior wall of the canal is strengthened by the conjoint tendon and the reflected part of the inguinal ligament precisely opposite to the superficial inguinal ring, and the fleshy fibres of the Internal oblique muscle take part in the formation of the anterior wall, where it lies opposite to the deep inguinal ring.

The **extraperitoneal connective tissue.**—Between the peritoneum and the inner surface of the general layer of the fascia which lines the interior of the abdominal and pelvic cavities, there is a considerable amount of connective tissue, termed the *extraperitoneal tissue*.

The extraperitoneal tissue varies in quantity in different situations. It is especially abundant on the posterior wall of the abdomen, and particularly around the kidneys, where it contains much fat. It is scanty on the antero-

lateral wall of the abdomen, except in the pubic region and above the iliac crest; there is a considerable amount in the pelvis.

2. The Posterior Muscles of the Abdomen

Psoas major.	Iliacus.
Psoas minor.	Quadratus lumborum.

The Psoas major, the Psoas minor, and the Iliacus, with the fasciæ covering them, are described with the muscles of the lower limb (pp. 621 to 623).

The **fascia covering the Quadratus lumborum** is the anterior layer of the lumbar fascia (p. 546). It is attached, medially, to the anterior surfaces of the transverse processes of the lumbar vertebræ; below, to the iliolumbar ligament; above, to the apex and lower border of the last rib. The upper margin of this fascia, which extends from the transverse process of the first lumbar vertebra to the apex and lower border of the last rib, constitutes the lateral arcuate ligament (lateral lumbocostal arch) (p. 555). Laterally, the fascia blends with the fused posterior and middle layers of the lumbar fascia (fig. 589).

The **Quadratus lumborum** (figs. 590, 638) is irregularly quadrilateral in shape, and broader below than above. It arises by aponeurotic fibres from the iliolumbar ligament and the adjacent portion of the iliac crest for about 5 cm., and is inserted into the medial one-half of the lower border of the last rib, and by four small tendons into the apices of the transverse processes of the upper four lumbar vertebræ. Occasionally a second portion of this muscle is found in front of the preceding; it arises from the upper borders of the transverse processes of the lower three or four lumbar vertebræ, and is inserted into the lower margin and the lower part of the anterior surface of the last rib.

In front of the Quadratus lumborum are the colon, the kidney, the Psoas major et minor, and the Diaphragm; the subcostal, iliohypogastric, and ilio-inguinal nerves lie in front of the fascia which covers the muscle but are bound down to it by the continuation medially of the transversalis fascia.

Nerve-supply.—The Quadratus lumborum is supplied by the anterior primary rami of the twelfth thoracic and upper three or four lumbar nerves.

Actions.—The Quadratus lumborum draws down the last rib, and acts as a muscle of inspiration by helping to fix the origin of the Diaphragm. If the thorax and vertebral column are fixed, it may act upon the pelvis, raising it towards its own side when only one muscle is put in action; and when both muscles act together they help to extend the lumbar part of the vertebral column.

V. The Muscles of the Pelvis

Obturator internus.	Levator ani.
Piriformis.	Coccygeus.

The muscles within the pelvis may be divided into two groups: (1) the Piriformis and the Obturator internus, which are described with the muscles of the lower limb (pp. 633, 635); (2) the Levator ani and the Coccygeus, which, with the corresponding muscles of the opposite side, form the *pelvic diaphragm*. The classification of the two groups under a common heading is convenient in connexion with the fasciæ investing the muscles. These fasciæ are closely related to one another and to the deep fascia of the perineum, and in addition are connected with the fascial coverings of the pelvic viscera; it is customary therefore to describe them together under the term *pelvic fascia*.

Pelvic fascia.—The fascia of the pelvis may be resolved into: (A) the fascial sheaths of the pelvic muscles; (B) the fascial sheaths of the pelvic viscera (see section on Splanchnology).

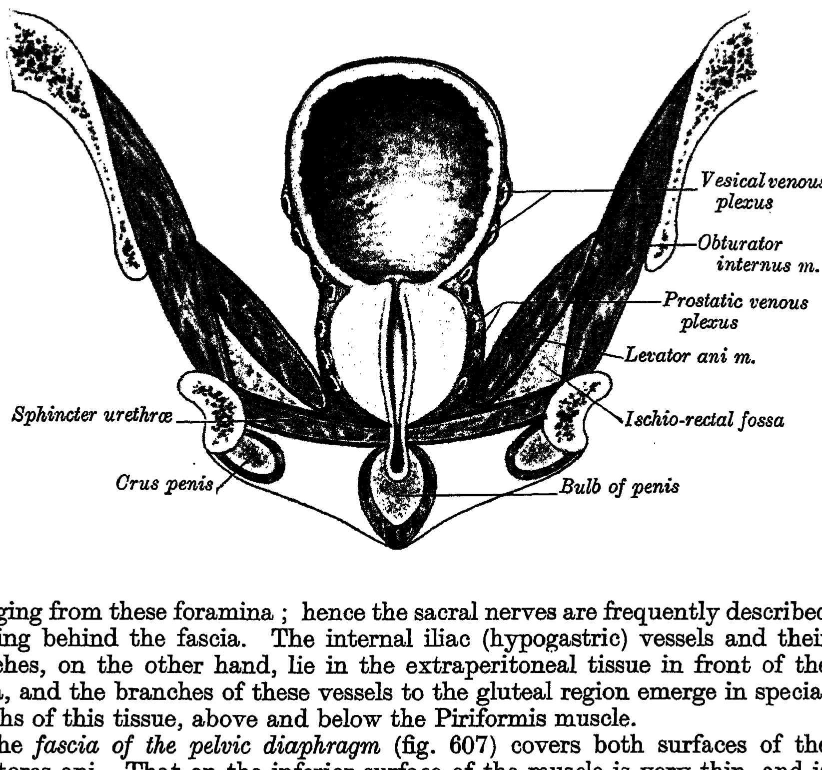
The *fascia of the Obturator internus* covers the pelvic surface of the muscle, and is attached round the margin of its origin. Above, it is connected to the posterior part of the arcuate line of the hip-bone, and is there continuous with the iliac fascia. In front of this, as it follows the line of origin of the

Obturator internus, it gradually separates from the iliac fascia, and the continuity between the two is retained only through the periosteum. It arches below the obturator vessels and nerve, completing the obturator canal, and at the front of the pelvis is attached to the back of the body of the pubis. The lower part of the obturator fascia forms the lateral wall of the ischiorectal fossa, and is attached inferiorly to the falciform process of the sacro-tuberous ligament and to the pubic arch; at the pubic arch it is continuous with the fascia on the deep surface of the Deep transversus perinei and the Sphincter urethræ. Behind, it is indirectly continuous with the fascia of the Piriformis.

The internal pudendal vessels and their accompanying nerves are placed in the lateral wall of the ischiorectal fossa, and are enclosed in a special sheath of the fascia, named the *pudendal canal.*

The *fascia of the Piriformis* is very thin and is attached to the front of the sacrum around the margins of the anterior sacral foramina. At its sacral attachment it comes into intimate association with and ensheathes the nerves

FIG. 607.—A coronal section through the pelvis, showing the arrangement of the fasciæ and the sheath of the prostate. Diagrammatic.



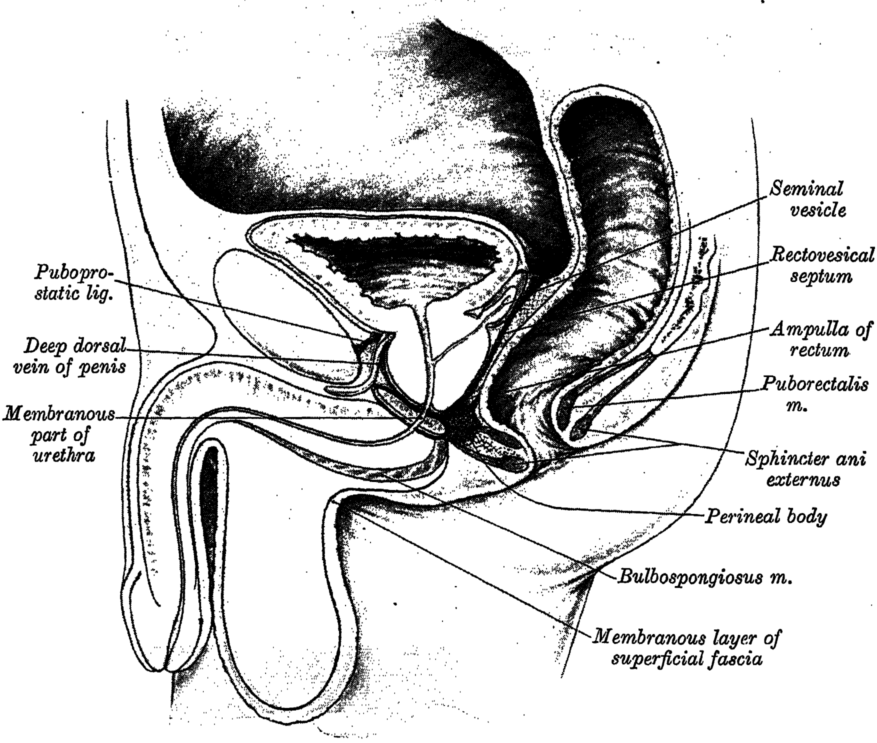
emerging from these foramina; hence the sacral nerves are frequently described as lying behind the fascia. The internal iliac (hypogastric) vessels and their branches, on the other hand, lie in the extraperitoneal tissue in front of the fascia, and the branches of these vessels to the gluteal region emerge in special sheaths of this tissue, above and below the Piriformis muscle.

The *fascia of the pelvic diaphragm* (fig. 607) covers both surfaces of the Levatores ani. That on the inferior surface of the muscle is very thin, and is known as the *anal fascia*; it forms the medial wall of the ischiorectal fossa, and above is continuous with the obturator fascia along the line of origin of the Levator ani; it is continuous below with the fascia on the Sphincter urethræ and the Sphincter ani externus. On the lateral side the layer covering the upper surface of the Levator ani follows the line of origin of the muscle, and is therefore somewhat variable. In front it is attached to the back of the symphysis pubis about 2 cm. above its lower border, and can be traced laterally across the back of the superior ramus of the pubis for a distance of 1·25 cm., when it reaches the obturator fascia. It blends with this fascia along a line which pursues a somewhat irregular course to the spine of the ischium. The irregularity of this line is explained by the fact that whereas in lower mammals the Levator ani arises posteriorly from the pelvic brim, in man it has descended to a lower level and arises from the obturator fascia. In some cases tendinous fibres of origin extend up towards, and may reach, the pelvic brim, carrying the fascia with them.

Internally the fascia covering the upper surface of the pelvic diaphragm blends with the fascial sheaths of the pelvic viscera. The fascia covering that part of the Obturator internus which lies above the origin of the Levator ani is therefore a composite structure and includes, (*a*) the obturator fascia, (*b*) the fascia of the Levator ani, and (*c*) the degenerated fibres of origin of the Levator ani.

At the level of a line extending from the lower part of the symphysis pubis to the spine of the ischium there is a thickened whitish band in this upper layer of the fascia of the pelvic diaphragm. It is termed the *tendinous arch* of the pelvic fascia, and marks the line of attachment of the lateral true ligament of the urinary bladder. Anteriorly the fascia forms two thickened bands, named the *puboprostatic ligaments*, one on each side of the median plane.

FIG. 608.—A median sagittal section through the pelvis, showing the arrangement of the fasciæ. Diagrammatic.

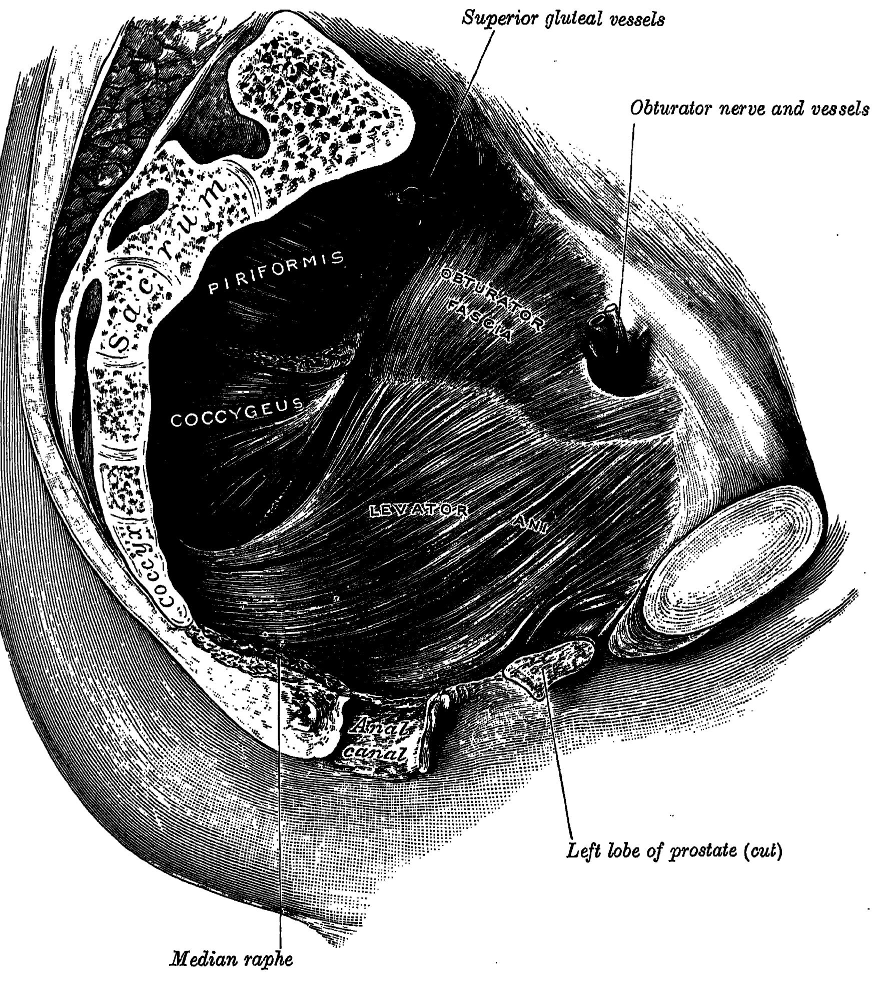


The **Levator ani** (fig. 609) is a broad, thin muscle; it is attached to the inner surface of the side of the false (lesser) pelvis, and unites with its fellow of the opposite side to form the greater part of the floor of the pelvic cavity. It arises, in front, from the pelvic surface of the body of the pubis lateral to the symphysis; behind, from the inner surface of the spine of the ischium; and between these two points, from the obturator fascia. Posteriorly this origin from the obturator fascia corresponds, more or less closely, with the tendinous arch of the pelvic fascia, but in front, the muscle arises from the fascia at a varying distance above the arch, in some cases reaching nearly as high as the canal for the obturator vessels and nerve. The fibres pass towards the median plane with varying degrees of obliquity. (*a*) The most anterior fibres sweep backwards and downwards across the side of the prostate to be inserted into the perineal body (central point of the perineum) (p. 577). They constitute the *Levator prostatæ* in the male, but in the female they cross the side of the vagina to reach their insertion, and so constitute an additional and important sphincter for that structure. (*b*) The succeeding fibres pass backwards and downwards across the side of the prostate and the upper end of the anal canal, and turn medially at the anorectal flexure to become continuous with the corresponding

fibres of the opposite side, but a number of them are lost in the wall of the anal canal. This part of the muscle is termed the *Puborectalis*. (*c*) The remaining fibres are inserted into the side of the last two segments of the coccyx and into a median fibrous raphe which stretches between the coccyx and the anorectal flexure.

Morphologically, the Levator ani may be divided into Iliococcygeus and Pubococcygeus. The *Iliococcygeus* arises from the ischial spine and from the posterior part of the tendinous arch of the pelvic fascia, and is attached to the coccyx and the median raphe; it

Fig. 609.—The left Levator ani. Pelvic surface.



is usually thin, and may fail entirely or be replaced largely by fibrous tissue. An accessory slip at its posterior part is sometimes named the *Iliosacralis*. The *Pubococcygeus* arises from the back of the pubis and from the anterior part of the obturator fascia, and is directed backwards almost horizontally along the side of the anal canal. Between the coccyx and the anal canal the Pubococcygei come together and form a thick, fibromuscular layer lying on the raphe formed by the Iliococcygei. In lower mammals both muscles are inserted only into the caudal vertebræ. The iliococcygeus is responsible for side to side movements of the tail, and the Pubococcygeus draws it downwards and forwards between the hind limbs. The gradual disappearance of the tail sets free these muscles to meet the demands for a more complete pelvic floor made by the gradual adoption of the erect attitude.

Relations.—The *upper* or *pelvic surface* of the Levator ani is separated by its covering fascia from the bladder, prostate, rectum, and peritoneum. Its *lower* or *perineal surface* forms the medial boundary of the ischiorectal fossa, and is covered by the anal fascia. Its *posterior border* is free and separated from the Coccygeus muscle by areolar tissue. Its

anterior border is separated from the muscle of the opposite side by a triangular space, through which the urethra and, in the female, the vagina pass from the pelvis.

Nerve-supply.—The Levator ani is supplied by a branch from the fourth sacral nerve and by a branch which arises either from the perineal, or from the inferior hæmorrhoidal, division of the pudendal nerve.

Actions.—The Levatores ani constrict the lower end of the rectum and vagina and steady the perineal body (central point of the perineum). Together with the Coccygei they form a muscular diaphragm which supports the pelvic viscera and opposes itself to the downward thrust produced by any increase in the intra-abdominal pressure.

The **Coccygeus** (fig. 609) is situated behind the Levator ani. It is a triangular sheet of muscular and tendinous fibres, arising by its apex from the pelvic surface of the spine of the ischium and from the sacrospinous ligament, and inserted by its base into the margin of the coccyx and into the side of the lowest piece of the sacrum. It assists the Levator ani and Piriformis in closing the posterior part of the outlet of the pelvis.

Nerve-supply.—The Coccygeus is supplied by a branch from the fourth and fifth sacral nerves.

Actions.—The Coccygei pull forward and support the coccyx, after it has been pressed backwards during defæcation or parturition.

Applied Anatomy.—Injury to the muscles forming the pelvic floor occurs not infrequently during parturition. When the perineal body (p. 577) has been torn through, and has not been repaired satisfactorily, the contraction of the anterior fibres of the Levator ani increases instead of diminishing the normal gap in the pelvic floor, and prolapse of the uterus results ; in severe cases the ovaries, bladder and rectum may also prolapse.

VI. The Muscles of the Perineum

The perineum corresponds to the outlet of the pelvis. Its deep boundaries are—in front, the pubic arch and the inferior pubic ligament ; behind, the tip of the coccyx ; and on each side the inferior ramus of the pubis and the ramus of the ischium, the ischial tuberosity and the sacrotuberous ligament. The space within these boundaries is somewhat lozenge-shaped. On the surface of the body the perineum is limited by the scrotum in front, the buttocks behind, and the medial sides of the thighs laterally. A line drawn transversely in front of the ischial tuberosities divides the space into two portions. The posterior contains the termination of the anal canal, and is known as the *anal region* ; the anterior contains the external urogenital organs, and is termed the *urogenital region.*

The muscles of the perineum may therefore be divided into two groups :

1. Those of the anal region.
2. Those of the urogenital region : A, In the male ; B, In the female.

1. The Muscles of the Anal Region

Sphincter ani externus.

The **superficial fascia** is very thick, areolar in texture, and contains much fat in its meshes. On each side a pad of fatty tissue extends deeply between the Levator ani and Obturator internus into a space known as the *ischiorectal fossa.*

The **deep fascia** forms the lining of the ischiorectal fossa ; it comprises the anal fascia, and that part of the obturator fascia which lies below the origin of Levator ani.

Ischiorectal fossa.—The fossa is somewhat wedge-shaped, with its base directed to the surface of the perineum, and its thin edge at the line of meeting of the obturator and anal fasciæ. It is bounded medially by the Sphincter ani externus and the anal fascia ; laterally, by the tuberosity of the ischium and the obturator fascia ; anteriorly, by the perineal membrane (inferior fascia of the urogenital diaphragm) ; posteriorly, by the Gluteus maximus and the sacro-

tuberous ligament. The inferior rectal vessels and the inferior hæmorrhoidal nerve cross the space transversely from the lateral to the medial side; the perineal and perforating cutaneous branches of the sacral plexus are found in the posterior part of the fossa; while from the anterior part the scrotal (or labial) vessels and nerves emerge. The internal pudendal vessels and pudendal nerve lie on the lateral wall of the fossa, in the pudendal canal (p. 573). The fossa is filled with fatty tissue, across which numerous fibrous bands extend.

The **Sphincter ani externus** (figs. 610, 612) is a flat sheet of muscular fibres, elliptical in shape and intimately adherent to the skin surrounding the anus. It measures from 8 to 10 cm. in length and is about 2·5 cm. in width opposite the anus. It consists of two portions, superficial and deep. The *superficial portion* constitutes the chief part of the muscle, and arises by a narrow tendinous band from the tip of the coccyx; the muscle consists of two flattened sheets which pass one on each side of the anus and meet in front to be inserted into the perineal body (central tendinous point of the perineum), joining with the Transversus perinei superficialis, the Levator ani, and the Bulbospongiosus (Bulbocavernosus). The *deep portion* forms a complete sphincter to the anal canal. Its fibres surround the canal, closely applied to the Puborectalis and the Sphincter ani internus, and in front blend with the other muscles at the perineal body. In a considerable proportion of cases the fibres decussate in front of the anus, and are continuous with the Transversi perinei superficiales. The upper edge of the muscle is ill-defined, since it receives numerous fibres from the Puborectalis.

Nerve-supply.—The Sphincter ani externus is supplied by a branch from the fourth sacral nerve and by twigs from the inferior hæmorrhoidal branch (S. 2 and 3) of the pudendal nerve.

Actions.—The Sphincter ani externus is normally in a state of tonic contraction, and having no antagonistic muscle it keeps the anal canal and orifice closed. It can be put into a condition of greater contraction under the influence of the will, so as to occlude the anal aperture more firmly. Taking its fixed point at the coccyx, it helps to fix the perineal body (central point of the perineum).

2. A. The Muscles of the Urogenital Region in the Male (fig. 610)

Transversus perinei superficialis.	Ischiocavernosus.
Bulbospongiosus.	Transversus perinei profundus.
Sphincter urethræ.	

The **superficial fascia** of this region consists of a superficial, fatty, and a deeper, membranous layer.

The *fatty layer* is thick, loose, areolar in texture, and contains a variable amount of fat in its meshes. In front, it is continuous with the dartos muscle of the scrotum; behind, with the subcutaneous areolar tissue surrounding the anus; and, on each side, with the same fascia on the medial sides of the thighs. In the median plane, it is adherent to the skin and to the membranous layer of the superficial fascia.

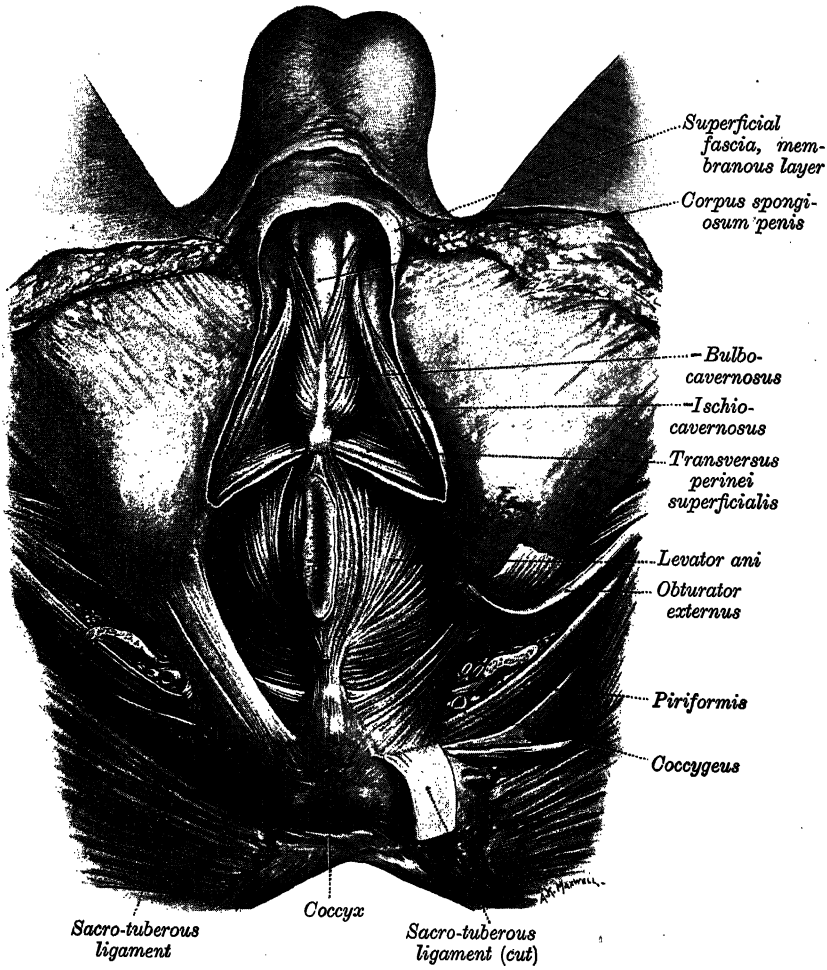
The *membranous layer of superficial fascia* (fig. 608) is thin, aponeurotic in structure, and of considerable strength, serving to bind down the muscles of the root of the penis. It is continuous, in front, with the dartos muscle, the deep fascia of the penis, and the membranous layer of the superficial fascia upon the anterior wall of the abdomen; on each side it is attached to the margins of the rami of the pubis and ischium, lateral to the crus penis and as far back as the tuberosity of the ischium; posteriorly it curves round the Transversi perinei superficiales to join the posterior margin of the perineal membrane (inferior fascia of the urogenital diaphragm) and the perineal body (central point of the perineum). In the median plane it is connected with the superficial fascia and with the median septum of the Bulbospongiosus. At its posterior part this fascia sends upwards from its deep surface a median septum, which incompletely divides the posterior portion of the subjacent space.

The *perineal body* (central tendinous point of the perineum).—This is a fibromuscular node in the median plane, about 1·25 cm. in front of the anus,

and close to the bulb of the penis (urethral bulb). Towards this point six muscles converge and are attached: viz. the Sphincter ani externus, the Bulbospongiosus, the two Transversi perinei superficiales, and the anterior fibres of the two Levatores ani. In addition, it receives longitudinal involuntary fibres from the rectal ampulla and the anal canal. It is a compact little node, and the importance of its integrity to the pelvic floor in the female has already been mentioned (p. 576).

The **Transversus perinei superficialis** is a narrow muscular slip which passes more or less transversely across the perineal space in front of the anus. It is

FIG. 610.—The muscles of the male perineum. (From Quain's *Anatomy*, XI. Edition).



often feebly developed, and is sometimes absent. It arises by tendinous fibres from the medial and anterior part of the tuberosity of the ischium, and, running medially, is inserted into the perineal body, joining in this situation with the muscle of the opposite side, with the Sphincter ani externus behind, and with the Bulbospongiosus in front. In some cases, the fibres of the deeper layer of the Sphincter ani externus decussate in front of the anus and are continued into this muscle. Occasionally it gives off fibres which join with the Bulbospongiosus of the same side.

Action.—The simultaneous contraction of the two Transversi perinei superficiales helps to fix the perineal body.

The **Bulbospongiosus** (Bulbocavernosus) is placed in the median line of the perineum, in front of the anus, and consists of two symmetrical parts, united

by a median tendinous raphe. It arises from this median raphe and from the perineal body (central tendinous point of the perineum). Its fibres diverge like the barbs of a quill-pen ; the most posterior form a thin layer, which is lost on the perineal membrane (inferior fascia of the urogenital diaphragm) ; the middle fibres encircle the bulb and the adjacent part of the corpus spongiosum penis (corpus cavernosum urethræ), and are inserted into a strong aponeurosis on the upper part of that structure ; the anterior fibres spread out over the side of the corpus cavernosum penis, to be inserted partly into that body, anterior to the Ischiocavernosus, and partly into a tendinous expansion which covers the dorsal vessels of the penis.

Actions.—The Bulbospongiosus serves to empty the canal of the urethra, after the bladder has expelled its contents ; during the greater part of the act of micturition its fibres are relaxed, and they only come into action at the end of the process. The middle fibres are supposed by Krause to assist in the erection of the corpus spongiosum penis, by compressing the erectile tissue of the bulb. The anterior fibres, according to Tyrrel, also contribute to the erection of the penis by compressing the deep dorsal vein of the penis, as their tendinous expansion is inserted into, and is continuous with, the fascia covering the dorsal vessels of the penis.

The **Ischiocavernosus** covers the crus penis. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus penis ; and from the ramus of the ischium on both sides of the crus. The muscular fibres end in an aponeurosis which is inserted into the sides and under surface of the crus penis.

Action.—The Ischiocavernosus compresses the crus penis, and retards the return of the blood through the veins, and thus serves to maintain the penis erect.

Between the muscles just examined a triangular space exists, bounded medially by the Bulbospongiosus, laterally by the Ischiocavernosus, and behind by the Transversus perinei superficialis ; the floor is formed by the perineal membrane (inferior fascia of the urogenital diaphragm). The scrotal vessels and nerves, and the perineal branch of the posterior femoral cutaneous nerve traverse the space from behind forwards ; the transverse perineal artery courses along its posterior boundary on the Transversus perinei superficialis.

The **deep fascia** of the urogenital region forms an investment for the Transversus perinei profundus and the Sphincter urethræ, but within it there are also the deep vessels and nerves of this part. It is stretched almost horizontally across the pubic arch, so as to close the anterior part of the pelvic outlet. It consists of two membranous laminæ (fig. 611), which are united at the free edges of the muscles. The stronger and more superficial of these laminæ is named the *perineal membrane* (inferior fascia of the urogenital diaphragm). Its base, directed backwards, is connected to the perineal body and is continuous with the anal fascia, and, behind the Transversus perinei superficialis, with the membranous layer of the superficial fascia. Its lateral margins are attached to the inferior ramus of the pubis and the ramus of the ischium, above the crus penis. Its apex, directed forwards, is thickened to form the *transverse perineal ligament* ; between this ligament and the inferior pubic ligament the deep dorsal vein of the penis (or clitoris) enters the pelvis. It is perforated, from 2 to 3 cm. below the symphysis pubis, by the urethra, the aperture for which is circular and about 6 mm. in diameter ; by the arteries and nerves to the bulb and, close to the urethra, by the ducts of the bulbo-urethral glands ; by the deep arteries of the penis, one on each side close to the pubic arch and about halfway along the attached margin of the membrane ; by the dorsal arteries and nerves of the penis near the apex of the membrane. Its base is also perforated by the scrotal vessels and nerves.

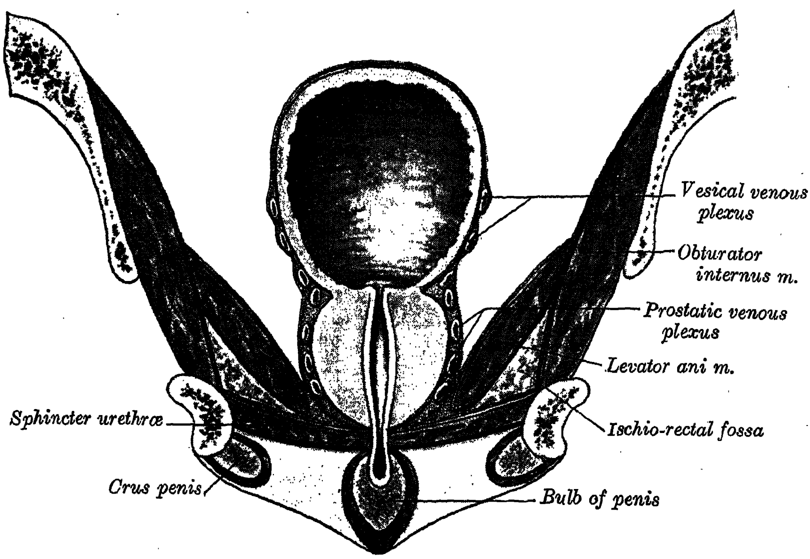
If the perineal membrane be detached the following structures will be exposed : the membranous portion of the urethra, the Transversus perinei profundus and Sphincter urethræ, the bulbo-urethral glands and their ducts, the pudendal vessels and dorsal nerves of the penis, the arteries and nerves of the bulb of the penis, and a plexus of veins.

These structures are separated from the pelvis by a second, but less definite

layer of fascia, which forms the deeper of the two laminæ of the deep fascia of the urogenital region. It is continuous with the obturator fascia and stretches across the pubic arch. If the obturator fascia be traced medially after leaving the Obturator internus muscle, it will be found attached by some of its anterior fibres to the inner margin of the pubic arch, while its posterior fibres pass over this attachment to become continuous with the fascia on the deep surface of the Sphincter urethræ and the Transversus perinei profundus. Behind, this layer of the fascia blends with the perineal membrane, the perineal body and the membranous layer of the superficial fascia; above, at the point where it is pierced by the urethra, it becomes continuous with the fascial sheath of the prostate.

The **Transversus perinei profundus** * arises from the rami of the ischium and runs to the median plane, where it interlaces in a tendinous raphe with its fellow of the opposite side. It lies in the same plane as the Sphincter urethræ; formerly the two muscles were described together as the *Constrictor* or *Compressor urethræ*.

FIG. 611.—A coronal section through the anterior part of the pelvis. Anterior aspect. Diagrammatic.



Action.—The Transversus perinei profundus is a tensor of the perineal body (central point of the perineum).

The **Sphincter urethræ** surrounds the membranous portion of the urethra, and lies between the two layers of the deep fascia of the urogenital region. Its *external* fibres arise from the junction of the rami of the pubis and ischium, to the extent of 1·25 or 2 cm., and from the neighbouring fasciæ. They arch across the front of the urethra and bulbo-urethral glands, pass round the urethra, and behind it unite with the muscle of the opposite side, by means of a tendinous raphe. Its *innermost* fibres form a continuous circular investment for the membranous urethra.

Actions.—The muscles of both sides act together as a sphincter, compressing the membranous portion of the urethra. During micturition they, like the Bulbospongiosus, are relaxed, and only come into action at the end of the process to eject the last drops of urine.

Nerve-supply.—All the muscles of the urogenital region are supplied by the perineal branch of the pudendal nerve (S. 2, 3 and 4).

* In the B.N.A. the Transversus perinei profundus and the Sphincter urethræ are included under the term 'urogenital diaphragm.'

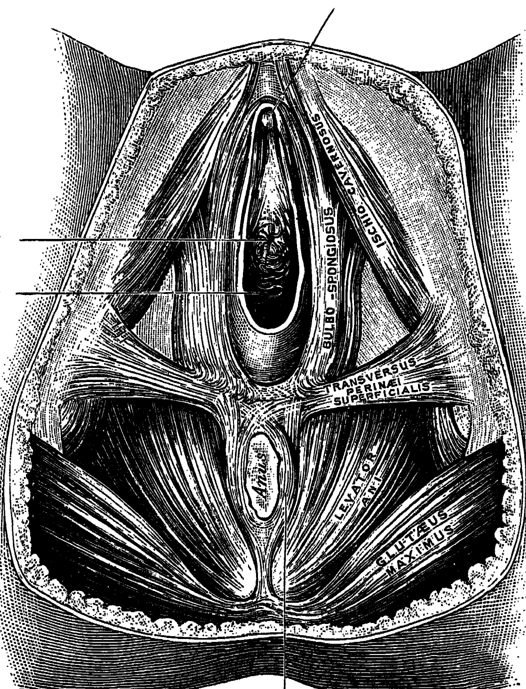
2. B. The Muscles of the Urogenital Region in the Female (fig. 612)

Transversus perinei superficialis. Ischiocavernosus.
Bulbospongiosus. Transversus perinei profundus.
Sphincter urethræ.

The **Transversus perinei superficialis** in the female is a narrow muscular slip, which differs but little from the corresponding muscle in the male (p. 578).

The **Bulbospongiosus** (Bulbocavernosus) surrounds the orifice of the vagina. It covers the lateral parts of the vestibular bulbs, and is attached posteriorly to the perineal body (central tendinous point of the perineum), where it blends with the Sphincter ani externus. Its fibres pass forwards on each side of the vagina, to be inserted into the corpora cavernosa clitoridis ; a fasciculus crosses over the body of the clitoris so as to compress the deep dorsal vein.

Fig. 612.—The muscles of the female perineum. (Modified from a drawing by Peter Thompson.)



Actions.—The Bulbospongiosus diminishes the orifice of the vagina. The anterior fibres contribute to the erection of the clitoris by the compression of its deep dorsal vein.

The **Ischiocavernosus**, smaller than the corresponding muscle in the male, covers the unattached surface of the crus clitoridis. It arises by tendinous and fleshy fibres from the inner surface of the tuberosity of the ischium, behind the crus clitoridis ; and from the adjacent portion of the ramus of the ischium. The muscular fibres end in an aponeurosis which is inserted into the sides and under surface of the crus clitoridis.

Actions.—The Ischiocavernosus compresses the crus clitoridis and retards the return of blood through the veins, and thus serves to maintain the clitoris erect.

The *perineal membrane* (inferior fascia of the urogenital diaphragm) in the female is weaker than that in the male, and is pierced by the aperture of the

vagina, with the external coat of which it blends. It covers the following structures: portions of the urethra and the vagina, the Transversus perinei profundus and Sphincter urethræ muscles, the greater vestibular glands and their ducts, the internal pudendal vessels, the dorsal nerves of the clitoris, the arteries and nerves of the vestibular bulbs, and a plexus of veins.

The **Transversus perinei profundus** arises from the ramus of the ischium and runs across behind the vagina to meet the corresponding muscle of the opposite side. The more anterior fibres become lost in the vaginal wall.

Action.—The Transversus perinei profundus helps to fix the perineal body (central tendinous point of the perineum).

The **Sphincter urethræ**, like the corresponding muscle in the male, consists of external and internal fibres. The *external* fibres arise on either side from the margin of the inferior ramus of the pubis. They are directed across the pubic arch in front of the urethra, and pass round it to blend with the muscular fibres of the opposite side, between the urethra and vagina. The *innermost* fibres encircle the lower end of the urethra.

Actions.—The muscles of the two sides act as a constrictor of the urethra.

THE FASCIÆ AND MUSCLES OF THE UPPER LIMB

The muscles of the upper limb are divisible into the following groups:

I. Muscles connecting the upper limb with the vertebral column.
II. Muscles connecting the upper limb with the anterior and lateral thoracic walls.
III. Muscles of the shoulder.
IV. Muscles of the upper arm.
V. Muscles of the forearm.
VI. Muscles of the hand.

I. The Muscles connecting the Upper Limb with the Vertebral Column

Trapezius.
Latissimus dorsi.
Rhomboideus major.
Rhomboideus minor.
Levator scapulæ.

The **superficial fascia** of the back forms a layer of considerable thickness and strength, and contains a quantity of granular fat. It is continuous with the general superficial fascia.

The **deep fascia** is a dense fibrous layer, attached above to the superior nuchal line of the occipital bone; in the median plane it is fixed to the ligamentum nuchæ and supraspinous ligament, and to the spines of all the vertebræ below the seventh cervical; laterally, in the neck it is continuous with the deep cervical fascia; over the shoulder it is attached to the spine and acromion of the scapula, and is continued downwards over the Deltoid to the arm; on the thorax it is continuous with the deep fascia of the axilla and chest, and on the abdomen with that covering the abdominal muscles; below, it is attached to the crest of the ilium.

The **Trapezius** (fig. 613) is a flat, triangular muscle, covering the back of the neck and shoulder. It arises from the medial one-third of the superior nuchal line of the occipital bone, the external occipital protuberance, the ligamentum nuchæ, the spine of the seventh cervical, and the spines of all the thoracic vertebræ, and the corresponding portion of the supraspinous ligament. The superior fibres proceed downwards and laterally, the inferior upwards and laterally, and the middle horizontally; the superior fibres are inserted into the posterior border of the lateral one-third of the clavicle; the middle fibres into the medial margin of the acromion and the superior lip of the crest of the spine of the scapula; the inferior fibres converge and end in an aponeurosis, which glides over the smooth triangular surface at the medial end of the spine of the scapula and is inserted into a tubercle at the apex of this smooth triangular surface. The upper part of the Trapezius is connected to the occipital bone by a thin fibrous lamina, firmly adherent to the skin; the middle part arises by a

broad semi-elliptical aponeurosis, which reaches from the sixth cervical to the third thoracic vertebra ; the lower part arises by short tendinous fibres. The two Trapezius muscles together resemble a trapezium, or quadrangle ; two angles corresponding to the shoulders ; a third to the occipital protuberance ; and the fourth to the spine of the twelfth thoracic vertebra.*

The clavicular insertion of this muscle varies in extent ; it sometimes reaches as far as the middle of the clavicle, and occasionally blends with the posterior edge of the Sternomastoid.

Nerve-supply.—The Trapezius is supplied by the accessory nerve and by branches from the third and fourth cervical nerves.

Actions.—When the head is fixed, the Trapezius acting with the Levator scapulæ elevates the scapula and with it the point of the shoulder ; acting with the Serratus anterior, the Trapezius rotates the scapula in a forward direction so that the arm can be raised above the head ; acting with the Rhomboids, the Trapezius retracts the scapula and so braces back the shoulder. When the shoulder is fixed, the Trapezius draws the head backwards and laterally.

The tonus of the Trapezius muscles is responsible for maintaining the level and poise of the shoulders ; when it is impaired, drooping of the shoulders is an obvious feature.

The **Latissimus dorsi** (fig. 613) is a large, triangular, flat muscle, which covers the lumbar region and the lower one-half of the thoracic region ; but its fibres converge to a narrow tendon of insertion. It arises by tendinous fibres from the spines of the lower six thoracic vertebræ under cover of the Trapezius, and from the posterior layer of the lumbar fascia (p. 546), by which it is attached to the spines of the lumbar and sacral vertebræ, to the supraspinous ligament, and to the posterior part of the crest of the ilium. In addition, it arises by muscular fibres from the posterior part of the outer lip of the crest of the ilium, lateral to the margin of the Sacrospinalis, and by fleshy slips from the three or four lower ribs ; the latter interdigitate with the lower digitations of the Obliquus abdominis externus (fig. 595). From this extensive origin the fibres pass in different directions, the upper ones horizontally, the middle obliquely upwards, and the lower almost vertically upwards, so as to converge and form a thick fasciculus, the upper part of which crosses, and usually receives a few fibres from, the inferior angle of the scapula. The muscle curves around the lower border of the Teres major, and is twisted upon itself, so that the superior fibres become at first posterior and then inferior, and the ascending fibres at first anterior and then superior. It ends in a quadrilateral tendon, about 7 cm. long, which passes in front of the tendon of the Teres major, and is inserted into the bottom of the bicipital groove (intertubercular sulcus) of the humerus, giving an expansion to the deep fascia of the upper arm ; its insertion extends higher on the humerus than that of the tendon of the Pectoralis major. The lower border of its tendon is united with that of the Teres major, the surfaces of the two tendons being separated near their insertions by a bursa ; another bursa is sometimes interposed between the muscle and the inferior angle of the scapula.

A muscular slip, named the *axillary arch*, varying from 7 to 10 cm. in length, and from 5 to 15 mm. in breadth, occasionally springs from the upper edge of the Latissimus dorsi about the middle of the posterior fold of the axilla, and crosses the axilla in front of the axillary vessels and nerves, to join the under surface of the tendon of the Pectoralis major, the Coracobrachialis, or the fascia over the Biceps. This axillary arch crosses the axillary artery, just above the spot usually selected for the application of a ligature, and may mislead the surgeon during the operation. It is present in about seven per cent. of subjects and may be recognised easily by the direction of its fibres.

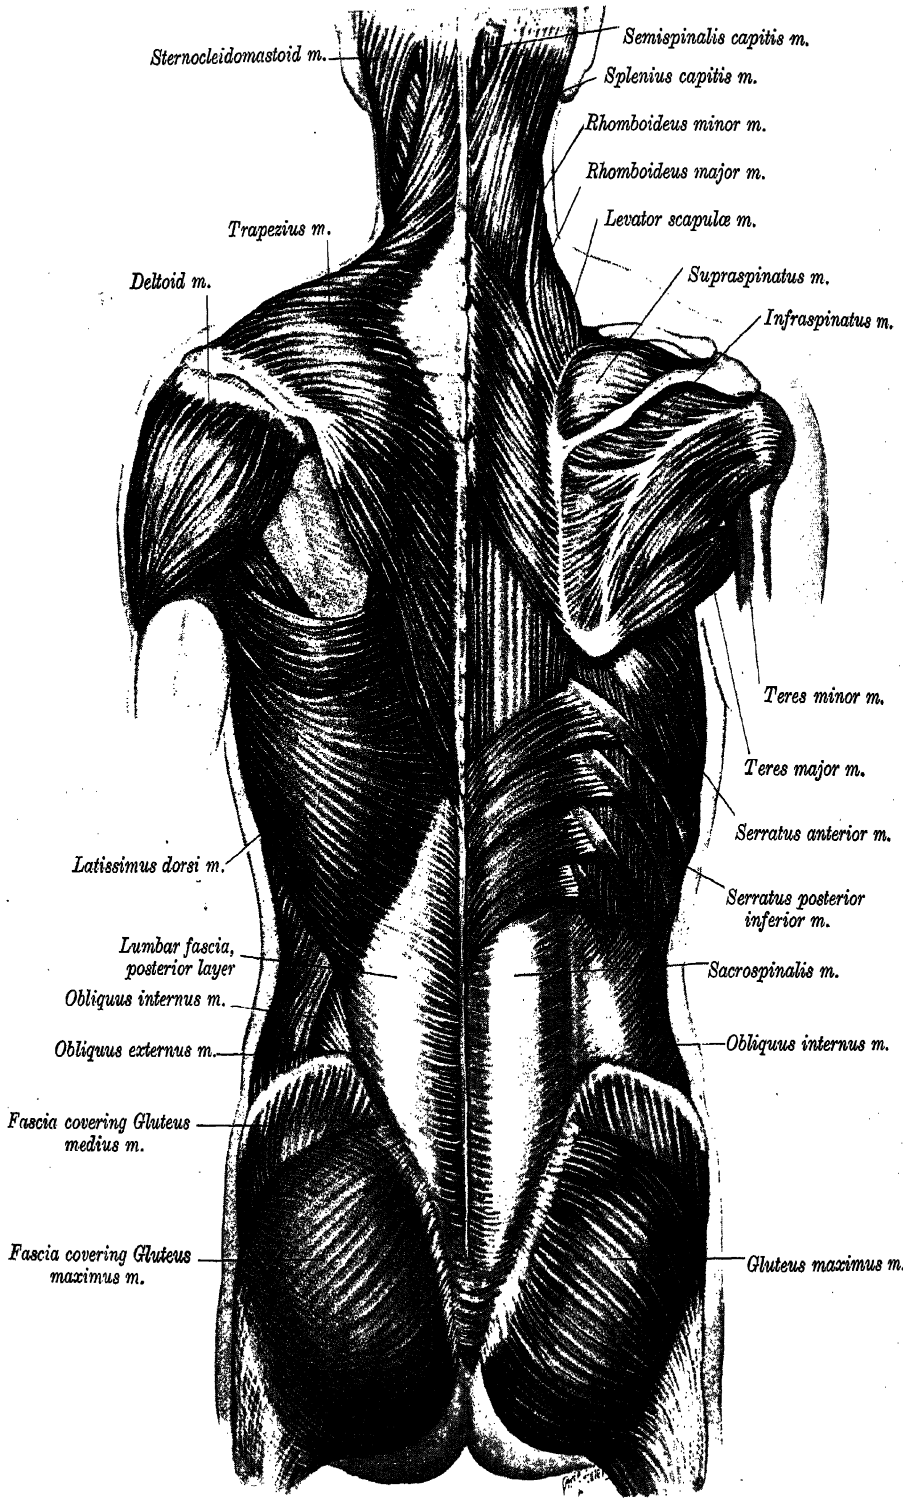
A fibrous slip usually passes from the lower border of the tendon of the Latissimus dorsi, near its insertion, to the long head of the Triceps. This is occasionally muscular, and is the representative of the *dorso-epitrochlearis brachii* of apes.

Nerve-supply.—The *nerve to Latissimus dorsi* (thoracodorsal nerve) is derived from the posterior cord of the brachial plexus (C. 6, 7 and 8).

Actions.—The Latissimus dorsi depresses and adducts the humerus, draws it backwards, and rotates it medially. When both arms are fixed it helps to

* The two muscles cover the back of the neck and shoulders like a monk's cowl, and therefore the Trapezius is sometimes termed the *Musculus cucullaris*.

FIG. 613.—The muscles connecting the upper limb with the vertebral column.



N.B.—On the right side, the Sternomastoid, Trapezius, Latissimus dorsi, Deltoid and Obliquus externus abdominis muscles have been removed.

pull the trunk upwards and forwards as in climbing. In addition, it takes part in violent expiratory efforts, such as coughing. The pressure exerted by the tonus of the muscle on the inferior angle of the scapula keeps it in contact with the chest-wall, more especially when the arm is elevated, as that movement puts the fibres of the muscle on the stretch.

The lower part of the lateral margin of the Latissimus dorsi is separated from the posterior free border of the External oblique muscle by a small triangular interval, named the *lumbar triangle*, the base of which is formed by the iliac crest, and the floor by the Internal oblique muscle (fig. 613). Another triangle, sometimes termed the *triangle of auscultation*, is situated behind the scapula. It is bounded above by the Trapezius, below by the Latissimus dorsi, and laterally by the medial border of the scapula; the floor is partly formed by the Rhomboideus major. If the scapula be drawn forwards by folding the arms across the chest, and the trunk bent forwards, parts of the sixth and seventh ribs and the interspace between them become subcutaneous and available for auscultation of the lung.

The **Rhomboideus major** (fig. 613) arises by tendinous fibres from the spines of the second, third, fourth, and fifth thoracic vertebræ and the supraspinous ligament. The fibres of the muscle are directed downwards and laterally and are inserted into the medial border (vertebral border) of the scapula between the triangular surface of the root of the spine and the inferior angle. Usually the insertion is an indirect one, the muscular fibres ending in a tendinous band which is fixed at its ends to the two points mentioned and joined to the medial border by a thin membrane; occasionally the arch is incomplete, and some of the muscular fibres are then inserted directly into the scapula.

The **Rhomboideus minor** (fig. 613) arises from the lower part of the ligamentum nuchæ and from the spines of the seventh cervical and first thoracic vertebræ; it is inserted into the base of the triangular smooth surface at the apex of the spine of the scapula. It is usually separated from the Rhomboideus major by a slight interval, but the adjacent margins of the two muscles are occasionally united.

Nerve-supply.—The *nerve to the Rhomboid muscles* arises from the anterior primary ramus of the fifth cervical nerve in the substance of the Scalenus medius muscle.

Action.—The Rhomboid muscles, acting with the Trapezius, retract the scapula and brace back the shoulder; acting with the Levator scapulæ and Pectoralis minor, they rotate the scapula so as to depress the point of the shoulder.

The **Levator scapulæ** (figs. 588, 613) is situated at the back and side of the neck. It arises by tendinous slips from the transverse processes of the atlas and axis and from the posterior tubercles of the transverse processes of the third and fourth cervical vertebræ. It is inserted into the medial border of the scapula, between the superior angle and the triangular smooth surface at the apex of the spine.

Nerve-supply.—The Levator scapulæ is supplied directly by branches from the third and fourth cervical nerves, and by a branch from the nerve to the Rhomboids (C. 5).

Actions.—If the cervical part of the vertebral column is fixed, the Levator scapulæ may act with the Trapezius to elevate the scapula, or to sustain a weight carried on the shoulder; or it may act with the Rhomboids and Pectoralis minor to rotate the scapula so as to depress the point of the shoulder. If the shoulder is fixed, the muscle inclines the neck to the same side.

II. The Muscles connecting the Upper Limb with the Anterior and Lateral Thoracic Walls

Pectoralis major.	Subclavius.
Pectoralis minor.	Serratus anterior.

The **superficial fascia** of the anterior thoracic region is continuous with that of the neck and upper limb above, and of the abdomen below. It encloses the mammary gland and gives off numerous septa which pass into it to support

its various lobes. From the fascia over the front of the gland, fibrous processes pass forwards to the integument and nipple; these were called by Sir Astley Cooper the *ligamenta suspensoria.*

The **pectoral fascia** is a thin lamina, covering the surface of the Pectoralis major and sending numerous prolongations between its fasciculi; it is attached in the median plane to the front of the sternum; above, to the clavicle; laterally and below, it is continuous with the fascia of the shoulder, axilla and thorax. It is very thin over the upper part of the Pectoralis major, but thicker in the interval between it and the Latissimus dorsi, where it forms the floor of the axillary space and is named the *axillary fascia*; this divides at the lateral margin of the Latissimus dorsi into two layers, which ensheathe this muscle and are attached behind to the spines of the thoracic vertebræ. As the fascia leaves the lower edge of the Pectoralis major to cross the floor of the axilla, it sends a layer upwards under cover of the muscle; this lamina splits to envelop the Pectoralis minor, and at the upper edge of this muscle is continuous with the clavipectoral fascia (coracoclavicular fascia) (p. 588). The hollow of the armpit, seen when the arm is abducted, is produced mainly by the traction of this fascia on the axillary floor, and hence the lamina is sometimes named the *suspensory ligament* of the axilla. At the lower part of the thoracic region the deep fascia is well developed, and is continuous with the fibrous sheath of the Rectus abdominis.

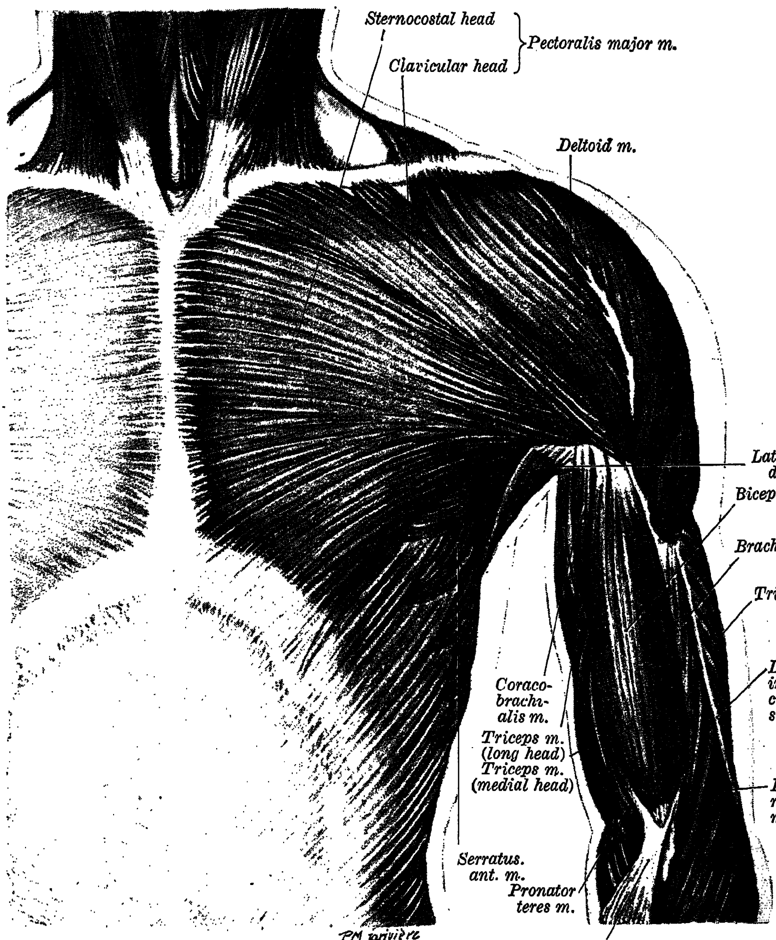
Applied Anatomy.—In cases of suppuration in the axilla, the pus is prevented from extending downwards by the axillary fascia, and therefore tends to spread upwards, behind the pectoral muscles, towards the root of the neck. Early evacuation of the pus is therefore necessary. The incision should be made midway between the anterior and posterior axillary folds, so as to avoid the lateral thoracic and subscapular vessels, and the edge of the knife should be directed away from the axillary vessels.

The **Pectoralis major** (fig. 614) is a thick, triangular muscle situated at the upper and front part of the chest. It arises from the anterior surface of the sternal half of the clavicle: from half the breadth of the anterior surface of the sternum, as low down as the attachment of the cartilage of the sixth or seventh rib: from the cartilages of all the true ribs, with the exception, frequently, of the first, or seventh, or both, and from the aponeurosis of the Obliquus externus abdominis. From this extensive origin the fibres converge towards their insertion; those arising from the clavicle pass obliquely downwards and laterally, and are usually separated from the rest by a slight interval; those from the lower part of the sternum, and the cartilages of the lower true ribs, run upwards and laterally; while the middle fibres pass horizontally. They all end in a flat tendon, about 5 cm. broad, which is inserted into the lateral lip of the bicipital groove (intertubercular sulcus) of the humerus. This tendon consists of two laminæ, placed one in front of the other, and usually blended together below. The anterior lamina, the thicker, receives the clavicular and the uppermost sternal fibres; they are inserted in the same order as that in which they arise: that is to say, the most lateral of the clavicular fibres are inserted at the upper part of the anterior lamina, and the uppermost sternal fibres to the lower part of the lamina, which extends as low as the tendon of the Deltoid muscle and joins with it. The posterior lamina of the tendon receives the attachment of the greater part of the sternal portion and the deep fibres, i.e. those from the costal cartilages. These deep fibres, and particularly those from the lower costal cartilages, turn backwards successively behind the superficial and upper ones and reach a higher level. As a result, the tendon appears to be twisted. The posterior lamina of the tendon reaches higher on the humerus than the anterior, and gives off an expansion which covers the bicipital groove and blends with the capsular ligament of the shoulder-joint. From the deepest fibres of this lamina at its insertion an expansion is given off which lines the bicipital groove, while from the lower border of the tendon a third expansion passes downwards to the fascia of the upper arm.

Relations.—*In front,* the Pectoralis major is related to the skin, superficial fascia, Platysma, medial and intermediate supraclavicular nerves, mammary gland, and deep fascia; its *posterior surface* is in contact with the sternum, ribs and costal cartilages, clavipectoral fascia, Subclavius, Pectoralis minor, Serratus anterior, and Intercostal muscles;

it forms the superficial stratum of the anterior wall of the axillary space, and so covers the axillary vessels and nerves and the upper parts of the Biceps and Coracobrachialis. Its *upper border* is separated from the Deltoid muscle by a slight interspace (*the infraclavicular fossa*), in which the cephalic vein and deltoid branch of the acromiothoracic (thoraco-acromial) artery lie. Its *lower border* forms the anterior fold of the axilla; it is separated from the Latissimus dorsi by a considerable interval at the medial wall of the axilla, but the two muscles gradually converge towards the lateral wall of the space.

FIG. 614.—The superficial muscles of the front of the chest and upper arm. Left side.



Nerve-supply.—The Pectoralis major is supplied by the lateral and medial pectoral nerves (lateral and medial anterior thoracic nerves); through these it receives filaments from all the nerves entering into the formation of the brachial plexus; the fibres for the clavicular part of the muscle are derived from C. *5* * and 6.

Actions.—The Pectoralis major adducts the arm and rotates it medially. When the arm is extended, i.e. drawn backwards and laterally, the Pectoralis major draws it forwards and medially. The two heads of the muscle work together in effecting these movements. When the arm is flexed, the sterno-

* Throughout the remainder of this section the use of italics for numerals denoting spinal nerves indicates that it is doubtful whether the nerve italicised contributes to the motor innervation of the muscle.

costal fibres take no part in the movement, which is carried out by the clavicular head (*portio attollens*) acting with the anterior fibres of the Deltoid muscle and the Coracobrachialis. When the opposite movement, usually carried out with the assistance of the force of gravitation, is resisted, the sternocostal head (*portio deprimens*) alone helps the Latissimus dorsi and Teres major to depress the arm. When the arms are fixed, the sternocostal fibres draw the trunk upwards and forwards as in climbing.

The **clavipectoral fascia** (coracoclavicular fascia) is a strong fascia situated under cover of the clavicular portion of the Pectoralis major. It occupies the interval between the Pectoralis minor and Subclavius, and protects the axillary vessels and nerves. Traced upwards, it splits to enclose the Subclavius, and is attached to the clavicle, in front of and behind the muscle: the layer behind the muscle fuses with the deep cervical fascia and with the sheath of the axillary vessels. Medially, the clavipectoral fascia blends with the fascia covering the first two intercostal spaces, and is attached also to the first rib medial to the origin of the Subclavius. Laterally, it is thick and dense, and is attached to the coracoid process, blending with the coracoclavicular ligament. The portion extending from the first rib to the coracoid process is often stronger than the rest, and is sometimes called the *costocoracoid ligament*. Below this, the fascia is thin; it splits to ensheathe the Pectoralis minor; and from the lower border of this muscle it is continued downwards to join the axillary fascia, and laterally to unite with the fascia covering the short head of the Biceps. The clavipectoral fascia is pierced by the cephalic vein, acromiothoracic artery and vein, and lateral pectoral (anterior thoracic) nerve.

The **Pectoralis minor** (fig. 615) is a thin, triangular muscle, situated at the upper part of the thorax, deep to the Pectoralis major. It arises from the upper margins and outer surfaces of the third, fourth and fifth ribs (frequently the second, third and fourth ribs) near their cartilages, and from the aponeuroses covering the External intercostal muscles; the fibres pass upwards and laterally, and converge to form a flat tendon, which is inserted into the medial border and upper surface of the coracoid process of the scapula. Sometimes a part or the whole of the tendon is continued over the coracoid process and through the coraco-acromial ligament; when this occurs the tendon blends with the coracohumeral ligament and thus gains an attachment to the humerus.

Relations.—Its *anterior surface* is in relation with the Pectoralis major, the lateral pectoral (anterior thoracic) nerve and the pectoral branches of the acromiothoracic artery; its *posterior surface*, with the ribs, External intercostal muscles, Serratus anterior, the axillary space, and the axillary vessels and brachial plexus of nerves. Its *upper border* is separated from the clavicle by a narrow triangular interval occupied by the clavipectoral fascia, behind which are the axillary vessels and nerves. Running parallel with the *lower border* of the muscle is the lateral thoracic artery; piercing and partly supplying the muscle is the medial pectoral (anterior thoracic) nerve.

Nerve-supply.—The Pectoralis minor is supplied by both the pectoral (anterior thoracic) nerves (C. 7 and 8, and T. *1*).

Actions.—The Pectoralis minor assists the Serratus anterior to draw the scapula forwards round the chest wall. Acting with the Levator scapulæ and the Rhomboids, the Pectoralis minor rotates the scapula so as to depress the point of the shoulder. When the arm is fixed, it assists in elevating the ribs in forced inspiration.

The **Subclavius** (fig. 615) is a small, triangular muscle, placed between the clavicle and first rib. It arises by a short, thick tendon from the junction of the first rib and first costal cartilage, in front of the costoclavicular ligament; the fleshy fibres proceed obliquely upwards and laterally, to be inserted into the groove on the under surface of the intermediate third of the clavicle.

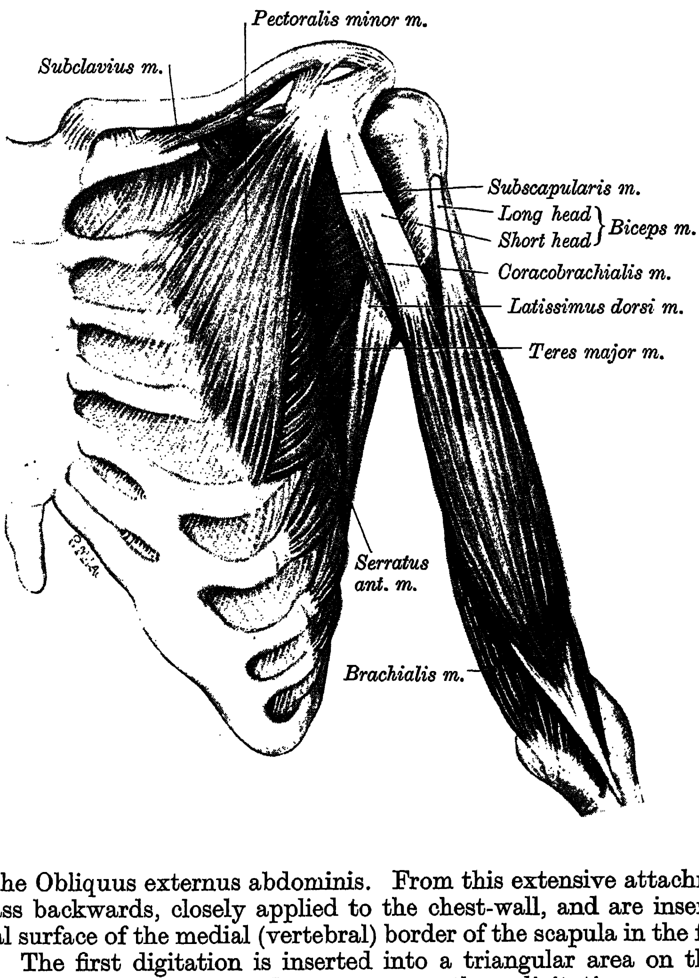
Relations.—Its *posterior surface* is separated from the first rib by the subclavian vessels and brachial plexus of nerves. Its *anterior surface* is separated from the Pectoralis major by the clavipectoral fascia, which, with the clavicle, forms an osseofibrous sheath for the muscle.

Nerve-supply.—The Subclavius is supplied by a branch which derives its fibres from C. 5 and *6*.

Action.—The Subclavius pulls the point of the shoulder downwards and forwards and steadies the clavicle, during movements of the shoulder, by bracing it against the articular disc of the sternoclavicular joint.

The **Serratus anterior** (fig. 615) is a muscular sheet, situated between the ribs and scapula at the upper and lateral parts of the chest. It arises by fleshy slips or digitations from the outer surfaces and superior borders of the upper eight or nine ribs, and from the aponeuroses covering the intervening Intercostal muscles. Each digitation arises from the corresponding rib, but the first springs in addition from the second rib, and from the fascia covering the first intercostal space. The lower four slips interdigitate with the upper five

FIG. 615.—The deep muscles of the front of the chest and arm. Left side.



slips of the Obliquus externus abdominis. From this extensive attachment the fibres pass backwards, closely applied to the chest-wall, and are inserted into the costal surface of the medial (vertebral) border of the scapula in the following manner. The first digitation is inserted into a triangular area on the costal surface of the superior angle. The next two or three digitations spread out to form a thin, triangular sheet, the base of which is directed backwards and is inserted into nearly the whole length of the costal surface of the medial border. The lower four or five digitations converge to form a fan-shaped mass, the apex of which is inserted, by muscular and tendinous fibres, into a triangular impression on the costal surface of the inferior angle.

Nerve-supply.—The nerve to Serratus anterior arises by three roots from the fifth, sixth and seventh cervical nerves (anterior primary rami) close to the intervertebral foramina and descends on the outer surface of the muscle.

Actions.—The Serratus anterior, acting with the Pectoralis minor, draws the scapula forwards, and is the chief muscle concerned in all pushing and

punching movements. Its lower and stronger fibres move the lower angle of the scapula forwards and assist the Trapezius in rotating the bone at the acromioclavicular joint, and thus aid this muscle in raising the arm above the head. It is also an assistant to the Deltoid in raising the arm, inasmuch as during the action of this latter muscle it helps the other muscles inserted into the scapula to steady the bone and so enables the Deltoid to exert its action on the humerus only. While the Deltoid is raising the arm to a right angle with the scapula, the Serratus anterior and the Trapezius are rotating the scapula, and the arm can be raised above the head as the result of this combination of movements. When the scapula is fixed, the lower part of the muscle will pull upon the ribs, and act as a muscle of inspiration.

Applied Anatomy.—When the Serratus anterior is paralysed, the medial (vertebral) border, and especially the lower angle of the scapula, leave the ribs and stand out prominently on the surface, giving a peculiar 'winged' appearance to the back. The patient is unable to raise the arm or to carry out pushing movements, and attempts to do so are followed by a further projection of the lower angle of the scapula from the back of the thorax.

III. The Muscles of the Shoulder

Deltoideus.	Infraspinatus.
Subscapularis.	Teres minor.
Supraspinatus.	Teres major.

The **deep fascia** covering the Deltoid invests the muscle, and sends numerous septa between the fasciculi. In front, it is continuous with the pectoral fascia; behind, where it is thick and strong, with the fascia infraspinata; above, it is attached to the clavicle, the acromion, and the crest of the spine of the scapula; below, it is continuous with the brachial fascia.

The **Deltoid** (fig. 614) is a thick, triangular muscle, which covers the shoulder-joint. It arises from the anterior border and upper surface of the lateral one-third of the clavicle; from the lateral margin and upper surface of the acromion, and from the lower lip of the crest of the spine of the scapula, as far back as the triangular surface at its medial end. The fibres converge towards their insertion, the middle passing vertically, the anterior inclining backwards, and the posterior forwards; they unite in a thick tendon which is inserted into the deltoid tuberosity on the lateral side of the shaft of the humerus. At its insertion the tendon gives off an expansion to the deep fascia of the upper arm. This muscle is remarkably coarse in texture, and the part arising from the acromion consists of oblique fibres; these arise in a bipennate manner from the sides of tendinous septa, generally four in number, which pass downwards from the acromion into the muscle. These oblique fibres are inserted into similar tendinous septa, generally three in number, which ascend from the tendon of insertion of the muscle and alternate with the descending septa. The portions of the muscle arising from the clavicle and spine of the scapula are not arranged in this manner, but are inserted into the margins of the inferior tendon.

Relations.—Its *superficial surface* is in relation with the skin, the superficial and deep fasciæ, Platysma, lateral supraclavicular and upper lateral brachial cutaneous nerves. Its *deep surface* covers the coracoid process, coraco-acromial ligament, subacromial bursa, Pectoralis minor, Coracobrachialis, both heads of the Biceps, the tendon of the Pectoralis major, the insertions of the Subscapularis, Supraspinatus, Infraspinatus, and Teres minor, the long and lateral heads of the Triceps, the circumflex humeral vessels, the circumflex (axillary) nerve and the surgical neck and upper part of the shaft of the humerus. Its *anterior border* is separated at its upper part from the Pectoralis major by the infraclavicular fossa, in which the cephalic vein and deltoid branch of the acromiothoracic artery lie; lower down the two muscles are in contact. Its *posterior border* rests on the Infraspinatus and Triceps. As the middle fibres pass from their origin to their insertion they curve over the bony prominence of the greater tuberosity of the humerus and this relationship determines the rounded contour of the normal shoulder.

Nerves.—The Deltoid muscle is supplied by the circumflex (axillary) nerve (C. 5 and *6*).

Actions.—The muscle is capable of acting in parts or as a whole. The anterior fibres cooperate with the Pectoralis major in drawing the arm forwards, and they can act as medial rotators of the humerus. The posterior fibres cooperate

with the Latissimus dorsi and the Teres major in drawing the arm backwards and they can act as lateral rotators of the humerus. The multipennate, acromial part is the strongest and most important part of the muscle. Aided by the Supraspinatus it raises the arm from the side so as to bring it at right angles with the trunk, *while retaining the humerus in the same plane as the body of the scapula.* This point is of importance because it is only when the humerus lies in the scapular plane that scapular rotation can have its full effect in raising the arm above the head. When the arm is actively maintained in the position of true abduction (p. 460, footnote), the acromial fibres are strongly contracted, but the clavicular and posterior fibres are put on the stretch and function as stays to steady the limb.

Applied Anatomy.—The Deltoid atrophies after injury to the circumflex nerve, and in this condition dislocation of the shoulder-joint is simulated, as there is flattening of the shoulder and apparent prominence of the acromion; the distance between the acromion and the head of the bone is increased also, and the tips of the fingers can be inserted between them.

The **subscapular fascia** is a thin membrane attached to the entire circumference of the subscapular fossa, and giving origin by its deep surface to some of the fibres of the Subscapularis.

The **Subscapularis** (fig. 615) is a large, triangular muscle, which fills the subscapular fossa and arises from its medial two-thirds, including the grooved area adjoining the lateral (axillary) border of the scapula. Some fibres arise from tendinous laminæ which intersect the muscle and are attached to ridges on the bone; others from an aponeurosis which separates the muscle from the Teres major and the long head of the Triceps. The fibres pass laterally, and, gradually converging, end in a tendon which is inserted into the lesser tuberosity of the humerus and the front of the capsular ligament of the shoulder-joint. The tendon of the muscle is separated from the neck of the scapula by a large bursa, which communicates with the cavity of the shoulder-joint through an aperture in the capsular ligament.

Relations.—The *anterior surface* of this muscle forms a considerable part of the posterior wall of the axilla. Its lower and medial two-thirds are in apposition with the Serratus anterior, and its upper and lateral portion is related to the Coracobrachialis and Biceps, the axillary vessels and brachial plexus of nerves, and the subscapular vessels and nerves. Its *posterior surface* is in relation with the scapula and the capsule of the shoulder-joint. Its *lower border* is in contact with the Teres major and Latissimus dorsi.

Nerves.—The Subscapularis is supplied by the upper and lower subscapular nerves (C. *5* and 6).

Actions.—The Subscapularis rotates the head of the humerus medially; when the arm is raised, it draws the humerus forwards and downwards. It is a powerful defence to the front of the shoulder-joint.

The **fascia supraspinata** completes the osseofibrous case in which the Supraspinatus muscle is contained, and its deep surface gives origin to some of the fibres of the muscle. It is thick medially, but thinner laterally under the coraco-acromial ligament.

The **Supraspinatus** (fig. 616) occupies the supraspinous fossa, arising from its medial two-thirds, and from the fascia supraspinata. The muscular fibres pass under the acromion, and converge to a tendon which crosses the upper part of the shoulder-joint and is inserted into the highest of the three impressions on the greater tuberosity of the humerus; the tendon is intimately adherent to the capsule of the shoulder-joint.

Nerve-supply.—The Supraspinatus is supplied by the suprascapular nerve (C. 5 and *6*).

Action.—The Supraspinatus abducts the arm.

The **fascia infraspinata** covers the Infraspinatus muscle, and is fixed to the circumference of the infraspinous fossa; its deep surface gives origin to some fibres of that muscle. It is attached to the deltoid fascia along the overlapping border of the Deltoid.

The **Infraspinatus** (fig. 616) is a thick triangular muscle, which occupies the chief part of the infraspinous fossa; it arises by fleshy fibres from the medial two-thirds of the fossa, and by tendinous fibres from the ridges on its surface: it also arises from the fascia infraspinata, which covers it and separates it from the Teres major and minor muscles. The fibres converge to a tendon, which

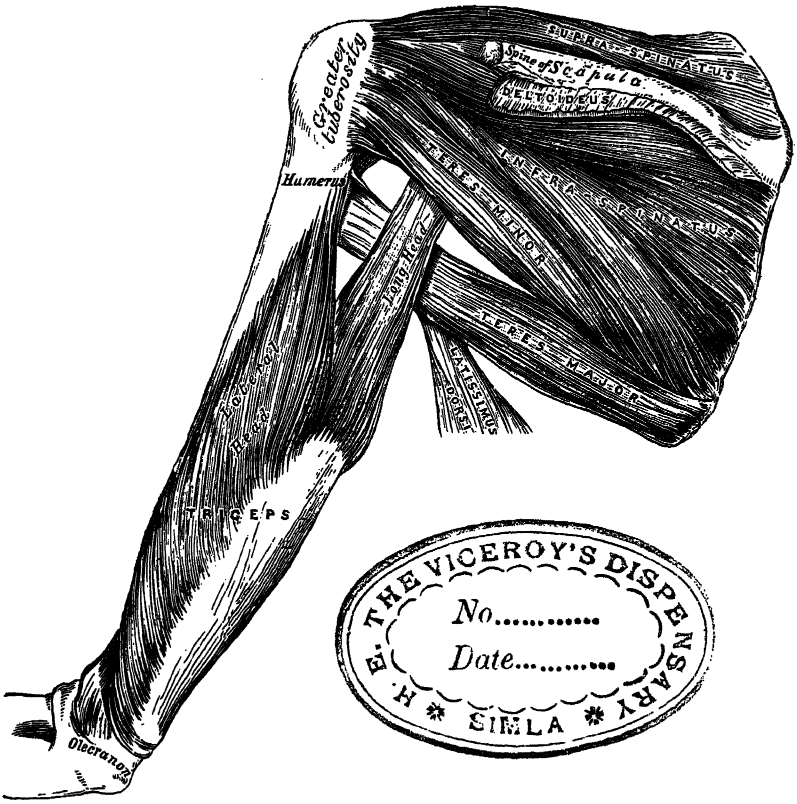
glides over the lateral border of the spine of the scapula, and, passing across the posterior part of the capsule of the shoulder-joint, is inserted into the middle impression on the greater tuberosity of the humerus. The tendon of this muscle is sometimes separated from the capsule of the shoulder-joint by a bursa which may communicate with the joint-cavity.

Nerve-supply.—The Infraspinatus is supplied by the suprascapular nerve (C. 5 and *6*).

Action.—The Infraspinatus rotates the arm laterally.

The **Teres minor** (fig. 616) is a narrow, elongated muscle, which arises from the upper two-thirds of a flattened strip on the lateral part of the dorsal surface

FIG. 616.—The muscles on the dorsum of the scapula, and the Triceps. Left side.



of the scapula, immediately adjoining the lateral (axillary) border, and from two aponeurotic laminæ, of which one separates it from the Infraspinatus, and the other from the Teres major. Its fibres run obliquely upwards and laterally; the upper ones end in a tendon which is inserted into the lowest of the three impressions on the greater tuberosity of the humerus; the lower fibres are inserted directly into the humerus immediately below this impression and just above the origin of the lateral head of the Triceps. The tendon of this muscle passes across, and is united with, the lower part of the posterior surface of the capsular ligament of the shoulder-joint.

Nerve-supply.—The Teres minor is supplied by the circumflex (axillary) nerve (C. 5).

Action.—The Teres minor rotates the arm laterally.

The **Teres major** (fig. 616) is a thick, somewhat flattened muscle, which arises from the oval area on the dorsal surface of the inferior angle of the scapula, and from the fibrous septa interposed between the muscle and the Teres minor and Infraspinatus; the fibres are directed upwards and laterally and end in a flat tendon, about 5 cm. long, which is inserted into the medial lip of the bicipital groove (intertubercular sulcus) of the humerus. At its insertion the

tendon lies behind that of the Latissimus dorsi, from which it is separated by a bursa, the two tendons being, however, united along their lower borders for a short distance.

Nerve-supply.—The Teres major is supplied by the lower subscapular nerve (C. 5 and 6).

Actions.—The Teres major draws the humerus medially and backwards, and rotates it medially.

IV. The Muscles of the Upper Arm

Coracobrachialis.	Brachialis.
Biceps (brachii).	Triceps.

The **brachial fascia** or deep fascia of the arm is continuous with that covering the Deltoid and the Pectoralis major; it forms a thin, loose sheath for the muscles of the upper arm, and sends septa between them; it is composed of fibres disposed in a circular or spiral direction, and connected together by vertical and oblique fibres. It is thin over the Biceps, but thicker where it covers the Triceps, and over the epicondyles of the humerus: it is strengthened by fibrous aponeuroses, derived from the Pectoralis major and Latissimus dorsi medially, and from the Deltoid laterally. On each side it gives off a strong intermuscular septum, which is attached to the corresponding supracondylar ridge and epicondyle of the humerus.

The *lateral intermuscular septum* extends from the lower part of the lateral lip of the bicipital groove (intertubercular sulcus), along the lateral supracondylar ridge, to the epicondyle; it is blended with the tendon of the Deltoid, gives attachment to the Triceps behind, to the Brachialis, Brachioradialis and Extensor carpi radialis longus in front, and is perforated at the junction of its upper and middle thirds by the radial nerve and the anterior descending branch of the arteria profunda brachii. The *medial intermuscular septum*, thicker than the preceding, extends from the lower part of the medial lip of the bicipital groove (intertubercular sulcus) below the Teres major, along the medial supracondylar ridge to the epicondyle; it is blended with the tendon of the Coracobrachialis, and affords attachment to the Triceps behind and the Brachialis in front. It is perforated by the ulnar nerve, the ulnar collateral artery, and the posterior branch of the supratrochlear (inferior ulnar collateral) artery.

At the elbow, the brachial fascia is attached to the epicondyles of the humerus and the olecranon of the ulna, and is continuous with the antebrachial fascia. Just below the middle of the medial side of the upper arm, an oval opening in the fascia transmits the basilic vein and some lymphatic vessels.

The **Coracobrachialis** (figs. 615, 617) is situated at the upper and medial part of the arm. It arises from the apex of the coracoid process, in common with the tendon of the short head of the Biceps, and by muscular fibres from the upper 10 cm. of this tendon; it is inserted into an impression, from 3 to 5 cm. in length, at the middle part of the medial border of the shaft of the humerus between the origins of the Triceps and Brachialis.

Relations.—*It is perforated by the musculocutaneous nerve*, and is in relation, in *front*, with the Pectoralis major above, and at its insertion with the brachial vessels and median nerve, which cross it; *behind*, with the tendons of the Subscapularis, Latissimus dorsi, and Teres major, the medial head of the Triceps, the humerus and the anterior circumflex humeral vessels; by its *medial border*, with the third part of the axillary artery, the upper part of the brachial artery, the median and musculocutaneous nerves; by its *lateral border*, with the Biceps and Brachialis.

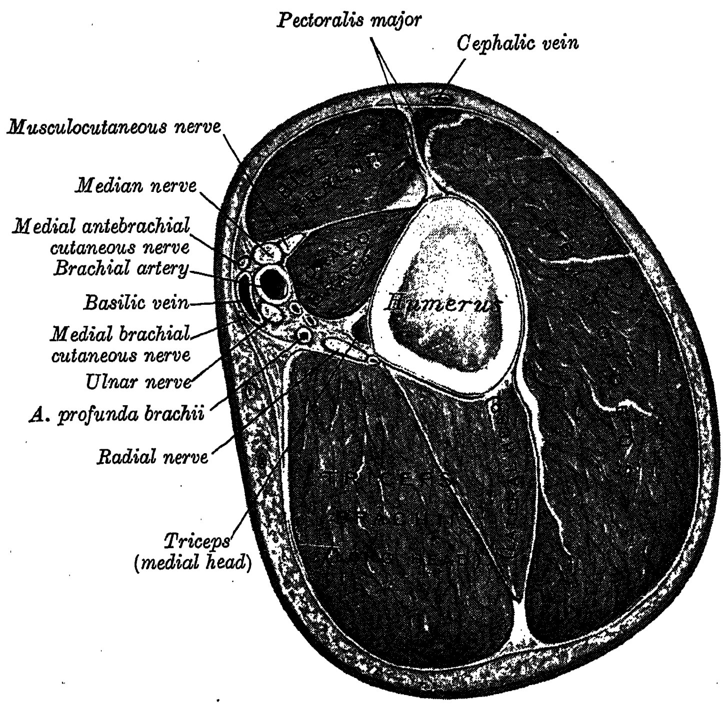
Nerve-supply.—The Coracobrachialis is supplied by the musculocutaneous nerve (C. 7).

Action.—The Coracobrachialis draws the arm forwards and medially.

The **Biceps (brachii)** (figs. 615, 617, 618), a long, fusiform muscle placed on the front of the arm, has received its name from the circumstance that it has two heads of origin. The *short head* arises by a thick flattened tendon from the apex of the coracoid process, in common with the Coracobrachialis. The *long head* takes origin within the capsule of the shoulder-joint. It arises by a long narrow tendon from the supraglenoid tubercle at the apex of the glenoid cavity, and is continuous with the glenoidal labrum (p. 458). The tendon of

the long head, enclosed in a sheath of the synovial membrane of the shoulder-joint, arches over the head of the humerus ; it emerges from the joint through an opening in the capsular ligament close to its humeral attachment and descends in the bicipital groove (intertubercular sulcus) ; it is retained in the groove by the transverse humeral ligament and by a fibrous expansion from the tendon of the Pectoralis major. Each tendon is succeeded by an elongated muscular belly, and the two bellies, although closely applied to each other, can be readily separated until within about 7·5 cm. of the elbow-joint. Here they end in a flattened tendon which is inserted into the rough posterior portion of the tuberosity of the radius, a bursa being interposed between the tendon and the front part of the tuberosity. As the tendon of the muscle approaches the radius

FIG. 617.—A transverse section through the upper arm at the junction of the proximal with the middle one-third of the humerus.



it is twisted upon itself, so that its anterior surface becomes lateral and is applied to the tuberosity of the radius at its insertion. Opposite the bend of the elbow the tendon gives off, from its medial side, a broad aponeurosis, named the *bicipital aponeurosis* (*lacertus fibrosus*), which passes obliquely downwards and medially across the brachial artery and is continuous with the deep fascia covering the origins of the flexor muscles of the forearm (fig. 614). With very little force the tendon of insertion can be split down to the radial tuberosity, when it can be seen that the anterior portion of the tendon receives the fibres of the short head, and the posterior portion those of the long head.

A third head to the Biceps is occasionally found, arising at the upper and medial part of the Brachialis, with which it is blended, and inserted into the bicipital aponeurosis and medial side of the tendon of the muscle ; in most cases this additional slip lies behind the brachial artery. In some instances the third head consists of two slips, which pass down, one in front of, the other behind the artery.

Relations.—The Biceps is overlapped above by the Pectoralis major and Deltoid ; in the rest of its extent it is covered by the fasciæ and skin. Its long head passes through the shoulder-joint, and its short head rests on the joint and on the upper part of the humerus ; below, it lies on the Brachialis, the musculocutaneous nerve, and the Supinator. Its *medial border* is in relation with the Coracobrachialis, and overlaps the brachial vessels and median nerve ; its *lateral border* is in relation with the Deltoid and Brachioradialis.

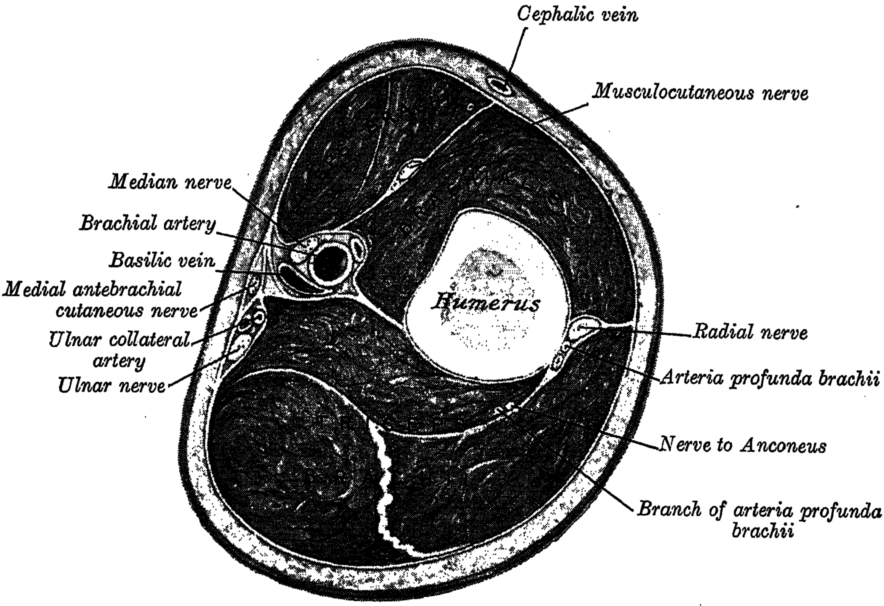
Nerve-supply.—The Biceps is supplied by the musculocutaneous nerve (C. 5 and *6*).

Actions.—The Biceps is a powerful supinator of the forearm ; it also flexes the elbow-joint, and to a slight extent the shoulder-joint. Through the bicipital aponeurosis it is a tensor of the antebrachial fascia.

Applied Anatomy.—The long tendon of the Biceps is sometimes dislocated from its groove on the humerus. When this occurs, the arm is fixed in a position of abduction, but the head of the humerus can be felt in its proper position. The tendon can generally be replaced by flexing the forearm on the arm and rotating the limb. Rupture of the long tendon of the Biceps may also take place.

The **Brachialis** (figs. 615, 618, 619) covers the front of the elbow-joint and the lower one-half of the humerus. It arises from the lower one-half of the front of the humerus, commencing above at the insertion of the Deltoid, which

Fig. 618.—A transverse section through the upper arm, a little below the middle of the shaft of the humerus.



it embraces by two pointed processes, and extending below to within 2·5 cm. of the margin of the articular surface. It also arises from the intermuscular septa, but more extensively from the medial than from the lateral ; it is separated from the lower part of the lateral intermuscular septum by the Brachioradialis and Extensor carpi radialis longus. Its fibres converge to a thick tendon which is inserted into the tuberosity of the ulna and the rough depression on the anterior surface of the coronoid process.

Relations.—It is in relation, in *front*, with the Biceps, the brachial vessels, musculocutaneous and median nerves ; *behind*, with the humerus and articular capsule of the elbow-joint ; by its *medial border*, with the Pronator teres, and with the medial intermuscular septum, which separates it from the Triceps and the ulnar nerve ; by its *lateral border*, with the radial nerve, radial recurrent and the anterior descending branch of the profunda brachii arteries, the Brachioradialis and Extensor carpi radialis longus.

Nerve-supply.—The Brachialis is chiefly supplied by the musculocutaneous nerve (C. 6 and 7), but receives an additional filament from the radial nerve (C. 7).

Action.—The Brachialis flexes the elbow-joint.

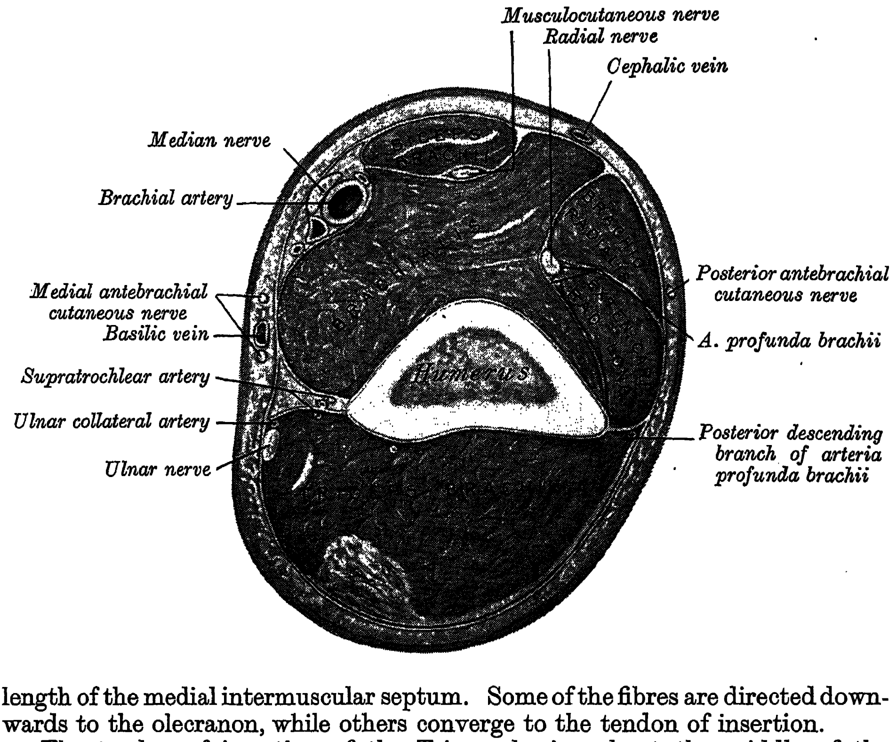
The **Triceps** (figs. 616 to 619), situated on the back of the upper arm, is of large size, and arises by three heads (long, lateral and medial), hence its name.

The *long head* arises by a flattened tendon from the infraglenoid tubercle of the scapula, being blended at its upper part with the capsular ligament of the shoulder-joint ; the muscular fibres pass downwards along the medial side of the lateral head and superficial to the medial head, and join with them in the tendon of insertion.

The *lateral head* arises from a narrow ridge on the posterior surface of the shaft of the humerus, extending from near the insertion of the Teres minor to the upper part of the spiral groove (sulcus for the radial nerve), and from the lateral border of the humerus and the lateral intermuscular septum ; the fibres from this origin converge towards the tendon of insertion.

The *medial head*, which is covered posteriorly by the lateral and the long heads, arises from the posterior surface of the shaft of the humerus, below the spiral groove ; it is narrow and pointed above, and extends from the insertion of the Teres major to within 2·5 cm. of the trochlea of the humerus ; it also arises from the medial border of the bone and from the back of the whole

Fig. 619.—A transverse section through the upper arm, 2 cm. proximal to the medial epicondyle of the humerus.



length of the medial intermuscular septum. Some of the fibres are directed downwards to the olecranon, while others converge to the tendon of insertion.

The tendon of insertion of the Triceps begins about the middle of the muscle. It consists of two aponeurotic laminæ, one of which covers the back of the lower one-half of the muscle ; the other is more deeply seated in the substance of the muscle. After receiving the attachment of the muscular fibres, the two lamellæ unite above the elbow, and are inserted, for the most part, into the posterior portion of the upper surface of the olecranon ; on the lateral side a band of fibres is continued downwards, over the Anconeus, to blend with the antebrachial fascia.

The long head of the Triceps descends between the Teres minor and Teres major, dividing the triangular space between these two muscles and the humerus into two smaller spaces, one triangular, the other quadrangular (fig. 616). The triangular space contains the circumflex scapular vessels ; it is bounded by the Teres minor above, the Teres major below, and the long head of the Triceps laterally. The quadrangular space transmits the posterior circumflex humeral vessels and the circumflex (axillary) nerve ; it is bounded by the Subscapularis, the Teres minor and the *capsular ligament of the shoulder-joint* above, the Teres major below, the long head of the Triceps medially, and the humerus laterally.

The **Subanconeus** is the name given to a few fibres which spring from the deep surface of the lower part of the Triceps, and are inserted into the posterior part of the articular capsule of the elbow-joint.

Nerves.—The Triceps is supplied by the radial nerve (C. *6*, 7, and *8*).*

Actions.—The Triceps is the great extensor muscle of the forearm. When the arm is extended, the long head of the muscle may assist in drawing the humerus backwards and in adducting it to the thorax. The long head supports the under part of the capsule of the shoulder-joint, when the arm is raised from the side. The Subanconeus draws up the posterior part of the articular capsule of the elbow-joint during extension of the forearm.

Applied Anatomy.—The insertion of the Triceps into the deep fascia of the forearm is of importance in the operation of excision of the elbow, and should always be carefully preserved. By means of it the patient is enabled to extend the forearm, a movement which would otherwise be accomplished mainly by gravity—that is to say, by allowing the forearm to drop by its own weight.

V. The Muscles of the Forearm

The **antebrachial fascia** (deep fascia of the forearm), continuous above with the brachial fascia, is a dense investment which forms a general sheath for the muscles in this region; it is attached, behind, to the olecranon and posterior border of the ulna, and sends off from its deep surface numerous intermuscular septa. It gives origin to muscular fibres, especially at the upper part of the medial and lateral sides of the forearm, and also ensheathes the different muscles; transverse septa are given off both on the anterior and posterior surfaces of the forearm, separating the deep from the superficial layer of muscles. It is much thicker on the posterior than on the anterior surface, and at the lower than at the upper part of the forearm, and is strengthened above by tendinous fibres derived from the Biceps in front, and from the Triceps behind. In the region of the carpus there are two localised thickenings in the fascia, termed the *flexor* (p. 609) and *extensor retinacula* (p. 612) (transverse and dorsal carpal ligaments). These two bands retain the digital tendons in position and so increase the efficiency of their actions on the fingers. Apertures exist in the fascia for the passage of vessels and nerves; one of these apertures, of large size and situated at the front of the elbow, transmits a communicating branch between the superficial and deep veins.

The antebrachial or forearm muscles consist of an anterior and a posterior group.

1. The Anterior Antebrachial Muscles

These muscles are divided for convenience of description into two groups, superficial and deep.

(*a*) *Superficial Group* (fig. 620)

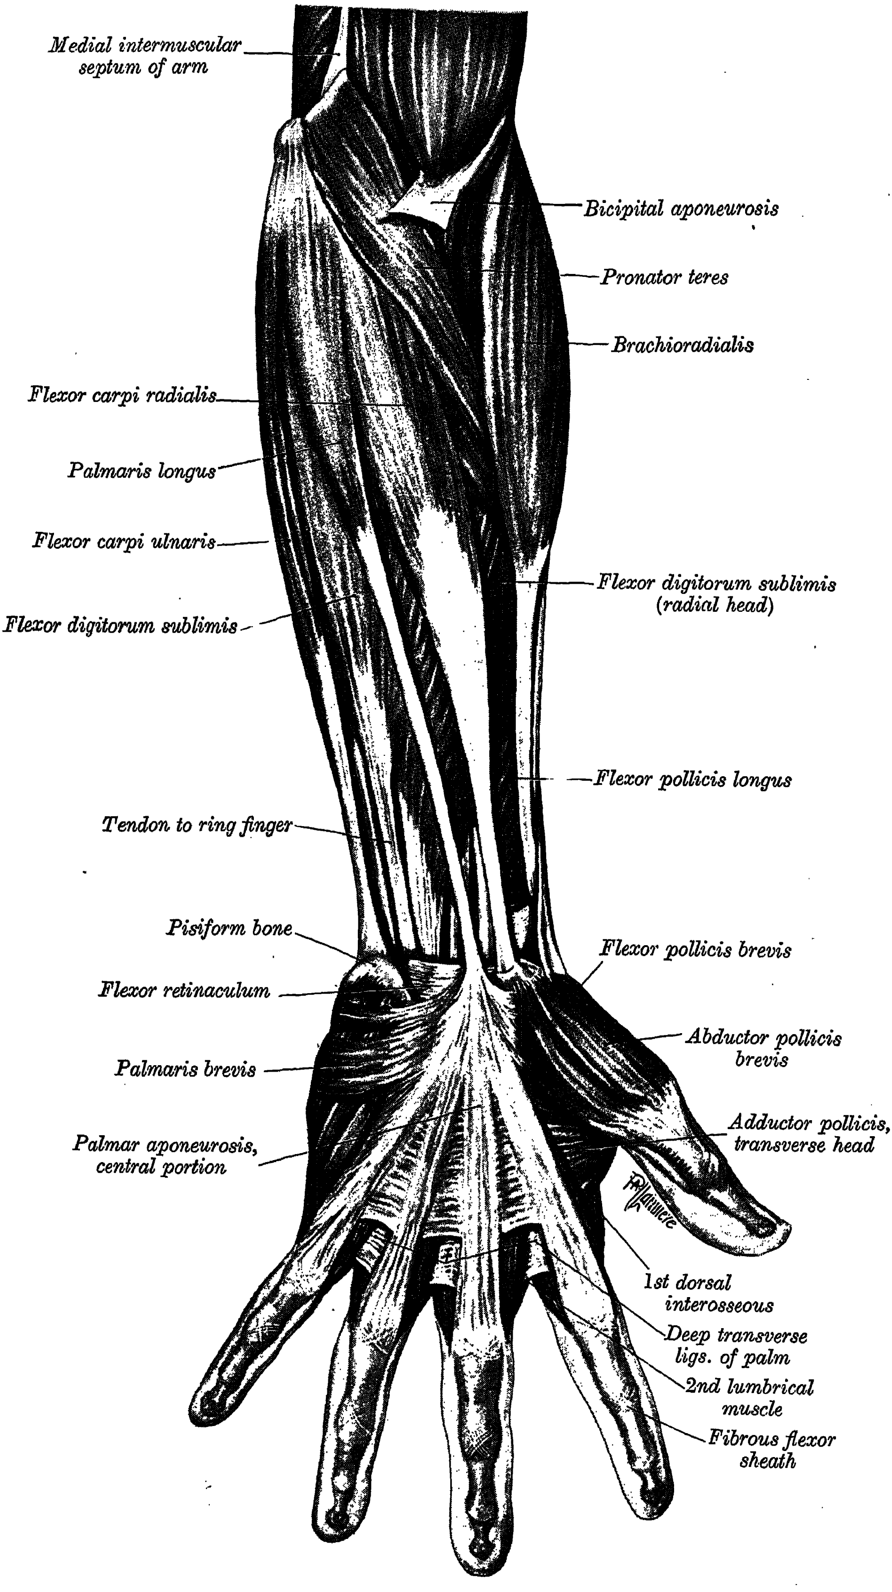
Pronator teres.	Palmaris longus.
Flexor carpi radialis.	Flexor carpi ulnaris.
Flexor digitorum sublimis.	

The muscles of this group take origin from the medial epicondyle of the humerus by a common tendon; they receive additional fibres from the antebrachial fascia near the elbow, and from the septa which pass from this fascia between the individual muscles.

The **Pronator teres** (figs. 620, 621) has a humeral and an ulnar head of origin. The *humeral head*, the larger and more superficial, arises immediately above the medial epicondyle, and from the tendon common to the origin of the other muscles; also from the intermuscular septum between it and the Flexor carpi radialis and from the antebrachial fascia. The much smaller *ulnar head* arises from the medial side of the coronoid process of the ulna below the origin of the flexor digitorum sublimis, and joins the humeral head at an acute angle. The median nerve enters the forearm between the heads of the muscle, and is separated from the ulnar artery by the ulnar head. The muscle passes obliquely across the forearm and ends in a flat tendon, which is inserted into a rough

* Wilfred Harris (*Journal of Anatomy*, vol. xxxviii.) is of opinion that the Triceps is mainly supplied by the sixth and seventh cervical nerves.

Fig. 620.—The superficial flexor muscles of the right forearm, the palmar aponeurosis and the digital fibrous flexor sheaths.



impression on the middle of the lateral surface of the shaft of the radius. The lateral border of the muscle forms the medial boundary of the triangular hollow which is situated in front of the elbow-joint, and contains the median nerve, brachial artery, and tendon of the Biceps.

Nerve-supply.—The Pronator teres is supplied by the median nerve (C. 6).

Actions.—The Pronator teres rotates the radius upon the ulna, turning the palm of the hand backwards, i.e. it pronates the forearm and hand; it also helps to flex the elbow-joint, when great force is required.

The **Flexor carpi radialis** (figs. 620, 621, 624) lies on the medial side of the Pronator teres. It arises from the medial epicondyle by the common tendon, from the antebrachial fascia, and from the intermuscular septa between it and the adjacent muscles. Its fleshy belly is fusiform in shape and, rather more than halfway down the forearm, ends in a long tendon, which passes through a canal in the lateral part of the flexor retinaculum (transverse carpal ligament) and occupies a groove on the trapezium (greater multangular bone); this groove is lined by a synovial sheath. The tendon is inserted into the palmar surface of the base of the second metacarpal bone, and sends a slip to the base of the third metacarpal bone. These bony attachments are hidden by the origin of the oblique head of the adductor pollicis (fig. 633). In the lower part of the forearm the radial artery lies between the tendon of this muscle and that of the Brachioradialis.

Nerve-supply.—The Flexor carpi radialis is supplied by the median nerve (C. 6).

Actions.—Acting with the Flexor carpi ulnaris, the Flexor carpi radialis flexes the wrist; acting with the radial extensors of the wrist, it helps to abduct the hand. It participates, as a synergic muscle, in flexion of the fingers.

The **Palmaris longus** (figs. 620, 621, 632) is a slender, fusiform muscle, lying on the medial side of the Flexor carpi radialis. It arises from the medial epicondyle of the humerus by the common tendon, from the intermuscular septa between it and the adjacent muscles, and from the antebrachial fascia. It ends in a long slender tendon, which passes in front of the flexor retinaculum (transverse carpal ligament), and is inserted into the anterior surface of the distal one-half of this structure and into the central part of the palmar aponeurosis, frequently sending a tendinous slip to the short muscles of the thumb. Just above the wrist the median nerve lies deep to the tendon, and projects a little beyond its lateral edge.

This muscle is often absent, and is subject to very considerable variations: it may be tendinous above and muscular below, or muscular in the middle with a tendon above and below; it may consist of two muscular bundles with a central tendon; or it may be represented solely by a tendinous band.

Nerve-supply.—The Palmaris longus is supplied by the median nerve (C. 8).

Actions.—The Palmaris longus tightens the palmar aponeurosis and flexes the wrist.

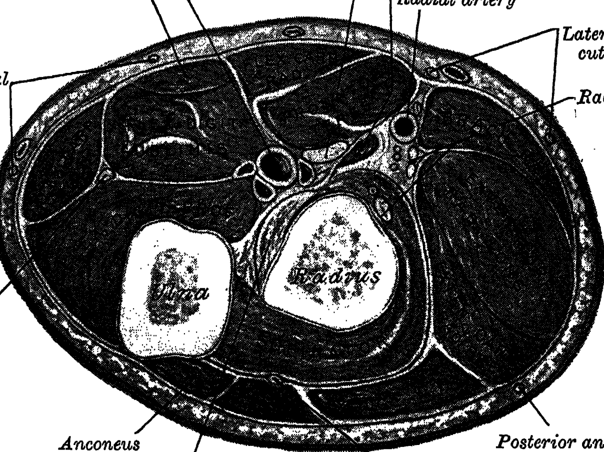
The **Flexor carpi ulnaris** (figs. 620, 621, 624) lies along the ulnar side of the forearm. It arises by two heads, humeral and ulnar, connected by a tendinous arch, beneath which the ulnar nerve passes downwards and the posterior ulnar recurrent artery upwards. The *humeral head* is very small and arises from the medial epicondyle of the humerus by the common tendon; the *ulnar head* arises from the medial margin of the olecranon, and from the upper two-thirds of the posterior border of the ulna by an aponeurosis common to it and the Extensor carpi ulnaris and Flexor digitorum profundus, and from the intermuscular septum between it and the Flexor digitorum sublimis. The fibres end in a tendon which is formed along the anterolateral border of the muscle in its distal one-half and is inserted into the pisiform bone, whence it is prolonged to the hamate and fifth metacarpal bones by the pisohamate and pisometacarpal ligaments (p. 474); it is also attached by a few fibres to the flexor retinaculum. The ulnar vessels and nerve lie on the lateral side of its tendon of insertion.

Nerve-supply.—The Flexor carpi ulnaris is supplied by the ulnar nerve (C. 8 and T. *1*).

Actions.—Acting with the Flexor carpi radialis, the Flexor carpi ulnaris flexes the wrist; acting with the Extensor carpi ulnaris, it is a powerful adductor of the hand. It participates, as a synergic muscle, in flexion of the fingers.

The **Flexor digitorum sublimis** (figs. 620, 621, 624) is deep to the preceding muscles; it is the largest of the muscles of the superficial group, and arises by two heads, humero-ulnar and radial. The *humero-ulnar head* arises from the medial epicondyle of the humerus by the common tendon, from the anterior portion of the medial (ulnar collateral) ligament of the elbow, from the intermuscular septa between it and the preceding muscles, and from the medial side of the coronoid process, above the ulnar origin of the Pronator teres. The *radial head,* which is a thin sheet of muscle, arises from the anterior border of the radius, extending from the radial tuberosity to the insertion of the Pronator teres. The median nerve and the ulnar artery pass downwards through the gap which intervenes between these two heads. The muscle speedily separates into two strata of muscular fibres, superficial and deep; the superficial stratum, which is joined on its lateral side by the radial head, divides into two parts, which end in tendons for the middle and ring fingers; the deep stratum gives

FIG. 621.—A transverse section through the forearm at the level of the radial tuberosity.



off a muscular slip to join that part of the superficial plane which is associated with the tendon of the ring finger, and then divides into two parts, which end in tendons for the index and little fingers. As the four tendons pass behind the flexor retinaculum (transverse carpal ligament), they are arranged in pairs, the superficial pair going to the middle and ring, the deep pair to the index and little fingers. The tendons diverge from one another in the palm and opposite the bases of the proximal phalanges each divides into two slips, to allow of the passage of the corresponding tendon of the Flexor digitorum profundus; the surfaces of the two slips become reversed and they then reunite, partially decussate, and so form a grooved channel for the reception of the tendon of the Flexor digitorum profundus. Finally the tendon divides and is inserted into the sides of the shaft of the middle phalanx.

Nerve-supply.—The Flexor digitorum sublimis is supplied by the median nerve (C. 7 and 8 and T. *1*).

Actions.—The Flexor digitorum sublimis flexes first the middle and then the proximal phalanges. It can also act as a flexor of the wrist.

Relations.—*In the forearm.* The Flexor digitorum sublimis is covered by the Palmaris longus, Flexor carpi radialis, Pronator teres, Brachioradialis, the radial artery and the radial nerve. It is placed in front of the Flexor digitorum profundus, the upper part of the ulnar artery, the median nerve (which is closely bound to it by fibro-areolar tissue) and the Flexor pollicis longus. *At the wrist,* the tendons of the Flexor digitorum sublimis pass

behind the flexor retinaculum, lying in front of the tendons of the Flexor digitorum profundus and sharing a common synovial sheath with them (fig. 629). The Flexor pollicis longus tendon and the median nerve lie to their lateral side. *In the hand,* the tendons lie behind the palmar aponeurosis, the superficial palmar (volar) arch and the digital branches of the median and ulnar nerves, but in front of the tendons of the Flexor digitorum profundus and the lumbrical muscles.

(*b*) *Deep Group* (fig. 622)

Flexor digitorum profundus. Flexor pollicis longus.
Pronator quadratus.

The **Flexor digitorum profundus** (figs. 621, 622, 624) is situated on the ulnar side of the forearm, deep to the superficial flexors. It arises from the upper three-fourths of the anterior and medial surfaces of the shaft of the ulna, embracing the insertion of the Brachialis above, and extending to within a short distance of the Pronator quadratus below. It also arises from a depression on the medial side of the coronoid process of the ulna, and from the upper three-fourths of the posterior border of the bone by an aponeurosis, in common with the Flexor and Extensor carpi ulnaris ; it also springs from the anterior surface of the ulnar half of the interosseous membrane. The muscle ends in four tendons, which run behind the flexor retinaculum deep to the tendons of the Flexor digitorum sublimis. The portion of the muscle for the index finger is usually distinct throughout, but the tendons for the middle, ring and little fingers are connected together by areolar tissue and tendinous slips, as far as the palm of the hand. Opposite the proximal phalanges the tendons pass through the openings in the tendons of the Flexor digitorum sublimis, and they are inserted into the palmar surfaces of the bases of the distal phalanges.

Nerve-supply.—The medial part of the Flexor digitorum profundus is supplied by the ulnar nerve and its lateral part by the anterior interosseous branch of the median nerve (C. *7* and 8 and T. *1*).

Actions.—The Flexor digitorum profundus flexes the distal phalanges, after the Flexor digitorum sublimis has bent the middle phalanges ; it can also assist in flexing the wrist.

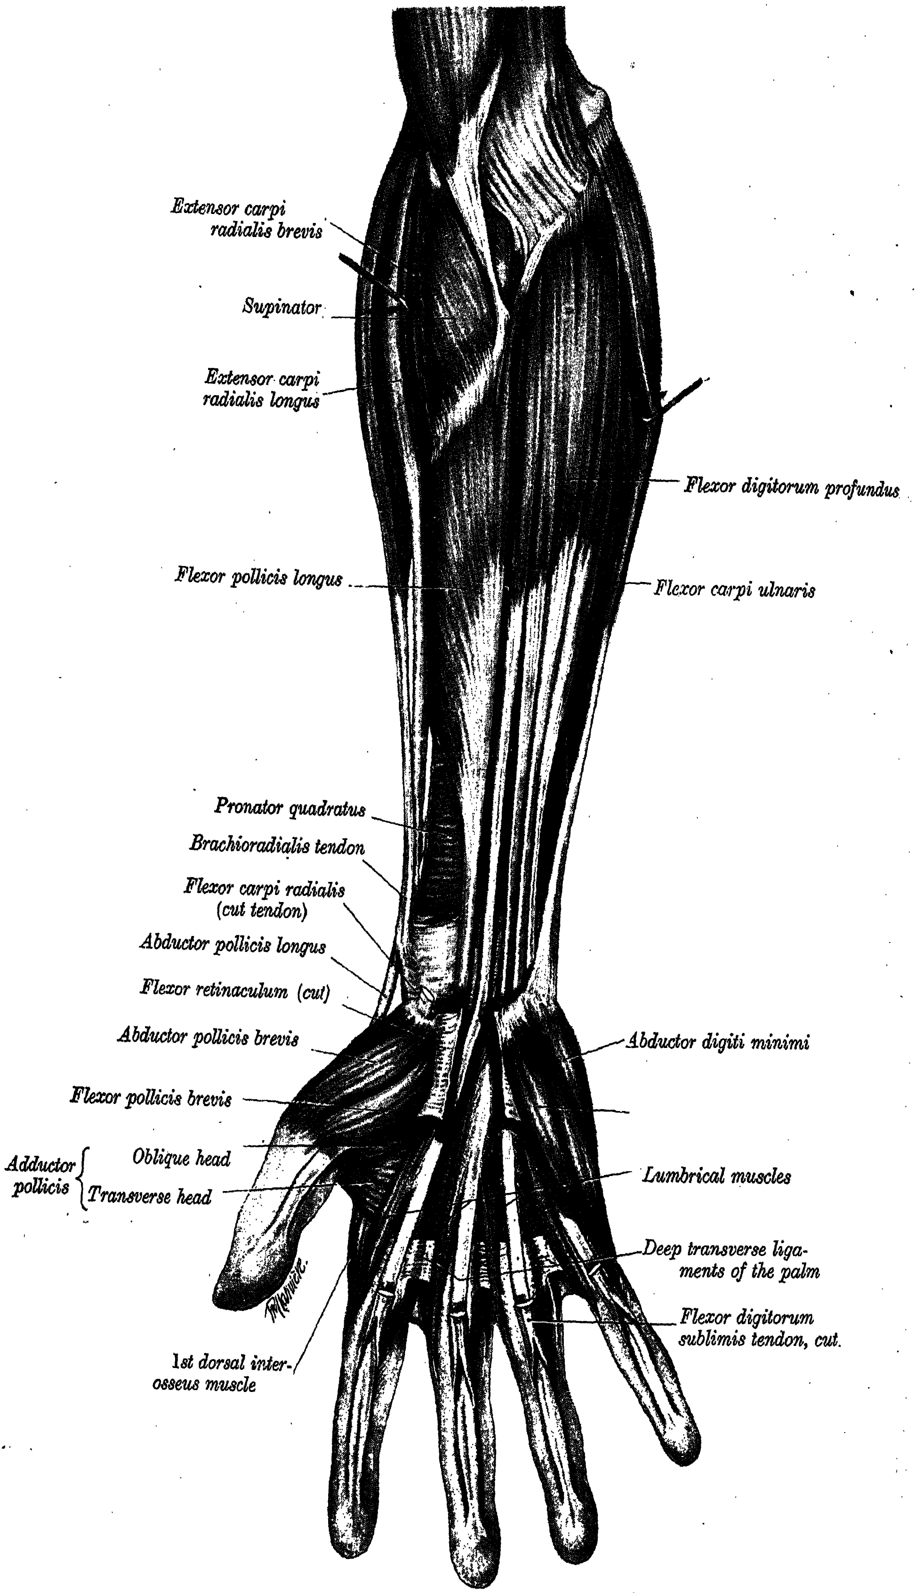
Four small muscles, named the Lumbricales, are connected with the tendons of the Flexor digitorum profundus in the palm, and are described with the muscles of the hand (p. 619).

Fibrous sheaths of the flexor tendons.—After leaving the palm, the tendons of the Flexores digitorum sublimis et profundus lie in osseo-aponeurotic canals (figs. 630, 635), formed behind by the phalanges, and in front by fibrous bands which arch across the tendons, and are attached on each side to the margins of the phalanges and to the palmar ligaments of the interphalangeal joints. Opposite the middle of the proximal and middle phalanges the bands (*digital vaginal ligaments*) are very strong, and the fibres are transverse ; but opposite the joints they are much thinner, and consist of *annular* and *cruciate* fibres. Each canal is lined by a synovial sheath, which is reflected on to the contained tendons.

As the flexor tendons approach their insertions they are connected to the dorsal parts of the enclosing synovial sheaths by triangular and thread-like bands of synovial membrane. These bands, termed *vincula tendinum* (fig. 623), convey minute vessels to the tendons, and are of two kinds, (*a*) vincula brevia and (*b*) vincula longa.

The *vincula brevia,* two in number in each finger, are triangular bands attached to the deep surfaces of the tendons close to their insertions ; one connects the tendon of the Flexor digitorum sublimis to the front of the proximal interphalangeal joint and adjacent part of the proximal phalanx, and the other the tendon of the Flexor digitorum profundus to the front of the distal interphalangeal joint and adjacent part of the middle phalanx. The *vincula longa* are thread-like slips, of which two are usually attached to each tendon of the Flexor digitorum sublimis, and one to each tendon of the Flexor digitorum profundus. Those of the Flexor digitorum sublimis are connected to the slips of that tendon where these fold over the tendon of the Flexor digitorum pro-

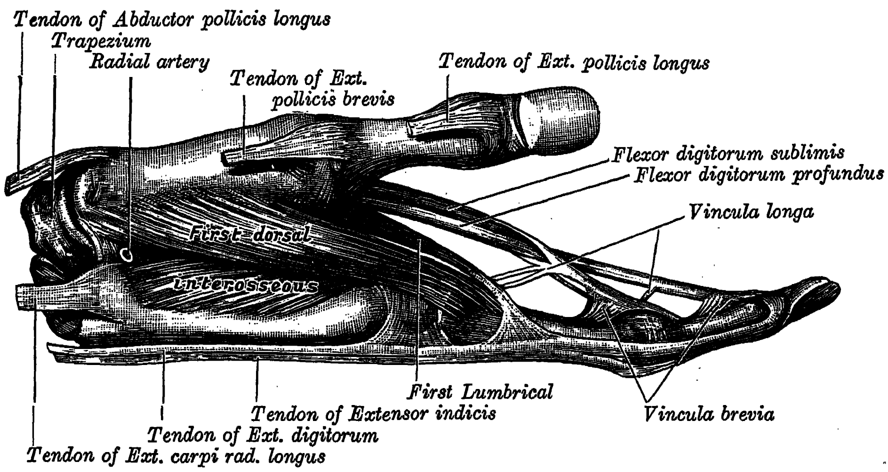
FIG. 622.—The deep muscles of the front of the right fore-arm.



fundus, and, passing one on each side of the latter tendon, are attached to the sheath at the lateral margins of the proximal end of the proximal phalanx. That of the tendon of the Flexor digitorum profundus is fixed to its tendon shortly after the latter has pierced the tendon of the Flexor digitorum sublimis. It runs upwards and backwards, perforates one of the two slips of the latter tendon, or passes between the two slips ; thereafter it blends with the vinculum breve of the Flexor digitorum sublimis, and is attached to the dorsal wall of the synovial sheath at the distal end of the proximal phalanx.

The **Flexor pollicis longus** (figs. 622, 624) is situated on the radial side of the forearm in the same plane as the Flexor digitorum profundus. It arises from the grooved, anterior surface of the shaft of the radius, extending from immediately below the tuberosity to within a short distance of the Pronator quadratus. It arises also from the adjacent part of the interosseous membrane, and generally by a fusiform, fleshy slip from the medial border of the coronoid process, distal to the Flexor digitorum sublimis and Pronator teres, or from the

FIG. 623.—The tendons and the vincula tendinum of the right index finger. Lateral aspect.



medial epicondyle of the humerus. The fibres end in a flattened tendon, which passes behind the flexor retinaculum, is then lodged between the opponens pollicis and the oblique head of the Adductor pollicis, and, entering an osseo-aponeurotic canal similar to those for the flexor tendons of the fingers, is inserted into the palmar surface of the base of the distal phalanx of the thumb. The anterior interosseous nerve and vessels descend on the front of the interosseous membrane between the Flexor pollicis longus and Flexor digitorum profundus.

Nerve-supply.—The Flexor pollicis longus is supplied by the anterior interosseous branch of the median nerve (C. 8 and T. *1*).

Actions.—The Flexor pollicis longus is a flexor of the phalanges of the thumb ; it can also act as a flexor of the wrist.

The **Pronator quadratus** (figs. 622, 628) is a flat, quadrilateral muscle, extending across the front of the lower parts of the radius and ulna. It arises from the oblique ridge on the lower part of the anterior surface of the shaft of the ulna (fig. 411) ; from the medial part of the anterior surface of the lower one-fourth of the ulna ; and from a strong aponeurosis which covers the medial one-third of the muscle. The fibres pass laterally and slightly downwards, to be inserted into the lower one-fourth of the anterior border and surface of the shaft of the radius ; the deeper fibres are inserted into the triangular area above the ulnar notch of the radius.

Nerve-supply.—The Pronator quadratus is supplied by the anterior interosseous branch of the median nerve (C. 6 and 7).

Action.—The Pronator quadratus pronates the forearm, i.e. turns it so that the palm of the hand is directed backwards.

2. The Posterior Antebrachial Muscles

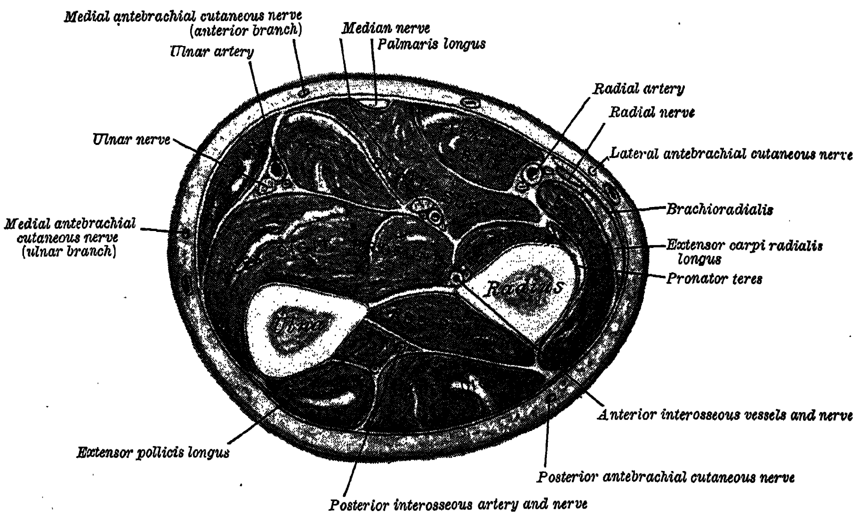
These muscles are divided for convenience of description into two groups, superficial and deep.

(a) *Superficial Group* (fig. 625)

Brachioradialis.	Extensor digitorum.
Extensor carpi radialis longus.	Extensor digiti minimi.
Extensor carpi radialis brevis.	Extensor carpi ulnaris.
Anconeus.	

The **Brachioradialis** (figs. 620, 621, 625) is the most superficial muscle on the radial side of the forearm. It arises from the upper two-thirds of the lateral

Fig. 624.—A transverse section through the middle of the forearm.



supracondylar ridge of the humerus, and from the front of the lateral intermuscular septum. The radial nerve and the anastomosis between the arteria profunda brachii and the radial recurrent artery are interposed between it and the Brachialis. The fibres end above the middle of the forearm in a flat tendon which is inserted into the lateral side of the lower end of the radius, immediately above the styloid process. The tendon is crossed at its insertion by the tendons of the Abductor pollicis longus and Extensor pollicis brevis ; the radial artery is on its ulnar side.

Nerve-supply.—The Brachioradialis is supplied by the radial nerve (C. 5 and 6).

Action.—The Brachioradialis is a flexor of the elbow-joint, but is supplied by the nerve of the extensor muscles, i.e. the radial nerve. It acts to best advantage when the forearm is in the midprone position.

The **Extensor carpi radialis longus** (figs. 621, 625) is partly covered by the Brachioradialis. It arises mainly from the lower one-third of the lateral supracondylar ridge of the humerus and from the front of the lateral intermuscular septum, but it receives a few fibres from the common tendon of origin of the extensor muscles of the forearm. The muscle ends at the junction of the upper and middle thirds of the forearm in a flat tendon, which runs along the lateral border of the radius, deep to the Abductor pollicis longus and Extensor pollicis brevis ; it then passes under cover of the extensor retinaculum (dorsal carpal ligament), where it lies on the back of the radius in a groove immediately behind the styloid process. It is inserted into the radial side of the dorsal surface of the base of the second metacarpal bone.

Nerve-supply.—The Extensor carpi radialis longus is supplied by the radial nerve (C. 6 and 7).

The **Extensor carpi radialis brevis** (figs. 621, 624, 625) is shorter than the preceding muscle and is covered by it. It arises from the lateral epicondyle of the humerus, by a tendon common to it and the next three muscles ; from the lateral ligament of the elbow-joint ; from a strong aponeurosis which covers its surface ; and from the intermuscular septa between it and the adjacent muscles. The fibres end about the middle of the forearm in a flat tendon which closely accompanies that of the preceding muscle to the wrist ; it passes deep to the Abductor pollicis longus and Extensor pollicis brevis, then under cover of the extensor retinaculum (dorsal carpal ligament), and is inserted into the dorsal surface of the base of the third metacarpal bone, on its radial side and distal to its styloid process, and into the adjoining part of the base of the second metacarpal bone. Under the extensor retinaculum the tendon lies on the back of the radius in a shallow groove, on the ulnar side of the groove which lodges the tendon of the Extensor carpi radialis longus, and separated from it by a faint ridge.

The tendons of the two preceding muscles pass through the same compartment of the extensor retinaculum in a single synovial sheath.

Nerve-supply.—The Extensor carpi radialis brevis is supplied by the posterior interosseous nerve (deep branch of the radial nerve) (C. 6 and 7).

Actions.—Both the preceding muscles, working with the Extensor carpi ulnaris, extend the wrist ; working with the Flexor carpi radialis, they abduct the hand. Both participate as synergic muscles in flexion of the fingers.

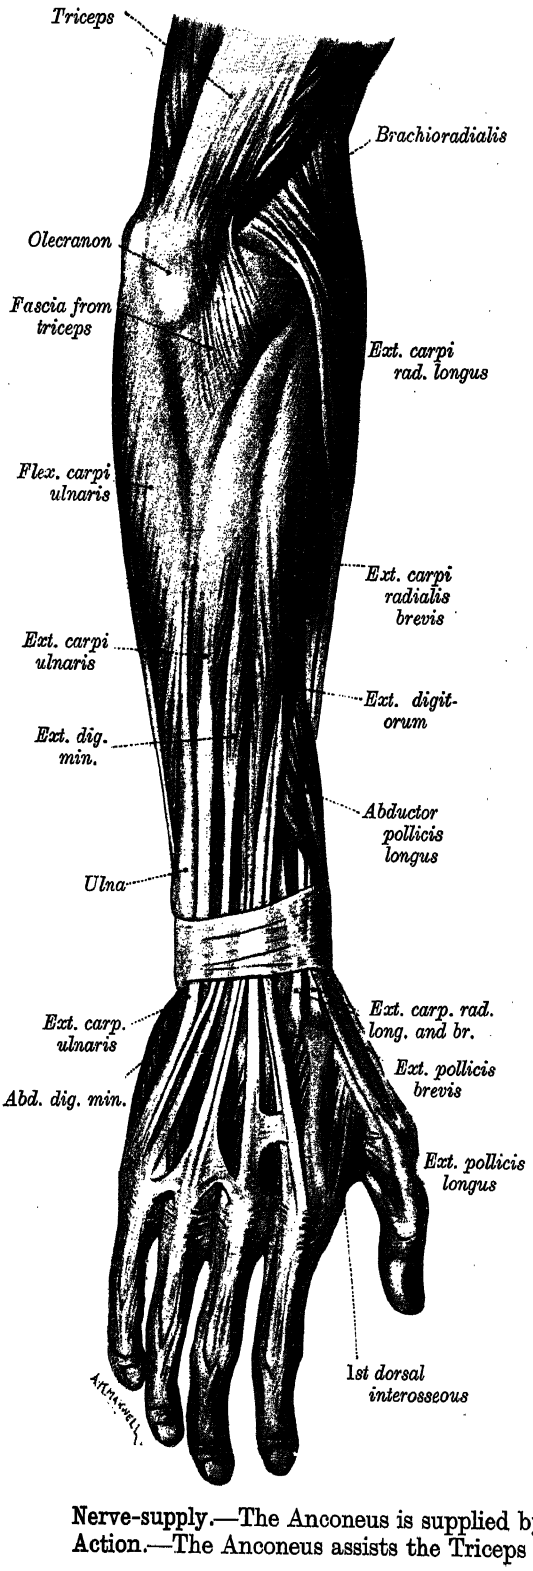
The **Extensor digitorum** (Extensor digitorum communis) (figs. 621, 624, 625) arises from the lateral epicondyle of the humerus by the common tendon ; from the intermuscular septa between it and the adjacent muscles, and from the antebrachial fascia. It divides below into four tendons, which pass, together with that of the Extensor indicis, through a compartment of the extensor retinaculum (dorsal carpal ligament), within a synovial sheath. The tendons then diverge on the back of the hand, and are inserted in the following manner. Opposite the metacarpophalangeal joint each tendon is bound by fasciculi to the collateral ligaments, and serves as the dorsal ligament of this joint ; after crossing the joint, it spreads into an aponeurosis which covers the dorsal surface of the proximal phalanx and is there reinforced by the corresponding tendons of the Interosseous and Lumbrical muscles. Opposite the proximal interphalangeal joint this aponeurosis divides into three slips, an intermediate and two collateral : the intermediate is inserted into the base of the middle phalanx ; the two collateral are continued onwards along the sides of the middle phalanx, and uniting by their contiguous margins, are inserted into the dorsal surface of the base of the distal phalanx. As the tendons cross the interphalangeal joints, they serve as their dorsal ligaments. The tendon to the index finger is accompanied by the Extensor indicis, which lies on its ulnar side. On the back of the hand, the tendons to the middle, ring and little fingers are connected by two obliquely placed bands, one from the third tendon passing downwards and laterally to the second tendon, and the other passing from the fourth to the third. Occasionally the second tendon is connected to the first by a thin, oblique band.

Nerve-supply.—The Extensor digitorum is supplied by the posterior interosseous nerve (deep branch of radial nerve) (C. 7).

Actions.—Owing to its attachments to the collateral ligaments of the metacarpophalangeal joints the Extensor digitorum acts only on the proximal phalanges, the middle and distal phalanges being extended by the Interosseous and Lumbrical muscles ; it tends to separate the fingers as it extends them. When required, it can assist in extending the wrist.

The **Extensor digiti minimi** (Extensor digiti quinti proprius) (fig. 625) is a slender muscle, medial to, and usually connected with, the Extensor digitorum. It arises from the common extensor tendon by a thin tendinous slip, and from the intermuscular septa between it and the adjacent muscles. Its tendon runs through a compartment of the extensor retinaculum behind the inferior radio-ulnar joint, then divides into two as it crosses the hand, and finally joins the expansion of the Extensor digitorum tendon on the dorsum of the proximal phalanx of the fifth digit.

FIG. 625.—Muscles of extensor aspect of forearm, superficial layer. (From Quain's *Anatomy*, XI. Edition.)



Nerve-supply.—The Extensor digiti minimi is supplied by the posterior interosseous nerve (C. 7).

Actions.—The Extensor digiti minimi extends the little finger at the metacarpophalangeal joint and can assist in extending the wrist.

The **Extensor carpi ulnaris** (figs. 624, 625) arises from the lateral epicondyle of the humerus, by the common extensor tendon; from the posterior border of the ulna by an aponeurosis in common with the Flexor carpi ulnaris and the Flexor digitorum profundus; and from the antebrachial fascia. It ends in a tendon which runs in the groove between the head and the styloid process of the ulna, passing through a separate compartment of the extensor retinaculum (dorsal carpal ligament), and is inserted into the tubercle on the ulnar side of the base of the fifth metacarpal bone.

Nerve-supply.—The Extensor carpi ulnaris is supplied by the posterior interosseous nerve (C. 7).

Actions.—The Extensor carpi ulnaris, acting with the Extensores carpi radiales, extends the wrist; acting with the Flexor carpi ulnaris it adducts the hand. In addition it functions as a synergic muscle in flexion of the fingers.

The **Anconeus** (figs. 625, 626) is a small, triangular muscle on the back of the elbow-joint, and appears to be a continuation of the Triceps. It arises by a separate tendon from the posterior surface of the lateral epicondyle of the humerus; its fibres diverge as they pass medially to reach the ulna, covering the posterior aspect of the annular ligament. They are inserted into the lateral side of the olecranon, and upper one-fourth of the posterior surface of the shaft of the ulna.

Nerve-supply.—The Anconeus is supplied by the radial nerve (C. 7 and 8).

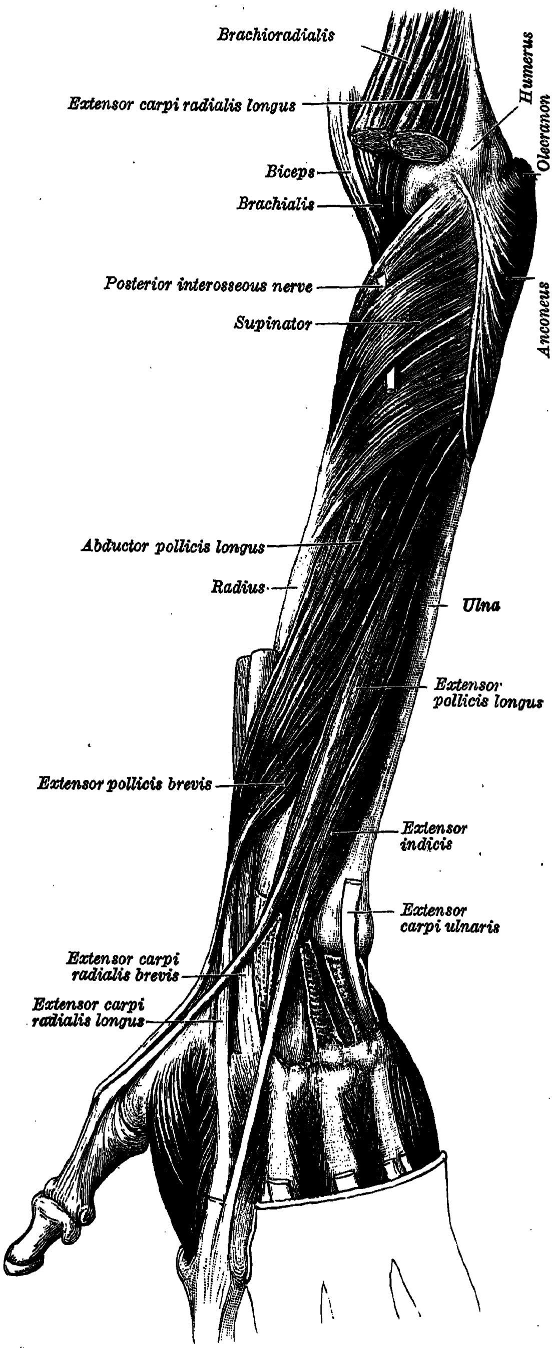
Action.—The Anconeus assists the Triceps in extending the elbow-joint.

(*b*) *Deep Group* (fig. 626)

Supinator. Extensor pollicis brevis.
Abductor pollicis longus. Extensor pollicis longus.
Extensor indicis.

The **Supinator** (figs. 621, 626, 627) surrounds the upper one-third of the radius, and consists of a superficial and a deep part, between which the posterior interosseous nerve (deep branch of the radial nerve) passes. The two parts arise in common—the superficial one by tendinous and the deeper by muscular fibres —from the lateral epicondyle of the humerus; from the lateral ligament of the elbow-joint, and the annular ligament of the superior radio-ulnar joint; from the supinator crest of the ulna and from the posterior part of the triangular depression in front of it; and from a tendinous expansion which covers the surface of the muscle. The muscle is inserted into the lateral surface of the proximal one-third of the radius, reaching as low as the insertion of the Pronator teres. The insertion extends on to the anterior and posterior aspects of the radius, for the anterior and posterior borders of the bone incline medially at their upper ends (p. 348) (fig. 412).

FIG. 626.—The left posterior antebrachial muscles. Deep group.



Nerve-supply.—The Supinator is supplied by the posterior interosseous nerve (C. 5 and 6).

Actions.—The Supinator rotates the radius so as to turn the palm of the hand forwards.

The **Abductor pollicis longus** (figs. 624, 625, 626) lies distal to the Supinator and is closely related to the Extensor pollicis brevis. It arises from the lateral part of the posterior surface of the shaft of the ulna below the insertion of the Anconeus, from the interosseous membrane, and from the middle one-third of the posterior surface of the shaft of the radius immediately adjoining the insertion of the supinator. Passing obliquely downwards and laterally, it ends in a tendon, (frequently two tendons),

which runs in a groove on the lateral side of the lower end of the radius, accompanied by the tendon of the Extensor pollicis brevis, and is inserted into the radial side of the base of the first metacarpal bone. It occasionally gives off two slips near its insertion: one to the trapezium (greater multangular bone), and the other to blend with the origin of the Abductor pollicis brevis.

Nerve-supply.—The Abductor pollicis longus is supplied by the posterior interosseous nerve (C. *6* and 7).

Actions.—The Abductor pollicis longus, acting with the Abductor pollicis brevis, abducts the thumb; acting with the Extensores pollicis, it extends the thumb at the carpometacarpal joint; acting with the Flexor carpi radialis and the corresponding extensors, it assists in abducting the hand, but it can only do so indirectly through the extended thumb.

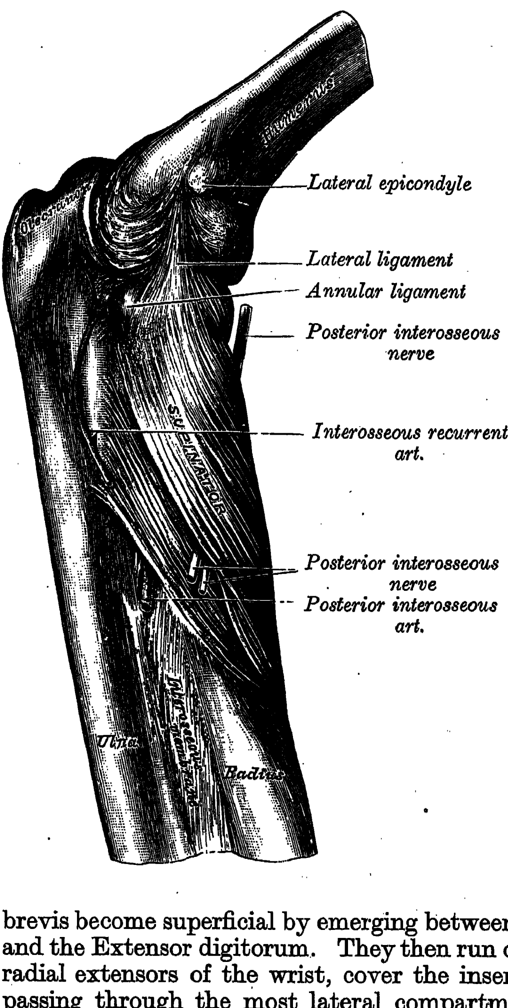


Fig. 627.—The right Supinator. Posterolateral aspect.

The **Extensor pollicis brevis** (figs. 625, 626) lies on the medial side of, and is closely connected with, the Abductor pollicis longus. It arises from the posterior surface of the shaft of the radius below that muscle, and from the interosseous membrane. Its direction is similar to that of the Abductor pollicis longus, its tendon passing through the same groove on the lateral side of the lower end of the radius, to be inserted into the dorsal surface of the base of the proximal phalanx of the thumb.

Nerve-supply.—The Extensor pollicis brevis is supplied by the posterior interosseous nerve (C. 7).

Actions.—The Extensor pollicis brevis extends the proximal phalanx of the thumb; when necessary, it can assist in extending the wrist and abducting the hand.

In the lower one-third of the forearm the Abductor pollicis longus and the Extensor pollicis brevis become superficial by emerging between the Extensor carpi radialis brevis and the Extensor digitorum. They then run obliquely across the tendons of the radial extensors of the wrist, cover the insertion of the Brachioradialis, and, passing through the most lateral compartment of the extensor retinaculum (dorsal carpal ligament), cross superficial to the styloid process of the radius and the radial artery.

The **Extensor pollicis longus** (figs. 625, 626) is larger than the Extensor pollicis brevis, the origin of which it partly covers. It arises from the lateral part of the middle one-third of the posterior surface of the shaft of the ulna below the origin of the Abductor pollicis longus, and from the interosseous membrane. It ends in a tendon, which passes through a compartment of the extensor retinaculum, lying in a narrow, oblique groove on the back of the lower end of the radius. It then crosses obliquely the tendons of the Extensores carpi radiales longus et brevis, and is separated from the Extensor pollicis brevis by a triangular interval, in which the radial artery lies; it is inserted into the base of the distal phalanx of the thumb.

Nerve-supply.—The Extensor pollicis longus is supplied by the posterior interosseous nerve (C. 7).

Actions.—The Extensor pollicis longus extends the distal phalanx of the thumb; it can assist, when required, in extending the wrist and abducting the hand.

The **Extensor indicis** (Extensor indicis proprius) (fig. 626) is a narrow, elongated muscle, medial to, and parallel with, the preceding. It arises from the posterior surface of the shaft of the ulna below the origin of the Extensor pollicis longus, and from the interosseous membrane. Its tendon passes under cover of the extensor retinaculum in the compartment which transmits the tendons of the Extensor digitorum; opposite the head of the second metacarpal bone it joins the ulnar side of the tendon of the Extensor digitorum which runs to the index finger.

Nerve-supply.—The Extensor indicis is supplied by the posterior interosseous nerve (C. 7).

Actions.—The Extensor indicis extends the index finger at the metacarpophalangeal joint, and can assist in extending the wrist.

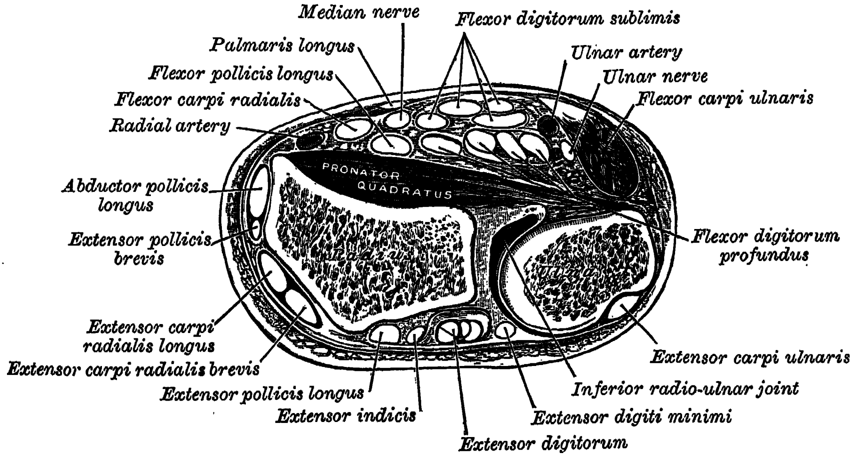
Applied Anatomy.—The tendons of the Abductor longus and extensors of the thumb are liable to become strained, and their sheaths inflamed (*tenosynovitis*) after excessive exercise, producing a sausage-shaped swelling along the course of the tendons and giving a peculiar grating sensation to the touch when the muscles are put in action.

Paralysis of the extensor muscles of the wrists and fingers resulting in 'wrist-drop' is common in lead poisoning in painters. The different extensor muscles are affected unequally as a rule. Thus the thumb, or index, or little finger may be but slightly implicated, and recover rapidly while the extensors of the other fingers or wrist remain powerless; and some of the flexor muscles of the fingers may become paretic. This apparently selective action of the lead in cases of lead poisoning depends in reality upon occupational over-use of the affected muscles or groups of muscles.

VI. The Muscles of the Hand

The muscles of the hand are subdivided into three groups: 1, those of the thumb, which occupy the lateral side and produce the *thenar* eminence; 2, those of the little finger, which occupy the medial side and give rise to the *hypothenar* eminence; 3, those in the middle of the palm and between the metacarpal bones.

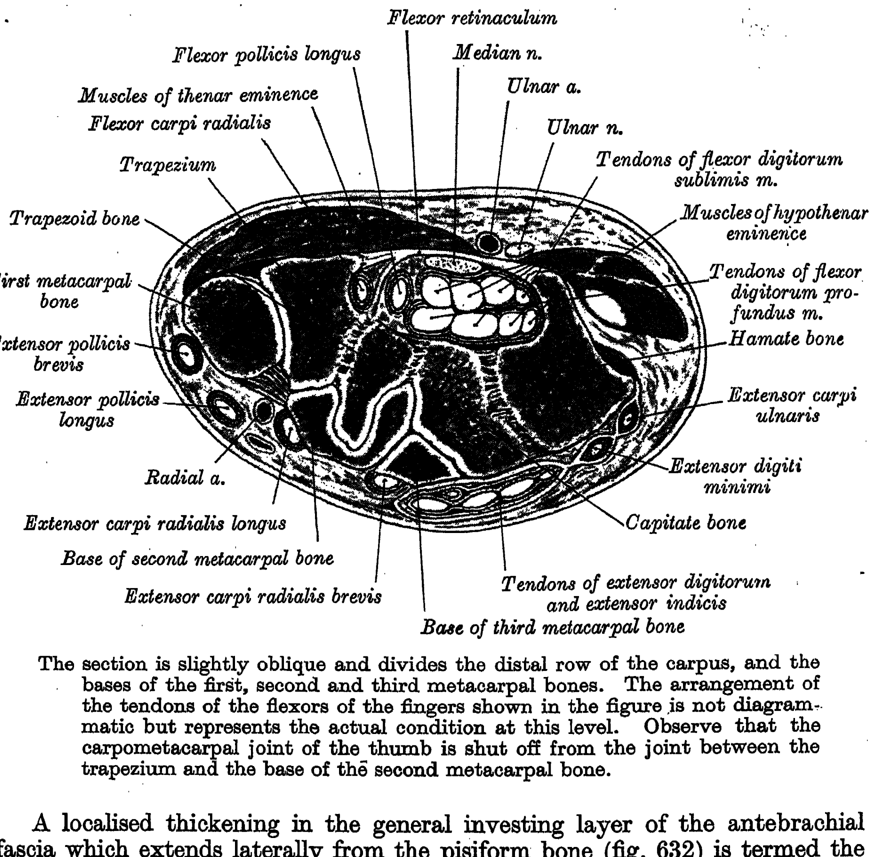
Fig. 628.—A transverse section through the distal ends of the left radius and ulna. Superior aspect.



The **flexor retinaculum** (transverse carpal ligament) (figs. 629, 630) is a strong, fibrous band which crosses the front of the carpus and converts the concavity formed by the anterior surfaces of the carpal bones into a tunnel, through which the flexor tendons of the digits and the median nerve pass. It is attached, medially, to the pisiform bone and to the hook of the hamate bone;

laterally, it splits into two laminæ, a superficial attached to the tubercle of the scaphoid (navicular) and the crest of the trapezium (greater multangular), and a deep, to the medial lip of the groove on the latter bone (fig. 629); the two laminæ form with the groove on the trapezium a tunnel, which is lined by a synovial sheath containing the tendon of the Flexor carpi radialis. The retinaculum is continuous, above, with the fascia covering the Flexor digitorum sublimis and with the general investing layer of the antebrachial fascia. It is these two layers which separate on reaching the trapezium. It is crossed superficially by the ulnar vessels and nerve, and the palmar cutaneous branches of the median and ulnar nerves. On its palmar surface the tendons of the Palmaris longus and Flexor carpi ulnaris are partly inserted; below, it gives origin to some of the short muscles of the thumb and little finger.

FIG. 629.—A transverse section through the left wrist, showing the tendons and their synovial sheaths.



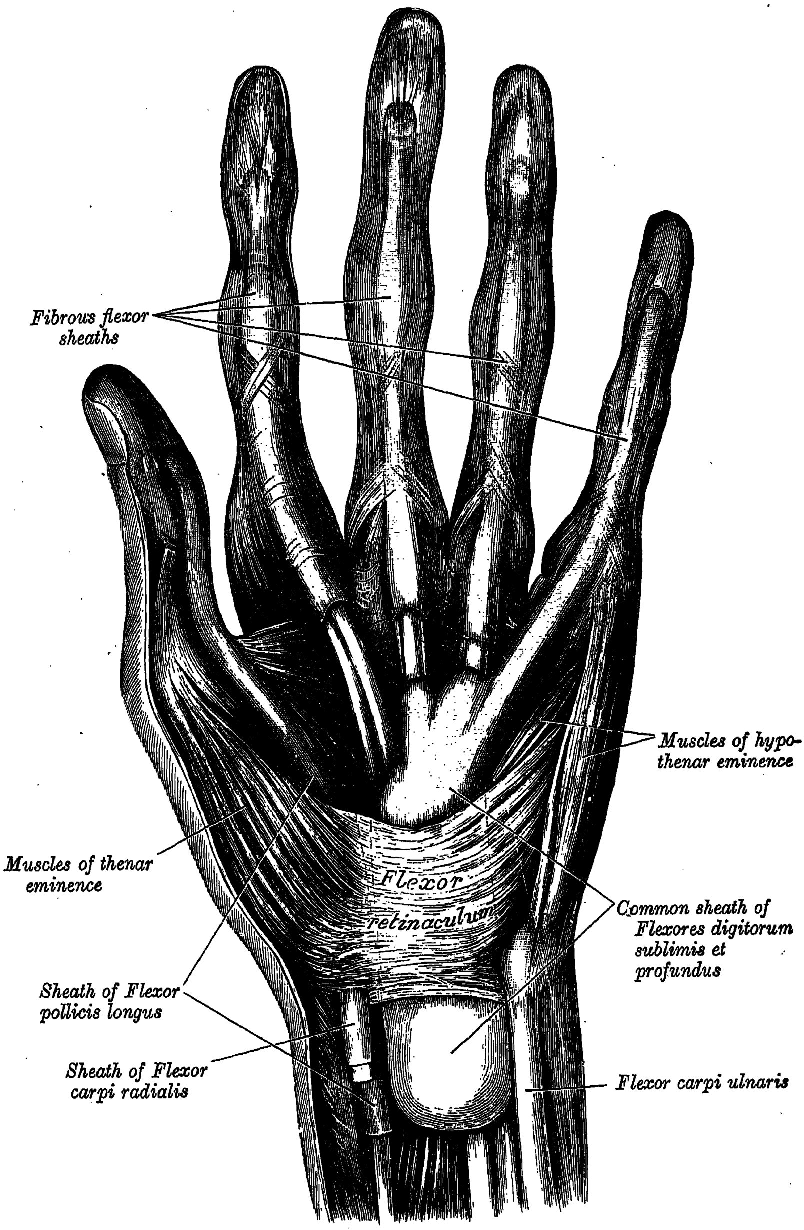
The section is slightly oblique and divides the distal row of the carpus, and the bases of the first, second and third metacarpal bones. The arrangement of the tendons of the flexors of the fingers shown in the figure is not diagrammatic but represents the actual condition at this level. Observe that the carpometacarpal joint of the thumb is shut off from the joint between the trapezium and the base of the second metacarpal bone.

A localised thickening in the general investing layer of the antebrachial fascia which extends laterally from the pisiform bone (fig. 632) is termed the *superficial part of the flexor retinaculum* (volar carpal ligament). It crosses in front of the ulnar vessels and nerves and blends with the rest of the retinaculum on their lateral side.

The synovial sheaths of the tendons on the front of the wrist.—Two synovial sheaths envelop the flexor tendons as they traverse the carpal tunnel, one for the Flexores digitorum sublimis et profundus, the other for the Flexor pollicis longus (fig. 630). These sheaths extend into the forearm for about 2·5 cm. above the flexor retinaculum, and occasionally communicate with each other behind that structure. The sheath of the Flexores digitorum tendons reaches about halfway along the metacarpal bones, where it ends in blind diverticula around the tendons to the index, middle, and ring fingers. It is prolonged on the tendons to the little finger and usually communicates with the digital synovial sheath of these tendons. A transverse section through the carpus (fig. 629) shows that the tendons have been invaginated into the sheath from

the lateral side. The parietal layer lines the flexor retinaculum and the floor of the carpal tunnel and is reflected, at the lateral side, on to the tendons of the flexor digitorum sublimis from in front, and on to those of the flexor digitorum profundus from behind. On the medial side a recess of the sheath is insinuated

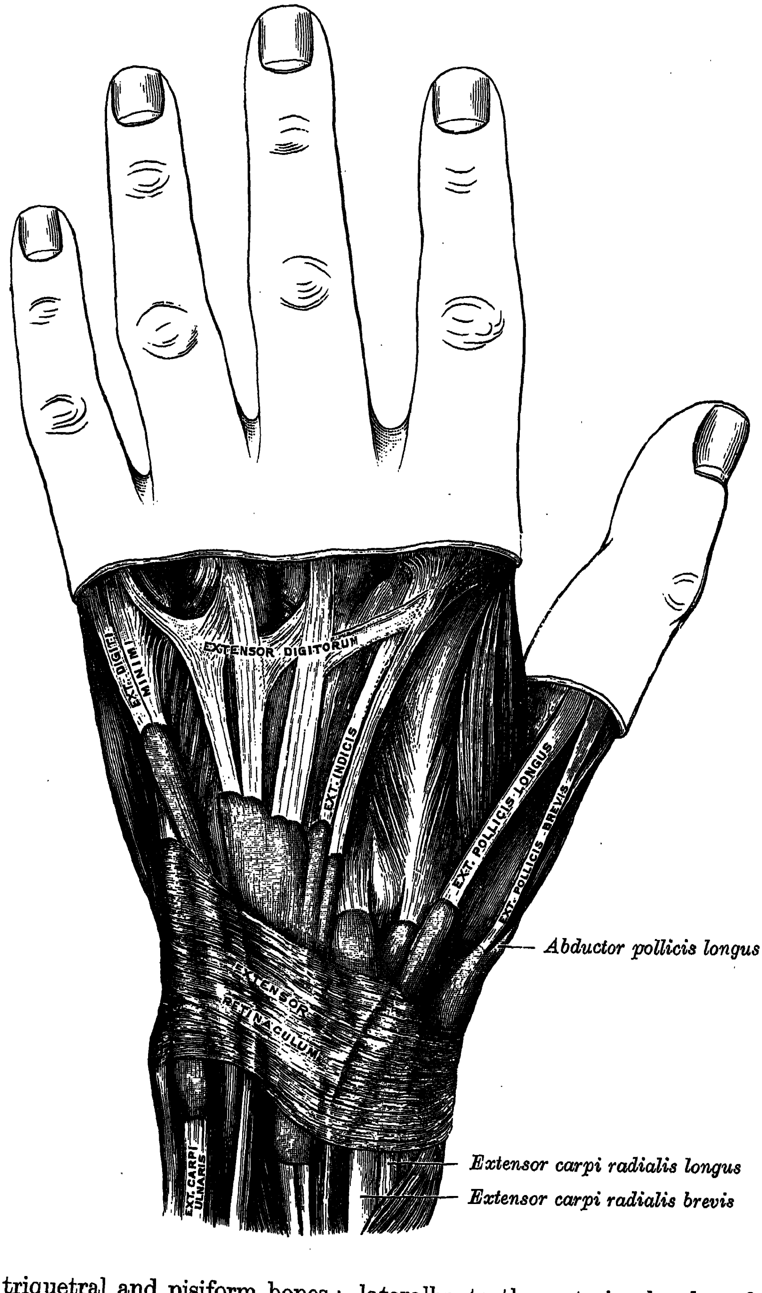
FIG. 630.—The synovial sheaths of the tendons on the front of the left wrist and hand. (From a specimen prepared by J. C. B. Grant.)



between the two groups of tendons for a variable distance. The sheath of the tendon of the Flexor pollicis longus, which may be separate or may communicate with the common flexor sheath behind the flexor retinaculum, is continued along the thumb as far as the insertion of the tendon. The fibrous sheaths enveloping the terminal parts of the tendons of the Flexores digitorum have already been described (p. 601).

The **extensor retinaculum** (dorsal carpal ligament) (fig. 631) is a strong, fibrous band, extending obliquely across the back of the wrist, and consisting of part of the antebrachial fascia, strengthened by the addition of some obliquely transverse fibres. It is attached, medially, to the styloid process of the ulna and

FIG. 631.—The synovial sheaths of the tendons on the back of the left wrist. (From a specimen prepared by J. C. B. Grant.)

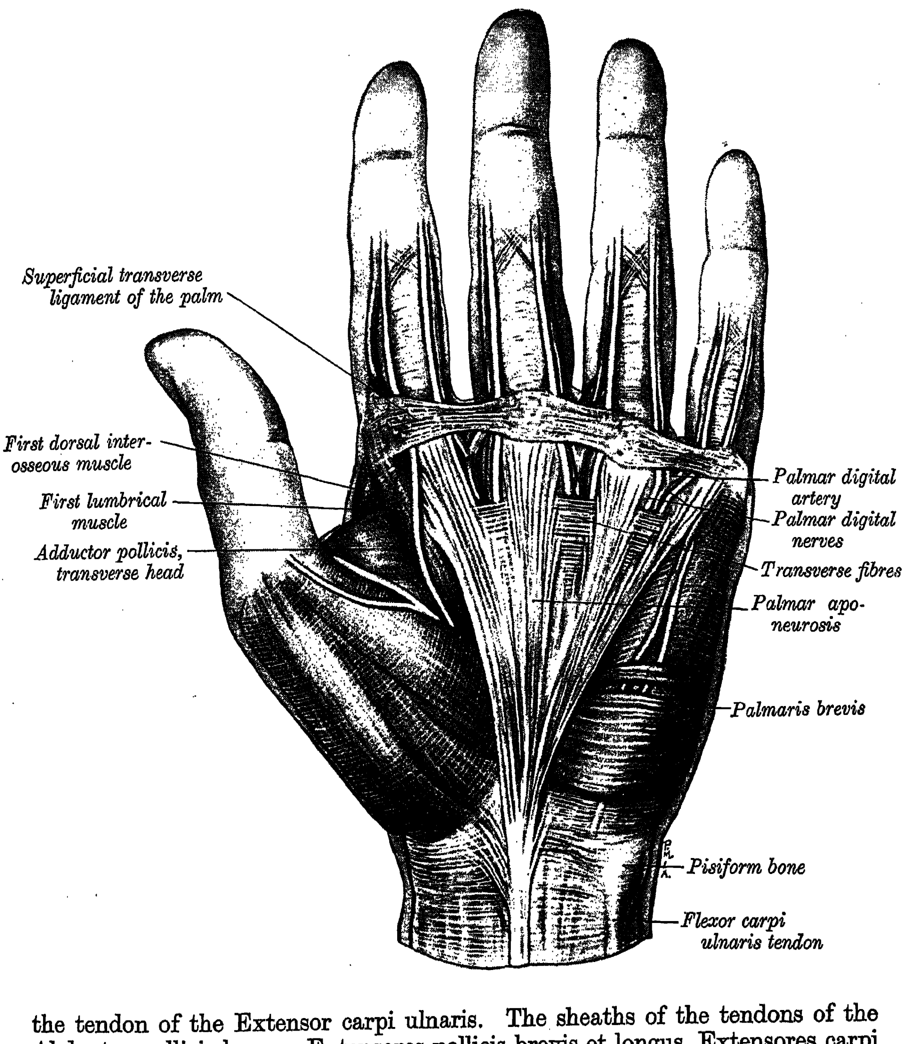


to the triquetral and pisiform bones; laterally, to the anterior border of the radius; and, in its passage across the wrist, to the ridges on the posterior surface of the radius.

The synovial sheaths of the tendons on the back of the wrist.—Deep to the extensor retinaculum there are six tunnels for the passage of the extensor tendons, each tunnel containing a synovial sheath. One is found in each

of the following positions (fig. 631): (1) on the lateral side of the styloid process of the radius, for the tendons of the Abductor pollicis longus and Extensor pollicis brevis; (2) behind the styloid process, for the tendons of the Extensores carpi radiales longus et brevis; (3) on the medial side of the dorsal tubercle of the radius, for the tendon of the Extensor pollicis longus; (4) on the medial side of the latter, for the tendons of the Extensor digitorum and Extensor indicis; (5) opposite the interval between the radius and ulna, for the Extensor digiti minimi; (6) between the head and the styloid process of the ulna, for

FIG. 632.—The left palmar aponeurosis.



the tendon of the Extensor carpi ulnaris. The sheaths of the tendons of the Abductor pollicis longus, Extensores pollicis brevis et longus, Extensores carpi radiales, and Extensor carpi ulnaris stop immediately proximal to the bases of the metacarpal bones, while those of the Extensor digitorum, Extensor indicis and Extensor digiti minimi are prolonged to the junction of the proximal with the intermediate one-third of the metacarpus.

The **palmar aponeurosis** (fig. 632) invests the muscles of the palm, and consists of central, lateral and medial portions.

The *central portion* occupies the middle of the palm, is triangular in shape, and of great strength and thickness. Its apex is continuous with the distal margin of the flexor retinaculum (transverse carpal ligament) and gives insertion to the expanded tendon of the Palmaris longus. Its base divides into four slips, one for each finger. The slips give off superficial fibres to the skin of the palm

and fingers ; those to the palm joining the skin at the furrow corresponding to the metacarpophalangeal joints, and those to the fingers passing into the skin at the transverse folds at the roots of the fingers. The deeper part of each slip subdivides into two processes which are inserted into the fibrous sheaths of the flexor tendons ; from the sides of these processes offsets are attached to the deep transverse ligaments of the palm (transverse metacarpal ligaments). By this arrangement short channels are formed on the front of the heads of the metacarpal bones ; through these the flexor tendons pass. The intervals between the four slips transmit the digital vessels and nerves, and the tendons of the Lumbrical muscles. At the points of division into the slips mentioned, numerous strong, transverse fibres bind the separate processes together. The central part of the palmar aponeurosis is intimately bound to the skin by dense fibro-areolar tissue, and the proximal part of its medial margin gives origin to the Palmaris brevis. It covers the superficial palmar arch, the tendons of the Flexores digitorum, the terminal part of the median nerve, and the superficial part of the ulnar nerve.

The *lateral* and *medial portions* of the palmar aponeurosis are thin, fibrous layers which cover the muscles of the ball of the thumb and the short muscles of the little finger respectively ; they are continuous with the central portion and with the fascia on the dorsum of the hand.

A septum passes dorsally from each border of the central portion of the palmar aponeurosis. The *medial palmar septum* lies close to the lateral side of the Opponens digiti minimi and reaches the palmar surface of the fifth metacarpal bone. At its distal end it is continuous with the slip of the palmar aponeurosis to the medial side of the fibrous sheath of the little finger ; at its proximal end it reaches the hook of the hamate bone and the pisohamate ligament and is pierced by the deep branches of the ulnar nerve and artery. The *lateral palmar septum* passes dorsally from the lateral border of the central portion of the palmar aponeurosis to reach the palmar surface of the first metacarpal bone. It lies along the medial side of the Flexor brevis and Opponens pollicis muscles ; intervening between them and the Flexor pollicis longus tendon and its synovial sheath. At its proximal end it reaches the crest of the trapezium and is pierced by the branch from the median nerve to the muscles of the thenar eminence.

The fascial spaces of the palm.—The central part of the palm, which lies behind the central portion of the palmar aponeurosis and between the lateral and medial palmar septa, is further subdivided into medial and lateral parts by an intermediate palmar septum. The medial area has been termed the *middle palmar space* (Kanavel) and the lateral area the *thenar space.*

The *intermediate palmar septum* lies between the flexor tendons of the index finger on the lateral side and the second lumbrical muscle on the medial side. At its distal end it is continuous with the slip given by the palmar aponeurosis to the medial side of the fibrous sheath of the index and the adjoining deep transverse ligament of the palm. Dorsally, it blends with the fasciæ covering the distal part of the second Palmar interosseous muscle and the transverse head of the Adductor pollicis, and it can be traced medially on the latter muscle to the third metacarpal bone. Anteriorly, it is attached to the deep surface of the palmar aponeurosis, but at its proximal end it meets the common flexor synovial sheath and blends with the connective tissue on its posterior surface.

The *middle palmar space* lies between the medial palmar septum and the intermediate septum. Its dorsal wall is formed by the third, fourth and fifth metacarpal bones, by the fascia covering the Interosseous muscles in the third and fourth spaces, and by the fascia covering the medial part of the transverse head of the Adductor pollicis. Its anterior wall is formed by the central portion of the palmar aponeurosis and, proximally, by the common flexor synovial sheath. The middle palmar space contains the flexor tendons of the fifth, fourth and third fingers, the fourth, third and second lumbrical muscles, the superficial palmar arch and the digital vessels and nerves for the fifth, fourth, third and ulnar side of the index finger. Distally, the space communicates with the subcutaneous tissues at the webs between the fingers : proximally, it may extend upwards dorsal to the common flexor synovial sheath.

The *thenar space* lies between the lateral and the intermediate palmar septum. Dorsally, it is bounded by the fasciæ covering the transverse head of the Adductor pollicis and, beyond its lower border, the first Dorsal interosseous muscle. Anteriorly, it is bounded by the palmar aponeurosis. It contains the Flexor pollicis longus tendon and its synovial sheath, the Flexor tendons of the index finger and the first Lumbrical muscle, and the

palmar digital vessels and nerves of the thumb and radial side of the index finger. Distally the space communicates with the subcutaneous tissues of the web of the thumb ; proximally it extends upwards behind the flexor retinaculum.

The **superficial transverse ligament of the palm** forms a thin band (fig. 632) which stretches across the roots of the fingers, and is attached to the skin of the clefts, and medially to the fifth metacarpal bone, forming a sort of rudimentary web. The digital vessels and nerves pass deep to these fasciculi.

Applied Anatomy.—The palmar aponeurosis is liable to undergo contraction, producing a very inconvenient deformity known as 'Dupuytren's contraction.' The ring and little fingers are most frequently implicated, but the others may also be involved. The proximal phalanx is flexed and cannot be straightened, and the middle and distal phalanges become similarly flexed as the disease advances.

Owing to their constant exposure to injury and septic influences, the fingers are very liable to become the seat of serious inflammatory mischief. In some cases, the inflammation may involve the sheath or theca of the flexor tendons, and may spread rapidly upwards along it ; but the extent will depend upon the particular digit involved. From the description of the flexor sheaths given above, it will be evident that inflammation of the synovial sheaths of the thumb and little finger may prove a far more formidable affection than that of the other three digits, because the sheaths of these two digits communicate with the large synovial sheath which surrounds the flexor tendons (p. 610), and the inflammation may extend into the palm of the hand and behind the flexor retinaculum into the forearm.

Chronic inflammation of the common flexor sheath is occasionally met with, constituting a disease known as *compound palmar ganglion* ; it presents an hour-glass outline, with a swelling in front of the wrist and another in the palm of the hand, and a constriction, corresponding to the flexor retinaculum, between the two. The fluid can be forced from the one swelling to the other under the retinaculum, and when this is done a creaking sensation is sometimes perceived, from the presence of 'melon-seed' bodies in the interior of the ganglion.

1. The Lateral Muscles of the Palm (figs. 633, 634, 635)

Abductor pollicis brevis.	Flexor pollicis brevis.
Opponens pollicis.	Adductor pollicis.

The **Abductor pollicis brevis** (fig. 635) is a thin, subcutaneous muscle which occupies the radial part of the thenar eminence ; its chief origin is from the flexor retinaculum (transverse carpal ligament), but a few fibres spring from the tubercle of the scaphoid bone and the crest of the trapezium and frequently some arise from the tendon of the Abductor pollicis longus (p. 607). It is inserted by a thin, flat tendon into the radial side of the base of the proximal phalanx of the thumb ; it also sends a slip to the tendon of the Extensor pollicis longus.

Nerve-supply.—The Abductor pollicis brevis is supplied by the lateral terminal branch of the median nerve.

Actions.—The Abductor pollicis brevis draws the thumb forwards in a plane at right angles to the palm of the hand. The movement occurs almost entirely at the carpometacarpal joint, but a minor degree of movement may occur at the metacarpophalangeal joint also.

The **Opponens pollicis** (figs. 633, 634) is placed under cover of the Abductor pollicis brevis. It arises from the crest on the trapezium and from the flexor retinaculum, and is inserted into the whole length of the lateral border, and the lateral one-half of the palmar surface, of the metacarpal bone of the thumb.

Nerve-supply.—The Opponens pollicis is supplied by the lateral terminal branch of the median nerve.

Actions.—The Opponens pollicis flexes the metacarpal bone of the thumb, i.e. bends it medially across the palm of the hand, and rotates it medially. By this combination, which is termed opposition, the palmar surface of the tip of the thumb can be brought into contact with the palmar surface of the tip of any of the fingers.

The **Flexor pollicis brevis** * (fig. 635) lies on the ulnar side of the Abductor pollicis brevis. It arises from the lower border of the flexor retinaculum and

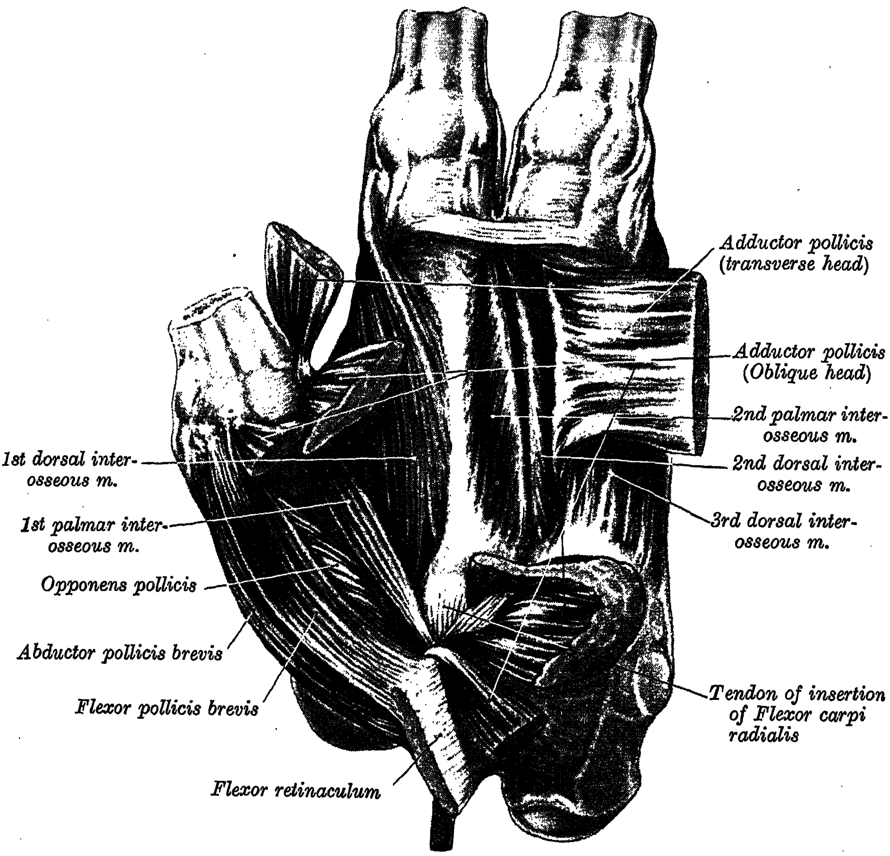
* In the B.N.A. the Flexor pollicis brevis has a deep head, which is now described as the first palmar interosseous muscle (p. 620).

the lower part of the crest on the trapezium ; it passes along the radial side of the tendon of the Flexor pollicis longus, and is inserted into the radial side of the base of the proximal phalanx of the thumb ; in its tendon of insertion there is a sesamoid bone. It is frequently more or less blended with the medial border of the opponens pollicis.

Nerve-supply.—The Flexor pollicis brevis is supplied by the lateral terminal branch of the median nerve.

Actions.—The Flexor pollicis brevis flexes the proximal phalanx of the thumb.

Fig. 633.—A dissection of the left hand to show the first palmar interosseous muscle (deep head of the Flexor pollicis brevis).



N.B.—The abductor and the flexor pollicis brevis have been displaced to the lateral side.

The **Adductor pollicis** (fig. 634) arises by two heads, an oblique and a transverse. The *oblique head* arises from the capitate and trapezoid (lesser multangular) bones, the bases of the second and third metacarpal bones, the palmar ligaments of the carpus and the sheath of the tendon of the Flexor carpi radialis. Most of its fibres converge to a tendon, which, uniting with the tendons of the first palmar interosseous muscle (deep portion of the Flexor pollicis brevis) and the transverse head of the Adductor, is inserted into the ulnar side of the base of the proximal phalanx of the thumb, a sesamoid bone being present in the tendon. A considerable fasciculus, however, passes deep to the tendon of the Flexor pollicis longus and joins the Flexor pollicis brevis and the Abductor pollicis brevis. The *transverse head* (fig. 634) is the most deeply seated of this group of muscles. It is of a triangular form, and arises from the distal two-thirds of the palmar surface of the third metacarpal bone ; the fibres converge

to be inserted, with the oblique head of the muscle and with the first palmar interosseous muscle, into the ulnar side of the base of the proximal phalanx of the thumb.

Nerve-supply.—The Adductor pollicis is supplied by the deep branch of the ulnar nerve.

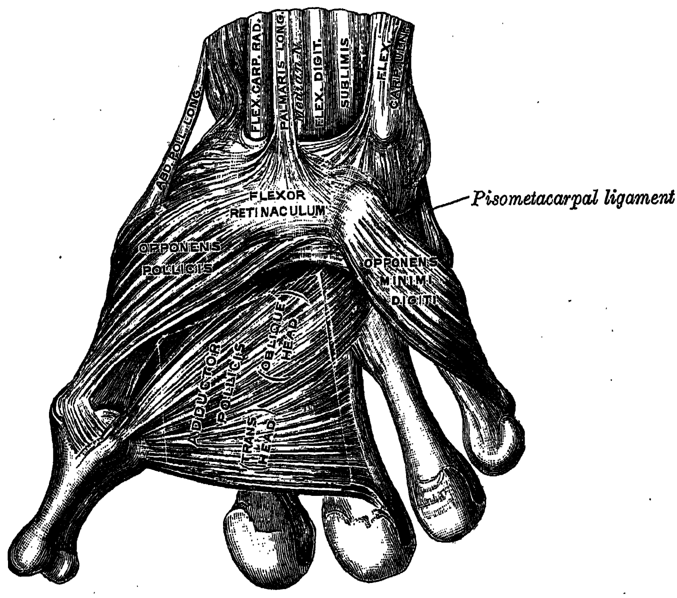
Action.—The Adductor pollicis approximates the thumb to the palm of the hand.

2. The Medial Muscles of the Palm (figs. 634, 635)

Palmaris brevis.	Flexor digiti minimi.
Abductor digiti minimi.	Opponens digiti minimi.

The **Palmaris brevis** (fig. 632) is a thin, quadrilateral muscle, placed beneath the skin of the ulnar side of the hand. It arises from the flexor retinaculum and from the medial border of the central part of the palmar aponeurosis; it is inserted into the skin on the ulnar border of the hand. It covers the ulnar artery and the superficial terminal branch of the ulnar nerve.

Fig. 634.—The right Opponens pollicis, Adductor pollicis and Opponens digiti minimi.



Nerve-supply.—The Palmaris brevis is supplied by the superficial branch of the ulnar nerve.

Action.—The Palmaris brevis wrinkles the skin on the ulnar side of the palm of the hand and deepens the hollow of the palm by accentuating the prominence of the hypothenar eminence. In this way it contributes to the security of the palmar grip.*

The **Abductor digiti minimi** (fig. 635) is situated on the ulnar border of the palm of the hand. It arises from the pisiform bone, from the tendon of the Flexor carpi ulnaris and from the pisohamate ligament. It ends in a flat tendon which divides into two slips; one is inserted into the ulnar side of the base of the proximal phalanx of the little finger, the other into the ulnar border of the aponeurosis of the Extensor digiti minimi.

Action.—The Abductor digiti minimi abducts the proximal phalanx of the little finger.

The **Flexor digiti minimi** (Flexor digiti quinti brevis) (fig. 635) lies on the radial side of the preceding muscle. It arises from the convex surface of the hook of the hamate bone and the palmar surface of the flexor retinaculum, and is inserted into the ulnar side of the base of the proximal phalanx of the little

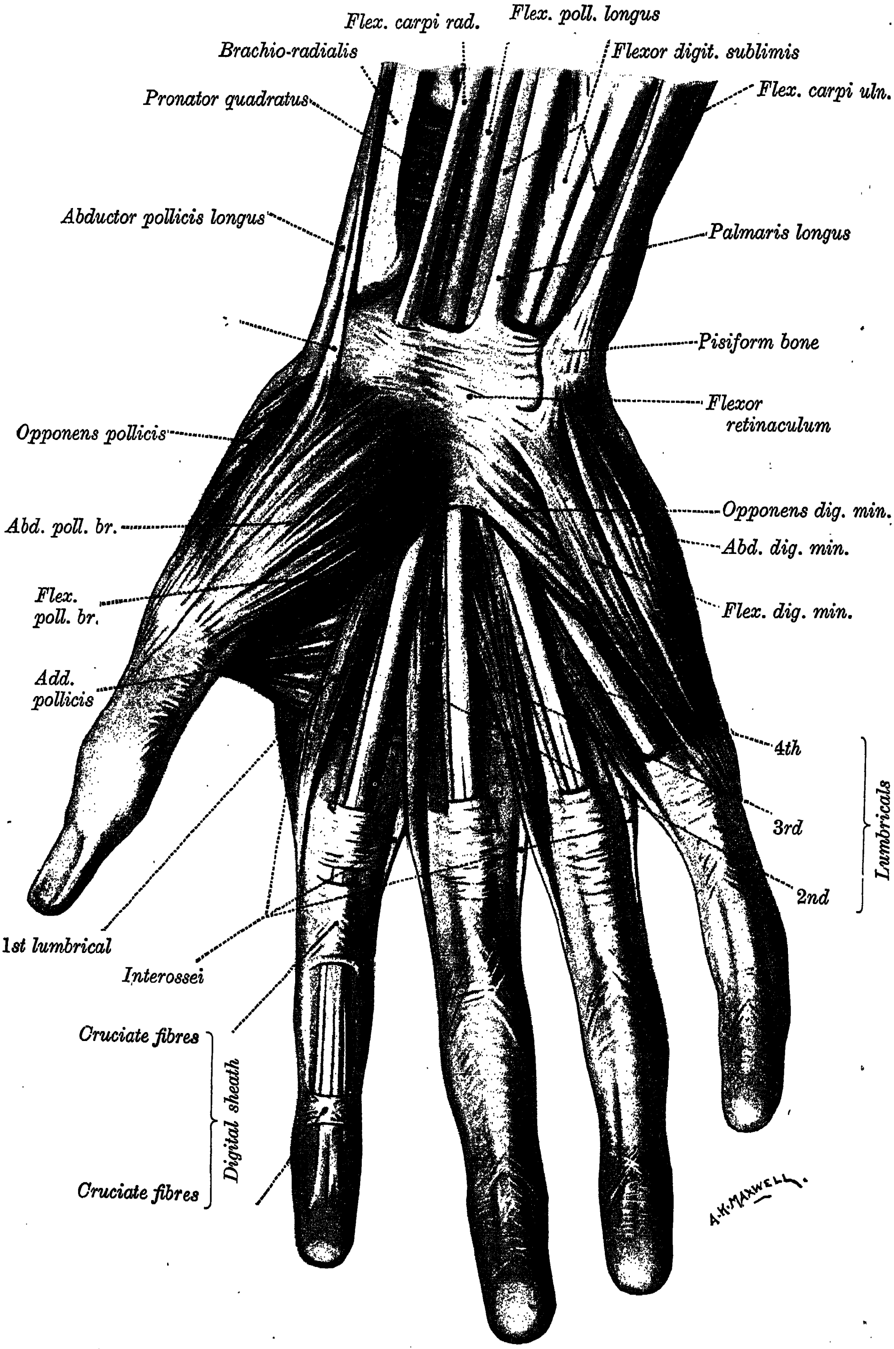
finger with the Abductor digiti minimi. Its origin is separated from that of the Abductor by the deep branches of the ulnar artery and nerve. This muscle may be wanting, or may be used with the Abductor.

Fig. 635.—Superficial dissection of muscles of the palm of the hand. (From Quain's *Anatomy,* XI. Edition.)



* An accessory slip frequently present connecting the long and short abductors of the thumb.

Actions.—The Flexor digiti minimi flexes the proximal phalanx of the little finger.

The **Opponens digiti minimi** (fig. 634) is of a triangular form, and placed under cover of the Flexor and Abductor. It arises from the convexity of the

hook of the hamate bone, and contiguous portion of the flexor retinaculum ; it is inserted into the whole length of the ulnar margin of the fifth metacarpal bone.

Action.—The Opponens digiti minimi draws the fifth metacarpal bone forwards and laterally, so as to deepen the hollow of the palm.

Nerve-supply.—All the muscles of the little finger are supplied by the deep branch of the ulnar nerve.

3. The Intermediate Muscles

Lumbricales. Interossei.

The **Lumbricales** (fig. 635) are four small fleshy fasciculi which take origin from the tendons of the Flexor digitorum profundus. The first and second arise from the radial sides and palmar surfaces of the tendons of the index and middle fingers respectively ; the third, from the contiguous sides of the tendons of the middle and ring fingers ; and the fourth, from the contiguous sides of

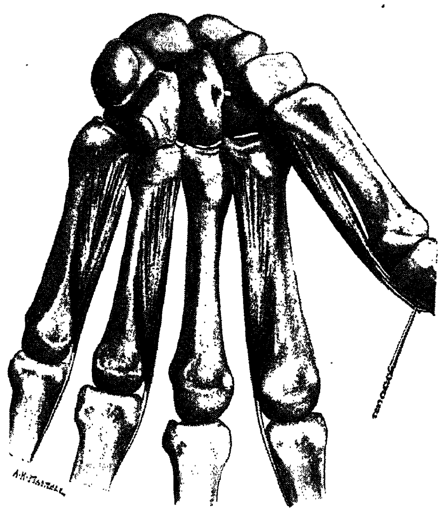
Fig. 637.—The Palmar interosseous muscles of the left hand. Viewed from in front.



the tendons of the ring and little fingers. Each passes to the radial side of the corresponding finger, and is inserted partly into the base of the proximal phalanx, but mainly into the lateral margin of the tendinous expansion of the Extensor digitorum covering the dorsal surface of the finger.

Nerve-supply.—The first and second Lumbricals are supplied by the median nerve ; the third and fourth Lumbricals by the deep terminal branch of the ulnar nerve. The third Lumbrical frequently receives a twig from the median nerve.

Actions.—The Lumbricals flex the proximal and extend the middle and distal phalanges, a combination of movements which is called for in the upstroke in writing, etc.

The **Interossei** occupy the intervals between the metacarpal bones, and are divided into a dorsal and a palmar set.

The **Interossei dorsales** (fig. 636), four in number, are bipennate muscles, each arising by two heads from the adjacent sides of the metacarpal bones, but more extensively from the metacarpal bone of the finger into which the muscle is inserted. They are inserted into the bases of the proximal phalanges and into the aponeuroses of the tendons of the Extensor digitorum. Between the double origin of each of these muscles there is a narrow triangular interval ; through the first of these intervals the radial artery passes ; through each of the others a perforating branch from the deep palmar arch is transmitted.

The *first*, and largest, is sometimes named the *Abductor indicis*; it is inserted into the radial side of the index finger. The *second* and *third* are inserted into the middle finger, the former into its radial, the latter into its ulnar side. The *fourth* is inserted into the ulnar side of the ring finger.

The **Interossei palmares** (fig. 637), four in number, are smaller than the dorsal interossei, and are placed upon the palmar surfaces of the metacarpal bones, rather than between them. With the exception of the first, each arises from the entire length of the metacarpal bone of one finger, and is inserted into the side of the base of the proximal phalanx of the same finger, and into the aponeurosis of the Extensor digitorum tendon.

The *first* (formerly known as the 'deep head of the Flexor pollicis brevis') arises from the ulnar side of the palmar surface of the base of the first metacarpal bone (fig. 633), and is inserted into the ulnar side of the base of the proximal phalanx of the thumb, in common with the principal part of the oblique head of the Adductor pollicis. It lies in front of the lateral head of the first Dorsal interosseous muscle, and is covered by the oblique head of the Adductor pollicis. The *second* arises from the ulnar side of the second metacarpal bone, and is inserted into the same side of the proximal phalanx of the index finger. The *third* arises from the radial side of the fourth metacarpal bone, and is inserted into the same side of the ring finger. The *fourth* arises from the radial side of the fifth metacarpal bone, and is inserted into the same side of the little finger. From this account it may be seen that each finger is provided with a pair of Interosseous muscles, with the exception of the little finger, in which the Abductor digiti minimi takes the place of one of the pair.

Nerve-supply.—Both dorsal and palmar interossei are supplied by the deep branch of the ulnar nerve.

Actions.—The dorsal interossei abduct the fingers (p. 478) from an imaginary line drawn longitudinally through the centre of the middle finger; and the palmar interossei adduct the fingers to that line. The Interossei, in conjunction with the Lumbricals, flex the proximal phalanges, and, in consequence of their insertions into the expansions of the Extensor tendons, extend the middle and distal phalanges. The first Palmar interosseous flexes the proximal phalanx of the thumb.

Segmental Innervation of the Muscles of the Hand

Clinical observations indicate that all the small muscles of the hand receive their motor innervation from T. 1.

THE FASCIÆ AND MUSCLES OF THE LOWER LIMB

The muscles of the lower limb are subdivided into groups corresponding with the different regions of the limb.

I. Muscles of the iliac region.
II. Muscles of the thigh.
III. Muscles of the leg.
IV. Muscles of the foot.

I. The Muscles of the Iliac Region (fig. 638)

Psoas major. Psoas minor. Iliacus.

The **fascia iliaca** covers the Psoas and Iliacus. It is thin above, but becomes gradually thicker as it approaches the inguinal ligament.

The *portion covering the Psoas* is thickened above to form the medial arcuate ligament (medial lumbocostal arch), which stretches from the transverse process of the first to the body of the first or second lumbar vertebra. Medially, the fascia covering the Psoas is attached by a series of arched processes to the intervertebral discs, and prominent margins of the bodies of the vertebræ, and to the upper part of the sacrum. Laterally, above the crest of the ilium, it blends with the fascia covering the front of the Quadratus lumborum (p. 572): below the crest, with the fascia covering the Iliacus.

The *portion covering the Iliacus* is connected, laterally, to the whole length of the inner lip of the iliac crest; and medially, to the brim of the true pelvis, where it blends with the periosteum. It is attached to the iliopubic (iliopectineal) eminence and there receives a slip from the tendon of insertion of the Psoas minor, when that muscle exists. The external iliac vessels lie in front of the fascia but the branches of the lumbar plexus of nerves are behind it; it is separated from the peritoneum by the extraperitoneal tissue.

Lateral to the femoral vessels, the iliac fascia is intimately connected to the posterior margin of the inguinal ligament, and is there continuous with the transversalis fascia. It passes behind the femoral vessels, and beyond the inguinal ligament becomes the *iliopectineal fascia*. This fascia divides the space between the inguinal ligament and the hip-bone into a medial and a lateral part; the medial part transmits the femoral vessels, the lateral the Psoas major, the Iliacus and the femoral nerve. Medial to the vessels, the iliopectineal fascia is attached to the pectineal line of the pubis and is continuous with the pectineal fascia. In the thigh the iliopectineal fascia covers the Iliacus and the Psoas major, and forms the posterior wall of the femoral sheath.

The **Psoas major** (fig. 638) is a long fusiform muscle placed on the side of the lumbar region of the vertebral column and the brim of the true pelvis. It arises (1) from the anterior surfaces and lower borders of the transverse processes of all the lumbar vertebræ; (2) by five slips or digitations, each of which takes origin from the bodies of two vertebræ and their intervertebral disc; the highest slip arises from the lower margin of the body of the twelfth thoracic vertebra, the upper margin of the body of the first lumbar vertebra and the interposed disc, the lowest slip from the adjacent margins of the bodies of the fourth and fifth lumbar vertebræ and the interposed disc; (3) from a series of tendinous arches extending across the constricted parts of the bodies of the lumbar vertebræ between the preceding slips; the lumbar arteries and veins, and filaments from the sympathetic trunk, pass deep to these arches. The muscle proceeds downwards across the brim of the true pelvis, passes behind the inguinal ligament and in front of the capsule of the hip-joint, and ends in a tendon. The latter receives nearly the whole of the fibres of the Iliacus and is inserted into the lesser trochanter of the femur. A large bursa, which occasionally communicates with the cavity of the hip-joint, separates the tendon from the pubis and the capsule of the joint.
